Message from the OSDI ’24 Program Co-Chairs

Dear Colleagues,

Welcome to the 18th USENIX Symposium on Operating Systems Design and Implementation (OSDI ’24).

We are pleased that, once again, OSDI is co-located with the USENIX Annual Technical Conference (USENIX ATC ’24). The two conferences combined are publishing a wide array of exciting papers representing some of the most innovative work in the systems research community. We hope you come away from OSDI and USENIX ATC with new colleagues, new friends, and new ideas.

This year, OSDI received 272 submissions. We accepted 49 submissions, which is an 18% acceptance rate. In addition to the papers accepted this year, 4 additional papers were accepted from the OSDI ’23 Revise and Resubmit process. This brings the total program to 53 papers being published in the OSDI proceedings. We continue to be committed to a single-track conference at OSDI, and we have put together a 3-day program in which all papers are being presented in the same room so attendees can watch every single talk if they so desire.

To deal with the number and technical breadth of the OSDI submissions, we assembled a program committee of 95 members not counting us, the Program Co-Chairs. Reviewing papers is a time-consuming task that requires high judgment, and we are grateful to the program committee for their diligence, professionalism, and cooperation during the review process. We are proud that OSDI is known for high quality reviews that help authors to produce their very best work and present it clearly to our community.

The program committee reviewed submissions in two rounds. Every paper received at least three reviews in the first round. Select papers then received 2 or 3 additional reviews in the second round. The accepted papers were chosen based on an online discussion phase and a two-day PC meeting. The committee completed more than 1,000 reviews and posted hundreds of comments as part of the online discussion process. Each accepted paper was assigned a shepherd to work with the authors to revise the paper in response to reviewer feedback.

OSDI ’24 had an artifact-evaluation committee, shared with USENIX ATC ’24, that organized and evaluated the artifacts submitted by authors. The committee co-chairs this year were Jianyu Jiang, Ji Qi, and Cesar A. Stuardo. The committee made one recommendation for a Distinguished Artifact Award.

OSDI ’24 had a poster submission process that was run by Aishwarya Ganesan and Amy Ousterhout, who graciously took on this task in addition to serving on the PC. They accepted 52 posters for display at the OSDI poster session, representing a mix of posters from papers presented at the conference as well as other work.

Once the accepted papers were decided, we began the process of deciding on the Jay Lepreau Best Paper Awards. A small committee of non-conflicted PC members read all of the top-ranked papers and agreed on the award recommendation.

As PC chairs, we are grateful to so many dedicated volunteers and professional staff whose efforts have made this conference a reality. We thank the authors who submitted such high-quality work. This conference is first and foremost a forum for disseminating, sharing, discussing, and debating world-class systems research. Thank you for your hard work and innovation! We thank the PC members and external reviewers for their significant investment of time, energy, and insight into shaping the program. We thank Vaibhav Bhosale and Vishal Suresh Rao, who helped us during the PC meeting and made sure we ran the technology and not the other way around. We especially thank the USENIX staff who have made chairing a conference like this one a well-oiled machine! Finally, we thank you for coming to this conference to engage with each other and with the authors of the accepted papers.

We are honored to have served as the OSDI ’24 Program Co-Chairs. Thank you for entrusting us with this important role. We hope that you enjoy the conference!

Sabre: Hardware-Accelerated Snapshot Compression for Serverless MicroVMs

Nikita Lazarev Varun Gohil James Tsai[†] Andy Anderson[†] Bhushan Chitlur[†]
Zhiru Zhang[§] Christina Delimitrou
MIT, CSAIL [†]*Intel Labs* [§]*Cornell University*

Abstract

MicroVM snapshotting significantly reduces the cold start overheads in serverless applications. Snapshotting enables storing part of the physical memory of a microVM guest into a file, and later restoring from it to avoid long cold start-up times. Prefetching memory pages from snapshots can further improve the effectiveness of snapshotting. However, the efficacy of prefetching depends on the size of the memory that needs to be restored. Lossless page compression is therefore a great way to improve the coverage of the memory footprint that snapshotting with prefetching achieves. Unfortunately, the high overhead and high CPU cost of software-based (de)compression make this impractical.

We introduce Sabre, a novel approach to snapshot page prefetching based on hardware-accelerated (de)compression. Sabre leverages an increasingly pervasive near-memory analytics accelerator available in modern datacenter processors. We show that by appropriately leveraging such accelerators, microVM snapshots of serverless applications can be compressed up to a factor of 4.5×, with nearly negligible decompression costs. We use this insight to build an efficient page prefetching library capable of speeding up memory restoration from snapshots by up to 55%. We integrate the library with the production-grade Firecracker microVMs and evaluate its end-to-end performance on a wide set of serverless applications.

1 Introduction

Serverless is an emerging cloud computing paradigm gaining widespread popularity across applications of different classes, from lightweight interactive services [73] to highly data-parallel applications, such as machine learning and video encoding [21, 24, 40, 47, 67]. Serverless offers a Function-as-a-Service (FaaS) execution model, where applications instantiate short-lived, fine-grained resources on-demand without the overhead of provisioning and deployment typical cloud environments incur. When requests are processed, the resources are terminated, achieving a pay-as-you-go model. This both avoids resource overprovisioning, which has been a long-standing issue with cloud infrastructures [22, 28, 58] and reduces the end-to-end deployment cost [33, 46].

Serverless is based on lightweight virtualization/isolation technologies [19] such as Docker, Google gVisor [3], Kata containers [10], NEC's LightVMs [53], and AWS Firecracker microVMs [17]. These technologies implement sandboxes for executing containerized applications with different levels of isolation. For example, gVisor implements a lightweight user space kernel capable of executing most of the system calls within the sandbox. On the other hand, Firecracker is a full lightweight virtualization technology, based on KVM, which can boot standard Linux kernels in sub-second time [17]. Due to the high isolation guarantees of microVMs, security, and performance, Firecracker is widely used in serverless clouds.

Despite its advantages, serverless and microVMs introduce a few critical overheads to performance. A major overhead is cold starts (or cold boots) – the overhead of the initial boot of container sandboxes upon a function invocation. Both industry and academia have proposed numerous techniques to mitigate cold start overheads [31, 35, 64, 73], with one of the most promising being VM snapshotting [31]. VM snapshots capture the current state of the VM and its physical memory and save them in a file. During the next boot, the guest system is restored from the file instead of booting from scratch. Several different techniques can be used to make snapshots, depending on which parts of the guest's physical memory should be saved. For instance, Firecracker can snapshot the full guest memory or only the dirty pages. Additionally, recent studies have proposed using *working sets* of pages [71] to make serverless VM snapshots smaller, faster to fetch, and overall more efficient [20, 64] in reducing cold starts. However, independent of the underlying techniques used to create snapshots, the overhead of storing and prefetching them is non-negligible. Unfortunately, the latter is on the critical path of VM restoration and therefore directly impacts cold starts.

Reducing the size of snapshots can make them significantly more efficient, for example through lossless memory compression. While memory compression has been used in domains where the application performance is not critical (e.g., *zswap* [39], *zram* [38] in Android OS for mobile devices), in serverless the restoration of a memory snapshot is on the critical path, precluding the use of existing software-based (de)compression algorithms. At the same time, there are numerous hardware implementations of (de)compression [23, 41, 51, 52, 56], however, they had not, until now, been implemented in mainstream datacenter processors [43]. In particular, Intel recently released the In-Memory Analytics Accelerator (IAA) [6] in their 4^{th} Gen Xeon Scalable CPUs, which enables efficient compression for datacenter applications at scale.

We present Sabre, a hardware-accelerated *general-purpose* memory prefetching system, which uses lossless compression mechanisms, such as IAA, to compress and restore microVM snapshots. This paper makes two major contributions. First, we characterize, for the first time, the IAA accelerator on a set of diverse benchmarks, and show its potential for compressing memory pages. We show that IAA can compress pages by $2-4.5\times$, depending on the underlying page selection algorithm. Moreover, we show that decompression can be done up to $10\times$ faster with hardware acceleration, and with careful design, this time can be entirely hidden behind the disk I/O and page fault handling. This results in near-free decompression in terms of the overall memory restoration latency, while reducing the size and the loading time of snapshot pages.

Second, based on this characterization, we build Sabre and integrate it with the Firecracker virtual machine monitor (VMM) in a serverless environment with snapshotting support. Sabre is agnostic to the underlying page snapshotting policy, it operates entirely in the host's user space, and interacts with the IAA accelerator via the Shared Virtual Memory (SVM) mechanism. The latter enables out-of-box and transparent integration of Sabre with existing VMMs at scale.

We evaluate Sabre on its efficiency in restoring microVMs from snapshots across a wide range of end-to-end serverless applications using two methods of creating snapshots: dirty page-based and working set-based. We show that Sabre compresses microVM snapshots up to $4.5\times$ without introducing any decompression overheads. Moreover, we show that Sabre enables up to 55% faster memory restoration, which results in an additional reduction of the end-to-end cold start time by 20% with respect to already optimized state-of-the-art snapshotting baselines.

Sabre is open-source software and it is available at the following link [13].

2 Background

2.1 MicroVMs for Serverless

Serverless is gaining popularity across many application domains by reducing the cloud provisioning overhead and enabling higher elasticity for applications with high parallelism and intermittent activity. Lightweight virtualization technologies (or microVMs) became a popular choice for cloud providers due to the isolation and fast instantiation they provide [17, 69]. Fully virtualized VMs running over Type-1 hypervisors, such as KVM [37] or Hyper-V [70], allow isolating tenants down to hardware and provide the highest security guarantees for applications running in the cloud. On the other hand, microVMs are much faster to boot and have a much smaller memory footprint than traditional Type-1 virtual machines. This means that microVMs achieve the best of both worlds between containers and Type-1 hypervisors. MicroVMs are widely used in serverless, where applications require both strong isolation guarantees and fast start-up.

Modern microVMs, such as AWS Firecracker [17], use several optimizations to boot up in sub-seconds. However, booting the VM itself is only part of the end-to-end application execution latency [31, 64], with a significant component corresponding to the initialization of the software dependencies after the boot. For applications based on complex multi-layer stacks, such as gRPC servers and JavaScript runtimes, bringing up the dependencies might be as high as several seconds [31]. Additionally, the applications themselves can contain long-running initialization routines, which also contribute to end-to-end latency. For example, machine learning (ML) services need to load the models before serving inference queries. Altogether, this makes the end-to-end execution of the first batch of requests running on freshly booted microVMs an order of magnitude slower than subsequent requests. This is known as *cold start*, and all microVMs are prone to it.

Mitigating cold starts is one of the most well-researched aspects of microVMs [65]. Existing solutions range from scheduling techniques optimized for specific applications to runtime and infrastructure optimizations [54, 73]. One solution that is generally agnostic to applications is VM snapshotting [31].

2.2 MicroVM Snapshotting and Prefetching

Snapshotting is a technology that allows storing the VM state and guest OS physical memory in a file in the local or remote filesystem. Snapshots are usually created after the VM and the application logic with all its dependencies are fully initialized and ready to serve requests. Upon the next invocation of the VM the hypervisor restores the VM state and guest memory from the snapshot, instead of booting the VM from scratch. This dramatically reduces cold start overheads.

In the most basic case, snapshots contain the entire guest physical memory. Some hypervisors, such as Firecracker, also allow dirty-memory tracking, which only stores the dirty guest pages as seen by the hypervisor. Snapshots can be organized hierarchically following the software dependencies of applications [31]. However, recovering from snapshots is far from free. In some cases, the size of the snapshots can be as high as the whole guest memory, therefore precluding the possibility of loading pages from snapshots in advance. For this reason, existing commercial microVMs implement memory restoration via *on-demand* paging. Unfortunately, on-demand paging yields a lot of page faults on the critical path of the restoration from snapshots, which slows down request execution.

A way to reduce the overhead of page faults is to enable *prefetching* of pages from snapshots. This can be efficiently done through, for example, *working set* (WS) estimation. This approach has been used to create VM checkpoints [71], and recently – for serverless microVMs [64]. Here, each snapshot is accommodated in a WS file, storing pages that are likely to be accessed during subsequent invocations. There are different ways of constructing WS files [20, 64, 71] according to various working set estimation techniques. For example, in Record-and-Replay (REAP) [64], the authors propose to record all guest pages being accessed during the first invocation of serverless functions and put them into the WS file. Upon the next invocation, the WS file can be prefetched from the disk, and the WS pages can be installed in the guest's memory to speed up the next cold invocations. REAP works well for applications with a similar working set across different invocations of the same function. When this does not hold, REAP can fail to deliver good performance; in this case, prefetching some other subset of dirty pages (or even all dirty pages) can be more beneficial. Snapshots generally consume a lot of disk space and require cloud providers to carefully provision their storage resources [2]. Even working-set-based snapshots can sometimes be as large as a few hundred megabytes [20]. This is non-negligible given that a single server might host hundreds of microVMs.

Independently of the underlying technique to create microVM snapshots and/or WS files, the efficiency of prefetching depends on the memory size that needs to be restored from the disk into the guest memory. A general rule to make prefetching-based techniques more efficient is to reduce the size of the snapshots/WS files. This also reduces the disk space needed to store snapshots. This size reduction can be achieved through memory compression. However, memory restoration happens on the critical path of the VM boot-up, and for compression algorithms with high deflate ratios, the decompression might take a long time. Moreover, such algorithms usually consume a lot of CPU time for compression and therefore VM snapshotting. This makes the use of software memory compression for microVM snapshotting undesirable.

2.3 Hardware-Accelerated (De)Compression

Software-based memory compression has been extensively used in applications where performance is not critical. For example, *zram* [38] is used in Android OS on mobile devices, while *zswap* [39] can improve the efficiency of memory swapping for non-performance critical applications. Unfortunately, this does not apply to microVM memory restoration, where decompression directly impacts the cold start overhead.

There have been many proposals for accelerating memory compression in hardware. For example, Pekhimenko et. al. [56] propose base-delta compression for on-chip caches. Hoyong et. al. [41] derive a novel compression algorithm for GPU memory. Li et al. [52] introduced a hardware accelerator for the compression of genome sequences. All such proposals are based on application-specific, special-purpose compression accelerators and algorithms, and therefore have never been implemented on commodity datacenter processors. Many (de)compression accelerators are based on FPGA cards [25, 34, 50, 57] which are only available in a small set of public clouds. However, the demand for *general-purpose* (de)compression acceleration *at scale* is actively growing.

(De)Compression is known to be one of the major sources of datacenter tax [36,42,61]. A recent study from Google [36] showed that compression accounts for up to 30% of cycles for large-scale database applications, such as BigTable and BigQuery [32,62], and it is also extensively used in many other applications. This motivates cloud providers and chip vendors to build efficient hardware accelerators [43] for *general-purpose* lossless (de)compression. The primary use cases for such accelerators are databases and query-processing engines. In particular, Intel recently introduced the In-Memory Analytic Accelerator (IAA), which is now part of commodity datacenter processors, such as the Xeon 4^{th} Generation CPUs, which are already widely available. This accelerator can perform DEFLATE compression, which is suitable for compressing memory footprints. While other compression algorithms that are optimized for performance (e.g., *Snappy*, *zstd*, *LZ4*) can compress memory faster, they typically result in much lower compression ratios, which is critical for microVM snapshotting. Their software implementations increase the amount of CPU resources required for making snapshots, especially when configured for more aggressive compression [1]. At the same time, hardware-accelerated DEFLATE yields high compression ratios as well as high speed, while requiring no CPU cycles for (de)compression. It should also be noted that hardware accelerators for other compression algorithms are also feasible [16, 26, 60] but not yet implemented in mainstream datacenter processors at scale.

IAA and other similar accelerators are designed for cloud environments. They are typically implemented as on-chip near-memory PCIe components, which allows them to be easily integrated with cloud services. For instance, IAA can run entirely in user space, it operates transparently over the application's virtual memory and can be virtualized through standard technologies, such as S-IOV [8]. All this makes IAA attractive for microVM memory snapshotting and prefetching. In this work, we explore this direction.

We first characterize the capabilities of IAA when it comes to compressing memory pages. Based on this characterization, we design Sabre, a memory prefetching system for microVMs built using IAA. Finally, we show how our memory prefetching unit integrates with serverless microVMs and evaluate its impact on end-to-end serverless benchmarks.

3 In-Memory Analytic Accelerator: Overview, Characterization, Insights

We now present an overview and characterization of the Intel In-Memory Analytic Accelerator (IAA) [6] using a set of diverse benchmarks [15]. This work mainly focuses on the compression/decompression capabilities of the accelerator. However, given that other capabilities share the same IAA frontend pipeline, interfaces, and software semantics, most of our findings also apply to these other domains. To our knowledge, this is the first publicly available characterization of the IAA hardware. The insights from this characterization are used to derive the design of Sabre, described in Section 4.

Note that given the diverse set of execution models, configurations, workloads, and variations of IAA hardware in different SKUs, it may be possible to achieve even higher performance compared to what we showcase in our characterization. Specifically, benchmarks designed specifically to stress test the accelerator may be able to improve IAA's performance further. For the purpose of this paper, we only benchmark the accelerator with a set of scenarios required to give comprehensive insights into using in-memory compression techniques in serverlerss microVMs and to derive the design of Sabre.

3.1 Overview of the IAA

Intel's IAA is a hardware accelerator first introduced in Intel's 4^{th} Gen Xeon Scalable Processors (code-named Sapphire Rapids) [12] to speed up data processing across application classes. It was designed with the primary use case being databases and query processing systems [7]. The accelerator physically resides in the uncore part of the processor's SoC near the memory controller and Last Level Cache. A single CPU can accommodate multiple IAA devices on its SoC.

The IAA accelerators are logically integrated as PCIe devices and exposed to the host as a single root complex integrated endpoint. This is set up to enable transparent integration of the accelerators with software. IAA features scalability, full virtualization support via PCIe S-IOV, Shared Virtual Memory support (SVM or SVA as defined by Linux kernel documentation) [11], and transparent user-space interaction with applications via a new ISA extension, called *ENQCMD*.

Communication and job submission to the accelerator are handled via *Work Queues* (WQs), similar to another emerging hardware – Data Streaming Accelerator (DSA) [48]. For this, software needs to create *descriptors* and *completions* allocated anywhere in the application virtual address space. Descriptors contain information describing the jobs assigned to the accelerator's *Processing Units* (PEs), such as the locations of the source and destination buffers, opcodes, and operational and memory policy flags. Descriptors are submitted to the accelerator via the ENQCMD instruction directly from user space, which writes them into the device's memory-mapped I/O (MMIO) registers. Upon receiving descriptors, the PEs fetch data based on the pointers in the descriptors. This is done through SVM which enables transparent sharing of the application's virtual memory with accelerators. When a PE finishes processing, it writes the corresponding completion record with the status information. The software can poll the completion records to identify the termination of tasks and any error information. If some application memory pages associated with data buffers are not available, the accelerator can request them via either *Page Request Service* (PRS) or through userspace page fault handling. In the latter case, software applications can resolve the page faults in a more suitable for a particular usage scenario way (e.g., by requesting pages from, for example, the network) in the user space.

IAA's job submission mechanism enables asynchronous/non-blocking and out-of-order processing of descriptors. The current hardware permits a large number of in-flight requests, which can be submitted from different threads and processes/tenants. The micro-architectural pipeline of the IAA hardware contains multiple PEs that can execute jobs concurrently. The DSA specification [4] and in-depth characterization [48] contain more details since both accelerators share the same specification for this part.

The IAA hardware contains PEs implementing different processing capabilities. These include encryption, compression, CRC offload, data filtering, scanning, extraction, selection, and expansion [5] (Table 3-1). Due to the scope of this work, we only focus on characterizing the (de)compression capability of IAA. IAA performs DEFLATE [30] compression, as defined in RFC 1951. DEFLATE is based on LZ77 matching and Huffman encoding. LZ77 matching eliminates redundancy by replacing repeated occurrences of substrings with references to a single version of the substring. This is a computationally intensive process making software implementations slow. The Huffman coder further deflates data by re-encoding the most common symbols with fewer bits using statistics of data distribution in the input stream. Internally, the IAA compression unit operates in three modes.

In the first – *Huffman-mode*, IAA performs hardware-accelerated LZ77 dictionary coding, using 4 KB windows, and encodes the results with pre-defined static Huffman tables. The second IAA mode – *Statistics-mode* is designed to sample input streams and construct the statistical data distribution to optimize Huffman tables for a particular input. Compression with input-specific Huffman tables usually allows much higher compression ratios. In Statistics-mode, IAA only constructs the histogram of the distribution of Huffman codes, but it does not write the actual Huffman tables yet. The latter

Style	Description
Fixed Block	Standard static DEFLATE; based on Huffman-mode with standard Huffman tables; enables faster compression, but under general Huffman tables, which usually results in low compression ratios.
Static Block	Similar to Fixed Block, but using user-defined Huffman tables; can result in good compression ratios if the application is able to provide Huffman tables fitting all inputs well.
Dynamic Block	Standard dynamic DEFLATE; two-phase compression with Statistics-mode followed by Huffman-mode; enables optimal Huffman tables per block and a better compression ratio, but requires more time to compress.
Canned	Allows sharing the same Huffman tables between multiple blocks of compressed data; this is important when compressing many small scattered chunks to avoid having to keep/access Huffman tables per block.

Table 1: End-to-end compression styles supported in Intel IAA.

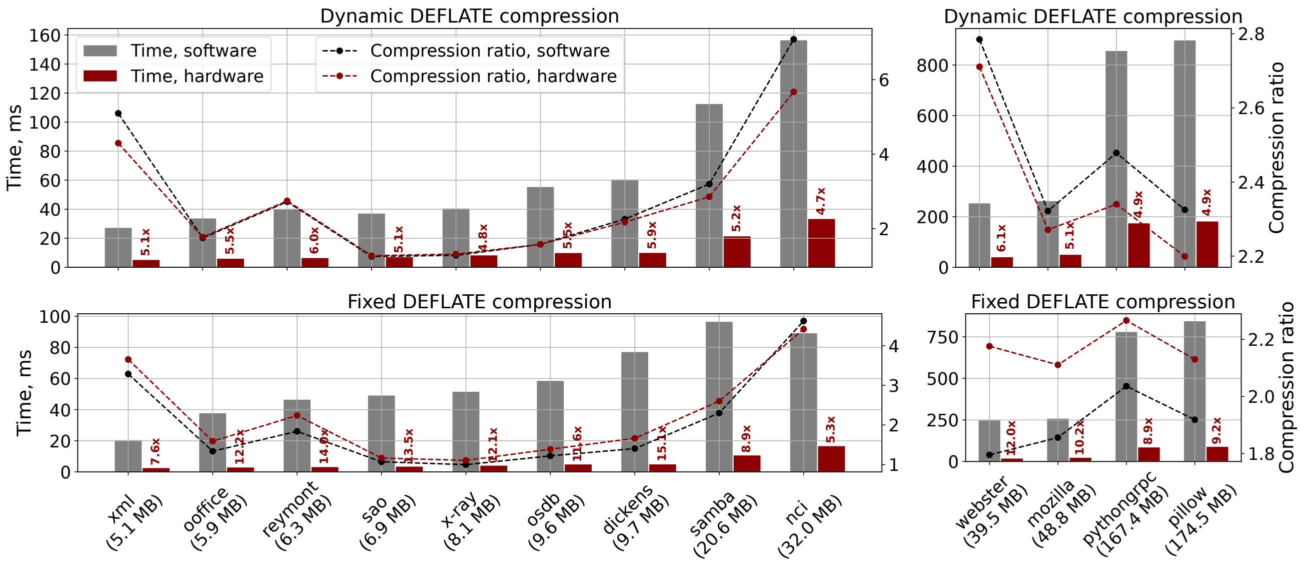

Figure 1: Comparison of software- and hardware-based DEFLATE *compression* for different datasets (sorted by uncompressed size) from Silesia Corpus and serverless VM snapshots (last two); the numbers denote speed-up of the hardware execution; a single IAA device with a single PE (engine) in blocking/synchronous mode is used; the software baseline runs on a single thread.

is done in the third mode – *Huffman-Generation mode*, which is only supported in some IAA implementations.

Based on these modes, IAA defines four main *styles* of compression (Table 1), and it is up to the control plane software to implement them. To make end-to-end (de)compression easier to implement, Intel has recently released the Query Processing Library (QPL) [7], which abstracts away the IAA modes and allows users to express compression in any of the supported modes. We next show the results of microbenchmarking IAA with different modes and implementations.

3.2 Characterizing Compression Using IAA

We characterize IAA (de)compression with a set of benchmarks written using the Intel QPL library v1.3.1. As input data, we use 11 datasets from the standard Silesia Corpus [29]; a common way to evaluate (de)compression. We also add two more datasets specific to our use case representing the dirty memory snapshots of microVMs. The snapshots were obtained during request execution for two serverless applications from vSwarm [66] and FunctionBench [44,45]: a Python gRPC server (*pythongrpc*) and the Pillow image processing library (*pillow*). Both datasets only contain dirty pages of guest memory. Table 2 shows the specification of our testbed. At the time of writing, we had access to two Sapphire Rapids systems (SKUs) with slightly different configurations. We use the most recent production-grade SKU (*Server #2* in Table 2) in all experiments unless otherwise noted.

3.2.1 Benchmarking IAA: Core Compute

We start with the characterization of the in-memory core computing capability of IAA. We assume that data is always available in memory, both for the source and destination buffers. We ensure that memories are initialized and touched to avoid page faults. This is important as page fault handling affects the accelerator's performance, and therefore we evaluate it separately. For all experiments in this section, we use a single

CPU
(Server #1)
	Intel 4^{th} Gen Xeon Scalable Processor;
	2 NUMA nodes, 56 cores/112 threads;
	Core/Uncore frequency (GHz): 1.7/ 1.8;
	LLC capacity (MB): 110
	IAA devices: 8 (4 per NUMA node)

CPU
(Server #2)
	Intel(R) Xeon(R) Gold 6438Y+;
	2 NUMA nodes, 32 cores/64 threads;
	Core/Uncore frequency (GHz): 2.3/ 1.8;
	LLC capacity (MB): 60
	IAA devices: 2 (1 per NUMA node)

IAA	available PEs per device: 8 capabilities (as per *GENCAP* register): - Huffman generation mode: *disabled*; - Page Request Service (PRS): *enabled*; - Block-on-Fault: *enabled*; WQ configuration: shared, 8 per device, size: 32
Memory	Type: DDR5; Capacity (GB): 250
Disk	Intel SSDSC2KG960G8 Sequential O_DIRECT read bandwidth (MB/s): 550

Host OS	Ubuntu 22.04;
	Kernel: 5.15, patched with [9] to enable ENQCMD;
	Kernel boot arguments: $intel\_iommu = on, sm\_on$

Guest OS **(Section 5)**	Rootfs: Debian GNU/Linux 12 (bookworm) Kernel: 4.14.174
IAA stack	Driver: idxd Middleware: Intel QPL v1.3.1

Table 2: Testbed hardware and software configuration.

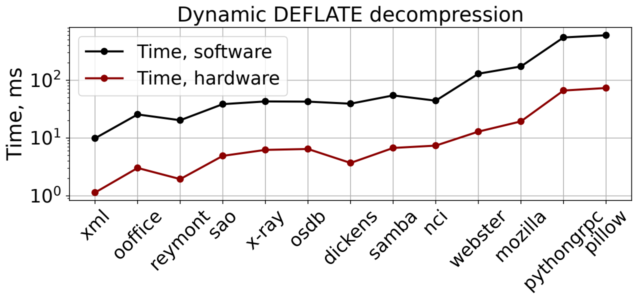

Figure 2: Comparison of software- and hardware-based DEFLATE *decompression* on the same datasets and setup as in Figure 1

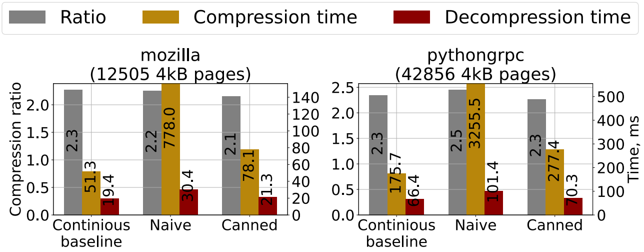

Figure 3: (De)compression of scattered 4kB pages across modes.

IAA device configured with a single PE (engine); we submit the jobs to the accelerator from a single CPU thread in the blocking/synchronous mode and wait till completion by polling associated completion records. The software baseline runs on a single CPU core.

We first compare the performance and compression ratios of IAA-enabled compression and its software implementation in QPL. Since the IAA hardware does not allow explicitly selecting compression levels (compression levels are subjective and vary across implementations), we set the default compression level-1, as defined by QPL, for the corresponding software implementation. Since our version of IAA does not offload Huffman table generation, the hardware implementation of dynamic DEFLATE compression is actually hybrid: statistics collection, LZ77 encoding, and compressed stream generation run in hardware, while Huffman table generation runs in software. The hybrid operations run on a single CPU core. Figure 1 shows the compression results.

The hardware implementation always overperforms software in compression time. The difference reaches 6.1× and 13.5× for dynamic and fixed compression, respectively. In our datasets of dirty memory snapshots, the speedup reaches 9×. The achieved compression ratios for software and hardware executions are similar. Figure 2 shows the performance of decompression. We only show the decompression of *dynamic* streams, as in these datasets, decompression performance does not depend on the compression mode. In all cases, IAA decompresses an order of magnitude faster than software.

Note that in this paper, our experiments only compare IAA to the software implementation of the same DEFLATE algorithm. To compare against many other software compression algorithms (e.g., Snappy, zstd, LZ4, etc.), please refer to the publicly available in-memory benchmarks based on the Silesia Corpus (for example, lzbench [1]). The *synchronous* throughput of IAA's (de)compression can be obtained from Figures 1 and 2 based on the size of the datasets. For example, the fixed-DEFLATE compression on the *nci* dataset reaches 1800 MB/s, and its decompression - 4600 MB/s on a single engine. These numbers are expected to be lower than the *asynchronous* streaming (de)compression (using the non-blocking mode of IAA) which we do not characterize in this paper.

We then profile (Figure 3) IAA's (de)compression for many small 4 KB sized chunks for the same datasets. As previously mentioned, the Canned—which is essentially a Static Block—mode allows sharing Huffman tables between data chunks, therefore reducing both the space and processing time when data is scattered over many small blocks. This is very useful when compressing individual memory pages. In Figure 3, the first group of bars shows the baseline compression using Dynamic Block over a continuous region. We then break it into 4 KB chunks and compress them naïvely, with the Dynamic Block, independently for each chunk. As a result, compression time explodes due to processing tables separately; the decompression time also suffers, as the Huffman tables need to be parsed. The Canned operation reduces the overhead of scattered compression. Most interestingly, it enables fast decompression of scattered data, which is only marginally higher than the continuous baseline.

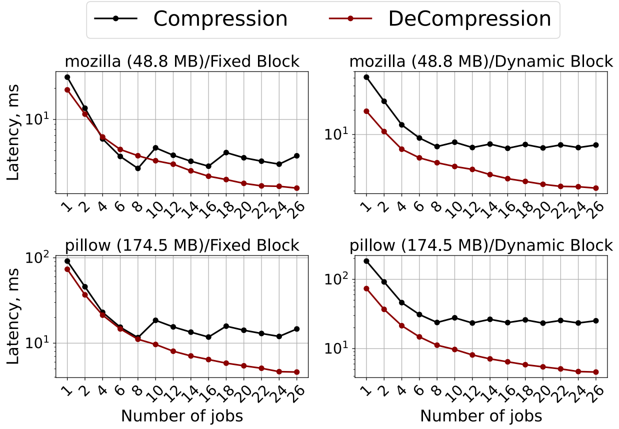

Figure 4: Latency of single-thread *synchronous* (de)compression with parallel *hardware* execution on 4 IAA devices with 8 engines each; only two benchmarks are shown for brevity.

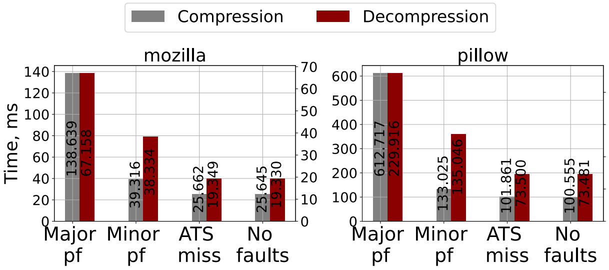

Figure 5: Impact of page faults and translation fetch on IAA performance via *PRS* with *block-on-fault* enabled

.

3.2.2 Benchmarking IAA: System Integration

We now characterize the IAA hardware together with system-level aspects. We use the same datasets and setup as before.

We first evaluate how job parallelization within the IAA PEs may further speed up (de)compression. Given that our earlier SKU has more IAA engines/PEs (refer to Table 2), we use *Server #1* in this experiment. Note that at the time of writing, the QPL library did not allow crossing NUMA boundaries between the data and IAA devices. Therefore, only 4 IAA devices (32 PEs/engines in total) are utilized at most for this experiment.

There are two main ways to leverage parallelism within the IAA: with synchronous and asynchronous job submission. In the first case, a large chunk of data can be split into multiple smaller blocks, and these blocks are then submitted to multiple available PEs. The software then blocks and waits until all PEs finish processing. This allows us to reduce the time/latency of a single (de)compression job. In the asynchronous case, a *stream* of multiple blocks from potentially different dataflows/threads is supplied into the accelerator without waiting for the completion of the previous blocks, therefore utilizing the hardware at maximum capacity. This yields the highest IAA utilization and *throughput*. For fast microVM restoration, the only performance metric that matters is how fast the system can decompress a single snapshot from a single CPU thread into the microVM guest memory. We therefore only benchmark the synchronous job parallelization in this paper.

We implement parallel synchronous processing via the *non-blocking synchronous* descriptor submission. Here multiple descriptors are submitted at the same time from a single CPU thread without waiting for immediate completion of individual descriptors. Figure 4 shows that for a hardware concurrency of up to 8 compression jobs, the latency reduction reaches $4-7\times$ with respect to sequential execution. Dynamic Block compression scales worse due to the software overhead of Huffman table creation. *Decompression* scales up to 26 jobs, reaching 17× latency reduction for the *pillow* dataset. These results demonstrate how multiple IAA engines can be used to achieve even lower (de)compression latency.

Until now, we have only tested the behavior of IAA when processing in-memory data, which was the majority of initial use cases for the accelerator. In-memory operation is achieved when source and destination buffers are present both in the memory and page table of the calling process. This holds when, e.g., streaming over the same buffers. However, in certain cases, data is not entirely present in memory, e.g., when processing inputs from a file or into newly allocated memory. In these cases, the accelerator must resolve page faults.

The fundamental source of page faults in systems such as IAA and DSA is the fact that they operate directly on the application's virtual address spaces via SVM [11]. As a result, similarly to CPU processing, when a page requested by the accelerator is not found in the page table, a major or minor page fault occurs. The result of the page fault handling (e.g., the translation) is then cached in the accelerator's Address Translation Service (ATS). When the translation is available in the CPU/kernel, the page fault does not happen, but the ATS must fetch the translation from the host via a translation fetch request. We now benchmark IAA in the case of page faults and translation fetch requests. We use standard 4 KB pages and an SSD disk with 550 MB/s of provisioned sequential read bandwidth. For compression, we use a single-pass Fixed Block to avoid the side effects of hybrid two-phase operations.

IAA supports two modes to handle page faults: via hardware-initiated on-demand paging via PRS or in user space with custom application-defined page fault handlers. The mode is controlled via the work queue configuration or through the PCIe device configuration if the former is not available. When PRS is enabled, the hardware can request up to *N* (specified in *PRSREQCAP* register) pages from the host concurrently. The actual page fault handling is done by the kernel through IOMMU interrupts. Figure 5 shows the time required to process descriptors in case of different hardware-

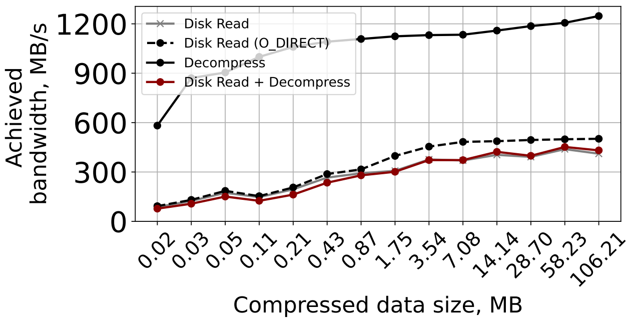

Figure 6: *Single-job, single-engine, synchronous* decompression bandwidth when reading disk inputs via *PRS* with *block-on-fault* enabled.

initiated page faults. We benchmark the worst-case scenario when the entire dataset causes page faults (12492 pages for *mozila* and 44672 pages for *pillow*). As expected, major page faults have a severe impact on the accelerator's performance. The impact of minor page faults is lower, but still $\approx 2\times$ for decompression. The ATS translation fetch has the smallest impact of ≈ 20 *us* across all pages. In general, decompression is more sensitive to page faults than compression; this is because the former is less compute-bounded.

Finally, we characterize the achieved decompression bandwidth when reading input data from an SSD (Figure 6), which is critical for our memory restoration use case. The dashed black and gray lines show achieved sequential disk read bandwidth with and without *direct I/O* (O_DIRECT). Direct I/O allows bypassing the page cache when reading files from the disk. In certain cases, this helps to reach the highest bandwidth of I/O operations. The solid black line shows the achievable bandwidth of a single-job synchronous decompression over data in memory, and the red line when reading input from the disk via hardware on-demand paging (i.e., via PRS). The latter is achieved through shared mapping of the input file into the IAA buffers and enforcing sequential I/O using *posix_fadvise*.

IAA decompression is a *streaming* operation, and it always accesses input buffers sequentially. In an ideal system, the decompression phase will completely overlap with the operation fetching data from the disk. Hence, the achieved end-to-end throughput will be decided by the slower operation - be it decompression or disk I/O. As Figure 6 shows, with default hardware on-demand paging, the achieved end-to-end bandwidth is the same as disk read without direct I/O. This demonstrates that IAA streaming processing can entirely overlap with disk I/O. It is $10-15\%$ lower, however, than the achievable bandwidth of reads with direct I/O, because IAA communicates with the disk via the OS page cache when running over PRS. A way to further improve IAA over data from disk is to replace PRS with application-specific page fault handling. However, in that case, the end-to-end behavior depends on whether IAA is configured with enabled *block-on-fault*, a feature that allows the accelerator to block and wait until data becomes available. Without block-on-fault, IAA terminates with partial completion and cannot continue decompression from the place where it stopped; as a result, the job needs to restart from scratch. Given the streaming nature of IAA, it is possible to entirely close the gap between direct disk I/O and decompression by using block-on-fault in combination with O_DIRECT reads in a custom page service handler, either in a driver or user space. We leave this to future work.

4 Sabre Design

4.1 Memory Prefetching Accelerator

We use the insights from the characterization study of Section 3 to design Sabre. Sabre is a hardware-accelerated memory snapshotting and restoration system for microVMs that is agnostic to the underlying algorithm used to identify dirty pages and create VM snapshots.

Sabre is designed to efficiently compress the guest VM physical pages to create snapshots, such that they can be decompressed (and mapped) quickly when restoring the snapshot upon a function invocation resulting in a cold start. As an input, Sabre accepts a vector of addresses for each of the guest physical memory pages which need to be placed in the snapshot, according to the underlying dirty page selection mechanism. It then compresses pages using IAA and writes them in a file. During the VM restoration process, Sabre uses fast IAA decompression in combination with efficient sequential disk I/O to quickly fetch the pages from the snapshot, decompress, and install them in the target VM's physical memory. The main goal of Sabre is to hide the decompression latency as much as possible behind the disk I/O and page fault handling (when mapping pages) such that the overhead of decompression is minimized. This is possible to achieve given the streaming nature of IAA decompression.

Sabre shows that irrespective of the method used to identify dirty pages and create VM snapshots, hardware-accelerated compression, and restoration can have a significant impact on performance. In the simplest case, dirty pages can be identified by the page tracking mechanism in the VMM (e.g., Firecracker's *Diff* snapshots); in more complicated cases, custom algorithms can be used (e.g., different working set estimation techniques [64, 72]).

Figure 7-A shows an overview of Sabre's snapshot creation pipeline along with two designs for memory prefetching, both of which are used by Sabre under different scenarios.

Snapshot creation: We first describe our snapshot creation process, which is based on two observations. First, creating a snapshot is outside of the VM restoration's critical path, so the objective is selecting the compression algorithm that achieves the highest compression ratio, which as we showed in Section 3 is dynamic DEFLATE. Second, since the VM dirty pages are distributed in a non-contiguous manner across the guest's physical memory space, the (de)compressor should operate over separate (often small) chunks of memory. As

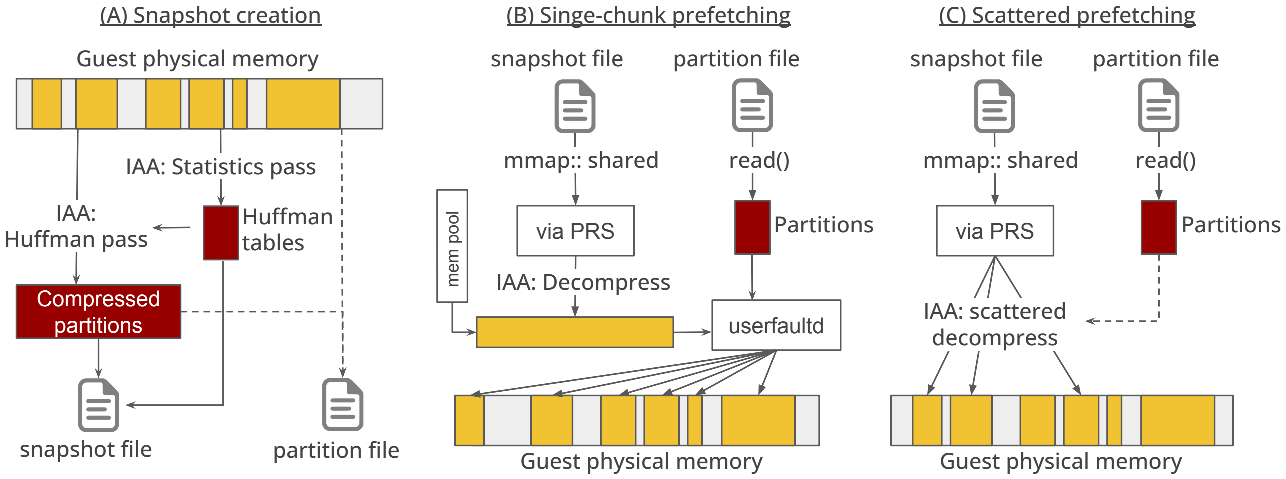

Figure 7: High-level overview of snapshotting with Sabre.

Figure 3 shows, the "Canned" style compression works best in this case: it enables implementing static DEFLATE with pre-computed Huffman tables, which closely resembles the efficiency of Dynamic DEFLATE. Sabre's snapshot creation process first runs IAA in Statistics mode to sample the statistical distribution of data in all dirty pages and create appropriate Huffman tables. It then compresses the scattered regions of dirty pages with these Huffman tables. The resulting compression stream alongside the Huffman tables is written into the snapshot file. For experimentation reasons, we also enable using Dynamic DEFLATE as well. In addition to the snapshot file itself, Sabre also writes the partition file containing the "schema" of the dirty pages, i.e., the offsets and original/compressed sizes of each partition.

Memory prefetching: The memory prefetching process is more complicated to engineer as it is on the critical path of VM restoration, and therefore needs to be carefully optimized. The main trade-off Sabre must navigate is balancing the desire to handle all partitions of dirty pages as a single contiguous memory region and the cost that comes with that.

Handling all partitions of dirty pages as a single continuous memory region is better for the accelerator, as continuous DMA is more efficient than scattered DMA, and it is also better for the PRS and disk I/O, as the underlying PRS-initiated page faults are sequential. The latter works well with sequential disk reads, therefore yielding the best utilization in terms of disk bandwidth. However, continuous decompressed partitions need to be placed by the same addresses in the guest VM physical memory as in the original VM when the snapshot was taken. Sabre implements it using *userfaultfd*, which comes at the cost of memory copy.

We implement this approach in Sabre's *single-chunk memory prefetching* shown in Figure 7-B. To reduce the overhead of allocating the decompression buffers, Sabre can optionally use a pre-allocated memory pool for the buffer for the time of decompression. The size of the pool is bounded by the sum of the sizes of dirty pages of the VMs currently restored simultaneously. This space is reusable across different restoration processes and therefore does not consume much memory. However, users of Sabre can always disable the memory pool (at $\approx 10\%$ cost of memory restoration) if the pool's impact on the memory density is an important concern. Sabre's memory prefetching relies heavily on the PRS hardware mechanism to bring snapshots from the disk. This is achieved by running IAA against a shared not pre-faulted (i.e. the actual file I/O gets initiated by PRS) mapping of the snapshot file. As Figure 6 shows, default PRS is near-optimal at handling IAA inputs from the disk, and it allows hiding the decompression time by overlapping it with the disk I/O. In most cases, the difference with sequential disk read bandwidth is marginal. We confirm that running IAA over pre-faulted or pre-fetched (via *read*) snapshot files is much slower than via PRS.

To address the high cost of partition placement when treating the entire memory region as contiguous, Sabre also implements memory prefetching based on scattered IAA decompression (Figure 7-C). Here, Sabre directly DMAs decompressed partitions into the right locations in the guest's physical memory, while still handling inputs from disk via PRS. This allows the system to bypass page installation, however, it makes the IAA hardware less efficient due to the large number of scattered DMAs and the bookkeeping of the corresponding descriptors (the current implementation of IAA does not allow chaining and batching of descriptors, so each one must be submitted separately by software). In addition, splitting the decompression stream into multiple jobs hurts the efficiency of PRS at reading data from the disk, which further slows down memory prefetching. The latter can be addressed by implementing a custom user-space page fault handler, as discussed in Section 3.

In both designs for memory prefetching, IAA decompression can be done using a single IAA job/engine or parallelized across all available engines. This is implemented via non-blocking job submission with a rotating pool of descriptors. In this mode, Sabre attempts to submit N decompression jobs at the same time, where N is the desired concurrency degree or the number of available free engines (whichever is smaller). Upon asynchronous out-of-order completion, the corresponding descriptors are returned to the pool for later reuse. This enables a streaming operation for Sabre's decompression when multiple engines are used. Note that a single IAA engine in blocking synchronous mode is capable of achieving $\approx 1.2\ GB/s$ at decompressing our snapshot datasets. Since this is higher than our disk read bandwidth, we always use a single IAA job in all remaining experiments, unless otherwise noted.

The exact operation of the memory prefetching unit, such as the choice of the restoration design (between single-chunk and scattered), the compression style (dynamic or static DEFLATE) for snapshot creation, the number of concurrent decompression jobs, etc. are configured by Sabre during runtime. The desired configuration can be selected differently for each microVM's snapshotting/restoration call. Next, we microbenchmark our memory prefetching unit under different configurations and types of snapshots.

4.2 Microbenchmarking Memory Restoration

We now analyze the two design options for memory prefetching shown in Figure 7 using a dataset of microVM dirty memory snapshots with different sparsities. We create synthetic datasets from the *pillow* snapshot (Section 3) that range from *most scattered*, when each page is separated, to a case with few large contiguous regions of dirty pages. In practice, the pattern depends on the underlying mechanism used to identify snapshot pages and the applications running in the VMs.

Figure 8 shows the restoration time with each of the two restoration mechanisms when the restoration is done in hardware and software. The x-axis shows the sparsity of the dataset. In all cases, the total size of the dataset is 174.5 MB. The sparsity index denotes the number of pages in continuous regions; each region is separated by its neighbor via an empty page, which is not included in the snapshot. For instance, in sparsity 1, each individual page is separated. We use a single IAA engine in all experiments. As the top figure shows, the scattered memory prefetching design outperforms single-chunk prefetching for sparsities of more than 4 pages. This is because this design avoids additional page copying during the installation phase via userfaultfd. However, when memory partitions become as sparse as every page or two pages, the overhead of scattered DMA and suboptimal PRS handling make scattered prefetching slower than single-chunk. Given this, Sabre uses different memory prefetching strategies depending on the sparsity of the underlying snapshots.

The dashed line in Figure 8 (Top) denotes the time required to restore memory from uncompressed snapshots. We optimize this path similarly to REAP [64], where the whole snapshot is fetched as a single continuous disk read via O_DIRECT file I/O and installed via $userfaultfd$. Sabre's memory restoration overperforms prefetching of uncompressed snapshots by up to 1.9×. Note that the achieved compression ratio on this dataset is 2.2×, meaning that the theoretical upper bound of memory restoration speed-up with respect to uncompressed baselines is also 2.2×. Sabre's memory prefetching is very close to this because it hides decompression behind disk I/Os. For faster disks, these results would still hold.

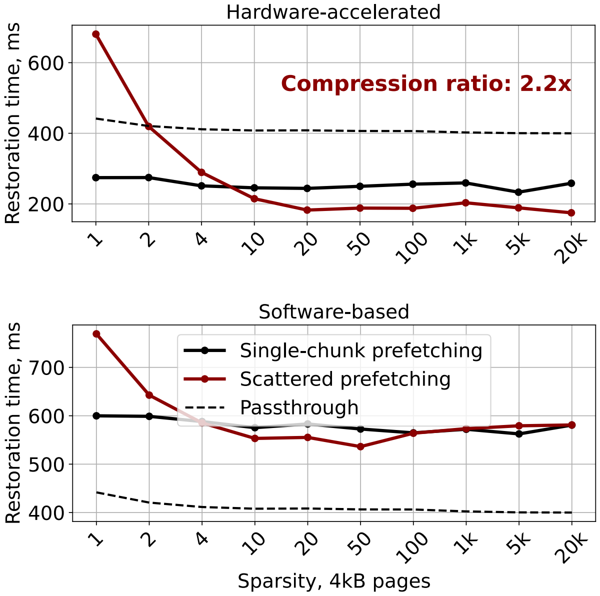

Figure 8: Single-chunk and scattered prefetching across different page sparsities; *passthrough* denotes the time to read uncompressed snapshots; the system runs at 2.3 GHz with a single IAA engine.

Figure 8 (bottom) shows the same results when running Sabre with software-based DEFLATE decompression. Across all different memory sparsities, the overhead of software decompression kills the speed-up of fetching deflated snapshots. This demonstrates that hardware acceleration is required to make snapshot compression practical.

For the sake of completeness, we additionally integrate other *software* compression algorithms optimized for performance in Sabre: *Snappy*, *Zstandard (zstd)*, and *LZ4*. We run them on a dedicated CPU core under the highest possible turbo boost frequency of *4 GHz* and repeat the snapshotting microbenchmark experiment. As Figure 9 shows, across all sparsities, the memory restoration with IAA outperforms these algorithms. The restoration times under *Zstd level-3,10*, and *20* are very close to IAA results and are much lower than prefetching uncompressed snapshots. However, as Figure 9 (Bottom) shows, they require a *significant* amount of CPU resources at the snapshot creation stage (up to several seconds at the highest frequency), and they do not demonstrate performance as high as IAA when running at lower CPU frequencies. We do not show results for *LZ4* as its compression ratios are low.

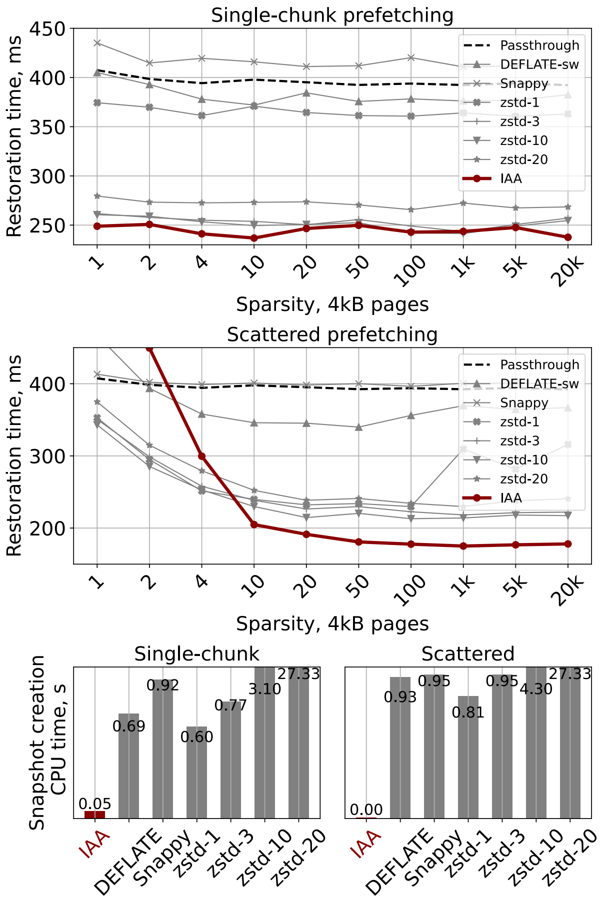

Figure 9: Sabre with different fast *software* (de)compression algorithms running on dedicated CPU cores under the turbo boost frequency of *4 GHz*; the bottom plots show CPU resources (in seconds) consumed to make the snapshots (averaged over sparsities).

4.3 Full System Implementation

We now discuss how we integrate Sabre's memory prefetching unit in an end-to-end serverless framework. We choose Firecracker microVMs [17] as the target serverless sandbox. Firecracker is the current industry-leading VMM, and it already provides good VM snapshotting capabilities. Most recent work in this space, such as REAP [64], is also based on Firecracker. To build the end-to-end serverless pipeline, we partially reuse the infrastructure of vHive – an academic framework for serverless used to showcase the effectiveness of REAP working sets. vHive allows running serverless Docker images inside Firecracker microVMs via *firecracker-containerd*. vHive also extends the native Firecracker Go SDK to support snapshotting and implements a simple orchestrator to simplify managing the serverless environment.

We write Sabre's snapshotting unit in ≈ 3500 LoC in C++17 excluding unit tests and benchmarks, using Intel's QPL library v1.3.1 and build it as a dynamic library. We then integrate it with Firecracker VMM v1.5.0 in only 50 LoC in Rust via FFI. Sabre runs in the default Firecracker's snapshotting/restoration thread, and does not require additional CPU resources. To expose Sabre's snapshotting to the higher layers of serverless frameworks, we additionally extend the Firecracker's Go SDK 1.0.0 with several new APIs. Figure 10 shows the simplified overview of the full system design. Similarly to vHive [64], our infrastructure enables running end-to-end serverless applications in Firecracker microVMs with standard Docker environments.

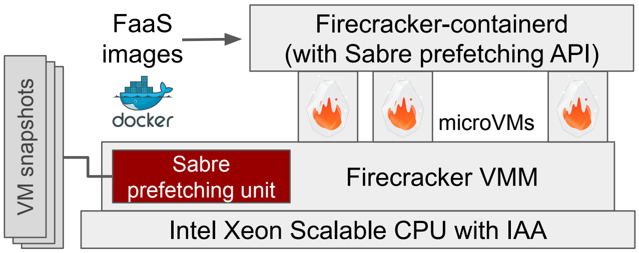

Figure 10: Sabre's integration in end-to-end serverless frameworks.

5 End-to-End Evaluation

Methodology: We evaluate Sabre on a large set of end-to-end serverless benchmarks from vSwarm [66], FunctionBench [44, 45], and SeBS [27]. We modify the benchmarks to run grpc servers and support server reflection so that we can invoke functions using grpcurl. The set includes only one synthetic benchmark – *python-list* implementing traversing a large sparse Python list; we include it to showcase the upper-bound of compression achievable with Sabre. We slightly modify the *dna-visualisation* benchmark from SeBS to make it use different DNA sequence datasets across different invocations (the default benchmark is always based on the same dataset; *dna-visualisation-1*). Similarly, we modify the datasets for the *model training* benchmark to use smaller 2 MB and larger 10 MB images. All other benchmarks are taken from the aforementioned suites. In all experiments, we use a single IAA engine for memory prefetching.

Sabre's memory prefetching unit is agnostic to the underlying mechanism of creating a snapshot. It can be used with dirty page-based snapshots, with working sets, and even when snapshotting the whole guest's VM memory. Since the latter is not practical for realistic serverless workloads, and therefore rarely used in practice, we only evaluate Sabre on the first two options. In all experiments, we use our testbed with the configuration shown in Table 2. We focus our evaluation on two metrics: (1) how well Sabre is able to compress snapshots of different types, and (2) what is the impact of decompression on the end-to-end cold start time.

End-to-end performance impact: Figure 11 shows the result of running the default dirty page-based snapshots of Firecracker (Diff snapshots [2]) with Sabre. Diff snapshotting is enabled via dirty page tracking in the hypervisor. We find Diff snapshots to be relatively large (a few hundred MB)

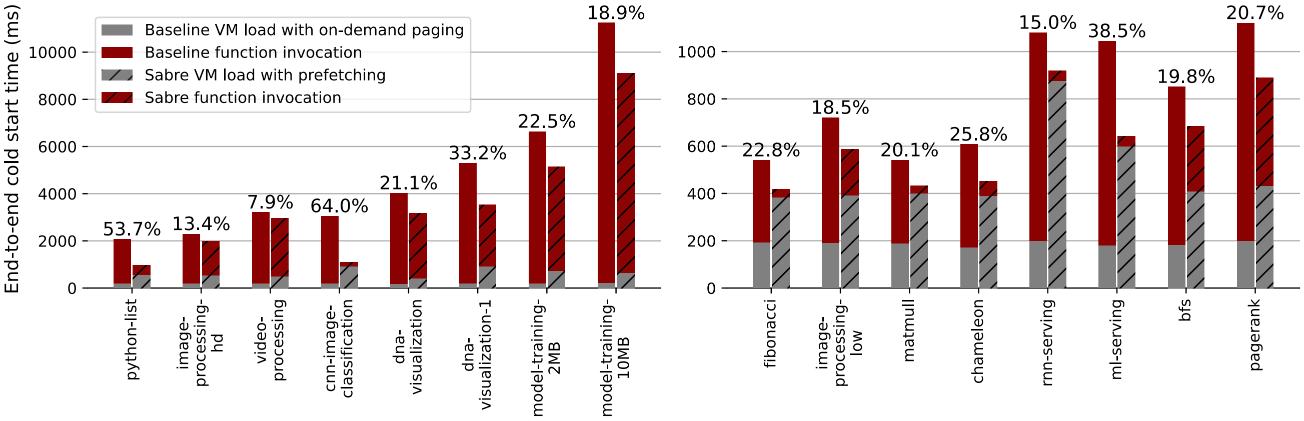

Figure 11: End-to-end evaluation of serverless cold starts with Sabre on Firecracker's default Diff snapshots with prefetching; annotated numbers show speedup of Sabre over the baseline.

and coarse-grained for all applications, which means that the scattered prefetching (Figure 7-C) works best in this case.

Figure 11 compares the end-to-end cold start latency when serving requests from a VM restored with on-demand paging (default mechanism in Firecracker) and via prefetching with Sabre. We find that in all cases, Sabre is able to compress Diff snapshots by up to 4×, and 2.5× on average. This is a significant reduction in storage requirements, given the large original size of Diff snapshots, ranging from hundreds of megabytes to several gigabytes. This is even more significant given that in serverless deployments, a physical node can host hundreds or thousands of snapshotted VMs [17].

Most importantly, in all cases, the hardware-accelerated decompression in Sabre allows restoring a compressed snapshot without any negative impact on the end-to-end latency. Moreover, in some applications, we observe up to 60% lower cold start overhead, enabled by the fast memory prefetching. The speed-up and compression effect are particularly evident for our synthetic *python-list* benchmark, where the dirty memory, i.e., the Python runtime heap storing the list, is well compressible. The same holds for *dna-visualization* as well.

Optimizing the VM snapshotting strategy: While Diff snapshots and dirty page tracking currently represent the industry standard in microVM snapshotting, they are not the most efficient way to restore memory via prefetching. More efficient mechanisms are enabled via working set estimation. We implement working sets in Sabre which are used with our memory prefetching unit for evaluation purposes. Our implementation is based on the record-and-replay technique. Similarly to the original paper [64], Sabre records working sets during the first invocation of serverless functions after the standard restoration from vanilla Firecracker snapshots. We intercept in user-space the guest memory page faults and record all accessed addresses in a vector. The recorder then groups the accessed pages to form continuous chunks, whenever possible, and saves them in a WS file. The REAP restoration uses the *passthrough* functionality of Sabre's memory prefetching unit, which resembles the original REAP specification [64], i.e., direct I/O disk reads combined with page installation in the guest physical memory via *userfaultfd*. After prefetching, the hypervisor continues serving the rest of the pages outside of the working set via standard on-demand paging.

REAP working set files tend to be much more scattered than Firecracker's Diff snapshots. We make a similar observation in our applications as well. Therefore, memory restoration through single-chunk prefetching works best in this case, and we configure Sabre accordingly for REAP snapshots. Table 3 shows the achieved compression ratios of REAP working set files and the corresponding prefetching speedup when using Sabre. Figure 12 shows the end-to-end cold start latencies across the same set of serverless benchmarks as before.

Table 3 shows that working set files are better compressible than dirty pages. The compression ratio reaches up to 4.7×; 3.2× on average. The prefetching time itself with Sabre is accelerated by $25-55\%$. On the synthetic application *python-list*, the speedup reaches 70%. As expected, there is an obvious correlation between the achieved compression ratio and prefetching speedup. End-to-end, working set prefetching speedup translates in up to 20% of improvement in the application's cold start latency. For several of the examined applications, the speedup is diminished due to the working set size being small or their compute time being high. In the latter case, the impact of accelerated restoration gets hidden behind computing. In general, compression of snapshots/working set files is more impactful on applications with larger working sets, especially if they are memory-bounded (as in the case of the *python-list* benchmark). Even when Sabre does not accelerate cold start time significantly, it still greatly reduces the size of the working set files without a negative impact on prefetching latency and/or CPU cycles for restoration.

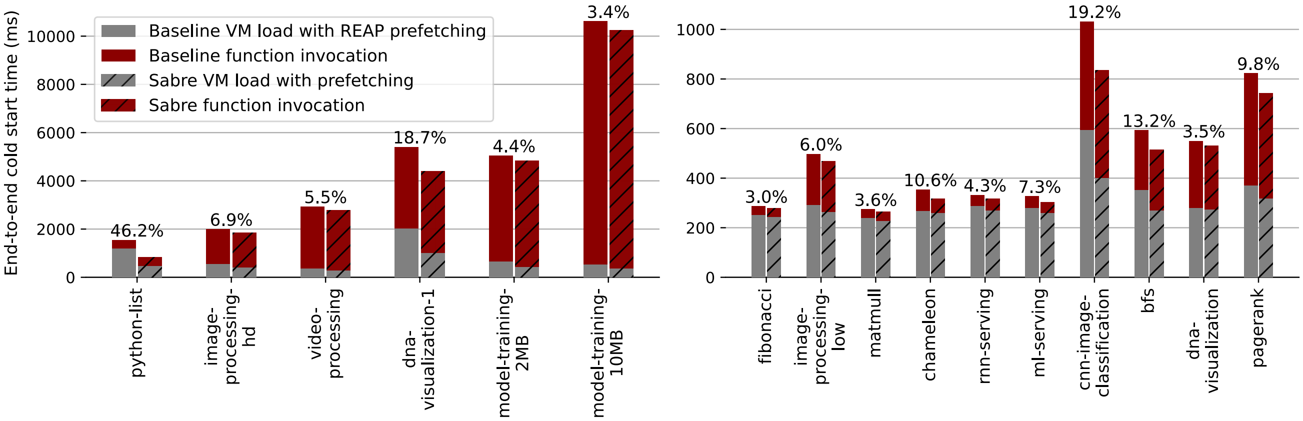

Figure 12: End-to-end evaluation of serverless cold starts with Sabre on REAP snapshots; annotated numbers show the speedup over REAP.

Table 3: Compression ratios and page prefetching speedup of Sabre over REAP working sets.

6 Discussion and Future Work

6.1 Prefetching on Faster Disks and Networks

While the performance impact of memory prefetching becomes less critical as the speed of disks and NVMe/persistent memory devices increases, Sabre benefits when it comes to storage space reduction remain. This is even more critical, given the higher cost per Byte of new memory technologies. CPU-free memory decompression, especially at zero negative impact on end-to-end latency will always be beneficial, independent of the underlying storage technology. In future work, we plan to evaluate Sabre on CXL-enabled memory devices and explore the potential of serving compressed snapshots from them. The byte-addressable organization of CXL and other similar memory disaggregation devices will make the integration with near-memory accelerators, such as IAA, much more efficient than when using commodity disks, essentially eliminating all overheads of PRS discussed in Section 3.

Additionally, the streaming nature of hardware accelerators, such as IAA, allows combining Sabre with any streaming I/O, including networking. This makes Sabre attractive for *remote snapshotting* – another technology in serverless microVMs where snapshots and/or working set files are served from centralized storage or a remote server. Fast streaming decompression can have a dramatic reduction of network bandwidth consumed for snapshotting, which is critical for highly multi-tenant and geographically distributed datacenters.

6.2 Further Optimizing Sabre

The biggest limitation in our current design of Sabre is its integration with the disk via the standard IAA's PRS mechanism. This disallows bypassing the OS page cache when feeding an input to IAA, and results in lower effective bandwidth utilization than direct I/O. This can be optimized by redesigning the default PRS in one of two ways.

First, PRS can be replaced with user-space page fault handling for input buffers. Disk I/O can be initiated separately in user space using the *read* system call combined with *O_DIRECT* file opening. In this case, the IAA page fault handler only needs to wait until the disk DMA catches up with the sequential data transfer. This requires enabling the *block-on-fault* feature of IAA, otherwise, the input stream would need to be resubmitted from the beginning every time IAA reaches pages that have not been fetched yet. Alternatively, one can directly connect the disk's and IAA's DMA engines, and allow streaming of compressed inputs directly into the accelerator through a small FIFO buffer. However, this can only be done in the host kernel in custom IAA drivers and is challenging to implement in a scalable way.

A second limitation in the current design's single-chunk prefetching (Figure 7-B) is using the COPY-based `userfaultfd` mechanism. The original REAP snapshots [64] suffer from the same inefficiency. Starting with Linux kernel 5.13, `userfaultfd` can be handled via minor page faults and *UFFDIO_CONTINUE* page installation. Instead of copying pages from the continuous buffers, one can install them from the page cache via the underlying page table modification with zero-copy. This will, however, complicate managing the decompression/prefetching buffers to ensure they are never reclaimed, while the corresponding microVM is running.

6.3 Beyond MicroVM Snapshotting

VM memory compression and fast restoration go well beyond microVM snapshotting and serverless. For example, VM live migration [18,59] can benefit from hardware-accelerated compression and on-the-fly decompression of memory pages. The recent work [14] is exploring this opportunity for KVM. This can dramatically accelerate applications heavily relying on VM migration, including VM bin-packing for cloud management [55], low-latency cloud-native applications such as vRAN [49, 68], and fast fault-tolerance solutions [63]. We plan to extend Sabre to benefit these applications as well.

7 Conclusion

MicroVM snapshotting and restoration via page prefetching is the most effective technique for reducing the cold start overhead in serverless. Memory compression is a promising technique to reduce the size of VM snapshots and speed up prefetching during memory restoration, but it is only efficient if decompression is fast. We showed that emerging hardware accelerators for *general-purpose* compression are suitable for microVM memory restoration as well. We first characterized the Intel IAA accelerator and then designed Sabre, a system for fast prefetching of VM memory from compressed snapshots. We showed that Sabre compresses snapshots of real serverless applications up to 4.5×, and speeds up prefetching by up to 55% compared to uncompressed baselines. This results in up to 20% of end-to-end performance improvement for cold function invocations over the most optimized snapshotting technologies.

NOMAD: Non-Exclusive Memory Tiering via Transactional Page Migration

Lingfeng Xiang, Zhen Lin, Weishu Deng, Hui Lu, Jia Rao, Yifan Yuan[†], Ren Wang[†]
The University of Texas at Arlington, [†]Intel Labs

Abstract

With the advent of byte-addressable memory devices, such as CXL memory, persistent memory, and storage-class memory, tiered memory systems have become a reality. Page migration is the *de facto* method within operating systems for managing tiered memory. It aims to bring hot data whenever possible into fast memory to optimize the performance of data accesses while using slow memory to accommodate data spilled from fast memory. While the existing research has demonstrated the effectiveness of various optimizations on page migration, it falls short of addressing a fundamental question: Is exclusive memory tiering, in which a page is either present in fast memory or slow memory, but not both simultaneously, the optimal strategy for tiered memory management?

We demonstrate that page migration-based exclusive memory tiering suffers significant performance degradation when fast memory is under pressure. In this paper, we propose *non-exclusive* memory tiering, a page management strategy that retains a copy of pages recently promoted from slow memory to fast memory to mitigate memory thrashing. To enable non-exclusive memory tiering, we develop NOMAD, a new page management mechanism for Linux that features *transactional page migration* and *page shadowing*. NOMAD helps remove page migration off the critical path of program execution and makes migration completely asynchronous. Evaluations with carefully crafted micro-benchmarks and real-world applications show that NOMAD is able to achieve up to 6x performance improvement over the state-of-the-art transparent page placement (TPP) approach in Linux when under memory pressure. We also compare NOMAD with a recently proposed hardware-assisted, access sampling-based page migration approach and demonstrate NOMAD's strengths and potential weaknesses in various scenarios.

1 Introduction

As new memory devices, such as high bandwidth memory (HBM) [4, 30], DRAM, persistent memory [7, 39], Compute Express Link (CXL)-based memory [1, 37, 44], and storage-class memory [53, 55] continue to emerge, future computer systems are anticipated to feature multiple tiers of memory with distinct characteristics, such as speed, size, power, and cost. Tiered memory management aims to leverage the strength of each memory tier to optimize the overall data access latency and bandwidth. Central to tiered memory management is *page management* within operating systems (OS), including page allocation, placement, and migration. Efficient page management in the OS is crucial for optimizing memory utilization and performance while maintaining transparency for user applications.

Traditionally, the memory hierarchy consists of storage media with at least one order of magnitude difference in performance. For example, in the two-level memory hierarchy assumed by commercial operating systems for decades, DRAM and disks differ in latency, bandwidth, and capacity by 2-3 orders of magnitude. Therefore, the sole goal of page management is to keep hot pages in, and maximize the hit rate of the "performance" tier (DRAM), and migrate (evict) cold pages to the "capacity" tier (disk) when needed. As new memory devices emerge, the performance gap in the memory hierarchy narrows. Evaluations on Intel's Optane persistent memory [56] and CXL memory [50] reveal that these new memory technologies can achieve comparable performance to DRAM in both latency and bandwidth, within a range of 2-3x. As a result, the assumption of the performance gap, which has guided the design of OS page management for decades, may not hold. It is no longer beneficial to promote a hot page to the performance tier if the migration cost is too high.

Furthermore, unlike disks which must be accessed through the file system as a block device, new memory devices are byte-addressable and can be directly accessed by the processor via ordinary `load` and `store` instructions. Therefore, for a warm page on the capacity tier, accessing the page directly and avoiding migration to the performance tier could be a better option. Most importantly, while the performance of tiered memory remains hierarchical, the hardware is no longer hierarchical. Both the Optane persistent memory and

CXL memory appear to the processor as a CPUless memory node and thus can be used by the OS as ordinary DRAM.

These unique challenges facing emerging tiered memory systems have inspired research on improving page management in the OS. Much focus has been on expediting page migrations between memory tiers. Nimble [54] improves page migration by utilizing transparent huge pages (THP), multi-threaded migration of a page, and concurrent migration of multiple pages. Transparent page placement (TPP) [44] extends the existing NUMA balancing scheme in Linux to support asynchronous page demotion and synchronous page promotion between fast and slow memory. Memtis [37] and TMTS [24] use hardware performance counters to mitigate the overhead of page access tracking and use background threads to periodically and asynchronously promote pages.

However, these approaches have two fundamental limitations. *First*, the existing page management for tiered memory assumes that memory tiers are *exclusive* to each other – hot pages are allocated or migrated to the performance tier while cold pages are demoted to the capacity tier. Therefore, each page is only present in one tier. As memory tiering seeks to explore the tradeoff between performance and capacity, the working set size of workloads that benefit most from tiered memory systems likely exceeds the capacity of the performance tier. Exclusive memory tiering inevitably leads to excessive hot-cold page swapping or memory thrashing when the performance tier is not large enough to hold hot data.

Second, there is a lack of an efficient page migration mechanism to support tiered memory management. As future memory tiers are expected to be addressable by the CPU, page migrations are similar to serving minor page faults and involve three steps: 1) unmap a page from the page table; 2) copy the page content to a different tier; 3) remap the page on the page table, pointing to the new memory address. Regardless of whether page migration is done synchronously upon accessing a hot page in the slower capacity tier or asynchronously in the background, the 3-step migration process is expensive. During migration, an unmapped page cannot be accessed by user programs. If page migration is done frequently, e.g., due to memory thrashing, user-perceived bandwidth, including accesses to the migrating pages, is significantly lower (up to 95% lower) than the peak memory bandwidth [54].

This paper advocates *non-exclusive* memory tiering that allows a subset of pages on the performance tier to have shadow copies on the capacity tier [1]. Note that non-exclusive tiering is different from *inclusive* tiering which strictly uses the performance tier as a cache of the capacity tier. The most important benefit is that under memory pressure, page demotion is made less expensive by simply remapping a page if it is not dirty and its shadow copy exists on the capacity tier. This allows for smooth performance transition when memory demand exceeds the capacity of the performance tier.

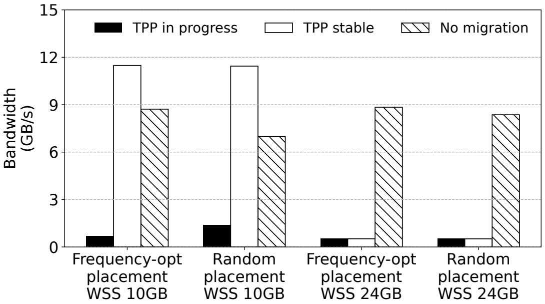

Figure 1: The comparison of achieved memory bandwidth in a micro-benchmark due to different phases in TPP and a baseline approach that disables page migration. Higher is better performance.

To reduce the cost of page migration, especially for promotion, this paper proposes *transactional page migration* (TPM), a novel mechanism to enable page access during migration. Unlike current page migrations, TPM starts page content copy without unmapping the page from the capacity tier so that the migrating page is still accessible by user programs. After page content is copied to a new page on the performance tier, TPM checks whether the page has been dirtied during the migration. If so, the page migration (i.e., the transaction) is invalidated and the copied page is discarded. Failed page migrations will be retried at a later time. If successful, the copied new page is mapped in the page table and the old page is unmapped, becoming a shadow copy of the new page.

We have developed NOMAD, a new page management framework for tired memory that integrates non-exclusive memory tiering and transactional page migration. NOMAD safeguards page allocation to prevent out-of-memory (OOM) errors due to page shadowing. When the capacity tier is under memory pressure, NOMAD prioritizes the reclamation of shadow pages before evicting ordinary pages. We have implemented a prototype of NOMAD in Linux and performed a thorough evaluation on four different platforms, including an FPGA-based CXL prototype, a persistent memory system, and a pre-market, commercial CXL system. Experimental results show that, compared to two representative page management schemes: TPP and Memtis, NOMAD achieves up to 6x performance improvement over TPP during memory thrashing and consistently outperforms Memtis by as much as 130% when the working set size fits into fast memory.

2 Motivation and Related Work

We introduce the background of page management in tiered memory systems and use TPP [44], a state-of-the-art page placement system designed for CXL-enabled tiered memory, as a motivating example to highlight the main limitations of current page management approaches.

[1] We assume that page migrations only occur between two adjacent tiers if there are more than two memory tiers.

2.1 Memory Tiering

Caching and tiering are two traditional software approaches to manage a memory, or storage hierarchy, consisting of various types of storage media (e.g., CPU caches, DRAM, and hard disks) differing in performance, capacity, and cost. Without loss of generality, we consider a two-level memory hierarchy with 1) a *performance* tier (i.e., the fast tier), backed with smaller, faster, but more expensive storage media; and 2) a *capacity* tier (i.e., the slow tier) with larger, slower, and cheaper storage media. For *caching*, data is stored in the capacity tier, and copies of frequently accessed or "hot" data are strategically replicated to the performance tier. For *tiering*, new data is first allocated to the performance tier and remains there if it is frequently accessed, while less accessed data may be relegated to the capacity tier when needed. At any moment, data resides exclusively in one of the tiers but not both. Essentially, caching operates in an *inclusive* page placement mode and retains pages in their original locations, only temporarily storing a copy in the performance tier for fast access. Conversely, tiering operates in an *exclusive mode*, actively relocating pages across various memory/storage mediums.

Diverse memory/storage devices, such as high bandwidth memory (HBM) [4], CXL-based memory [1], persistent memory (PM) [7], and fast, byte-addressable NVMe SSDs [31], have emerged recently. While they still make a tradeoff between speed, size, and cost, the gap between their performance narrows. For example, Intel Optane DC persistent memory (PM), available in a DIMM package on the memory bus enabling programs to directly access data from the CPU using `load` and `store` instructions, provides (almost) an order of magnitude higher capacity than DRAM (e.g., 8x) and offers performance within a range of 2-3x of DRAM, e.g., write latency as low as 80 *ns* and read latency around 170 *ns* [56]. More recently, compute express link (CXL), an open-standard interconnect technology based on PCI Express (PCIe) [1], provides a memory-like, byte-addressable interface (i.e., via the `CXL.mem` protocol) for connecting diverse memory devices (e.g., DRAM, PM, GPUs, and smartNICs). Real-world CXL memory offers comparable memory access latency (<2x) and throughput ($\sim$50%) to ordinary DRAM [50].

From the perspective of OS memory management, CXL memory or PM appears to be a remote, CPUless memory node, similar to a multi-socket non-uniform memory access (NUMA) node. State-of-the-art tiered memory systems, such as TPP [44], Memtis [37], Nimble [54], and AutoTiering [32], all adopt *tiering* to *exclusively* manage data on different memory tiers. Unlike the traditional two-level memory hierarchy involving DRAM and disks, in which DRAM acts as a cache for the much larger storage tier, current CXL memory tiering treats CXL memory as an extension of local DRAM. While exclusive memory tiering avoids data redundancy, it necessitates data movement between memory tiers to optimize the performance of data access, i.e., promoting hot data to the fast tier and demoting cold data to the slow tier. Given that all memory tiers are byte-addressable by the CPU and the performance gap between tiers narrows, it remains to be seen whether exclusive tiering is the optimal strategy considering the cost of data movement.

We evaluate the performance of transparent page placement (TPP) [44], a state-of-the-art and the default tiered memory management in Linux. Figure 1 shows the bandwidth of a micro-benchmark that accesses a configurable working set size (WSS) following a Zipfian distribution in a CXL-based tiered memory system. More details of the benchmark and the hardware configurations can be found in Section 4. We compare the performance of TPP while it actively migrates pages between tiers for promotion and demotion (denoted as *TPP in progress*) and when it has finished page relocation (*TPP stable*) with that of a baseline that disables page migration (*no migration*). The baseline does not optimize page placement and directly accesses hot pages from the slow tier. The tiered memory testbed is configured with 16GB fast memory (local DRAM) and 16GB slow memory (remote CXL memory). We vary the WSS to fit in (e.g., 10GB) and exceed (e.g., 24GB) fast memory capacity. Note that the latter requires continuous page migrations between tiers since hot data spills into slow memory. Additionally, we explore two initial data placement strategies in the benchmark. First, the benchmark pre-allocates 10GB of data in fast memory to emulate the existing memory usage from other applications. *Frequency-opt* is an allocation strategy that places pages according to the descending order of their access frequencies (hotness). Thus, the hottest pages are initially placed in fast memory until the WSS spills into slow memory. In contrast, *Random* employs a random allocation policy and may place cold pages initially in fast memory.

We have important observations from results in Figure 1. First, page migration in TPP incurs significant degradation in application performance. When WSS fits in fast memory, *TPP stable*, which has successfully migrated all hot pages to fast memory, achieves more than an order of magnitude higher bandwidth than *TPP in progress*. Most importantly, *no migration* is consistently and substantially better than *TPP in progress*, suggesting that the overhead of page migration outweighs its benefit until the migration is completed. Second, TPP never reaches a stable state and enters memory thrashing when WSS is larger than the capacity of fast memory. Third, page migration is crucial to achieving optimal performance if it is possible to move all hot data to fast memory and the initial placement is sub-optimal, as evidenced by the wide gap between *TPP stable* and *no migration* in the 10GB WSS and random placement test.

2.2 Page Management

In this section, we delve into the design of page management in Linux and analyze its overhead during page migration. We focus our discussions on 1) how to effectively track memory accesses and identify hot pages, and 2) the mechanism to migrate a page between memory tiers.

Tracking memory access can be conducted by software (via the kernel) and/or with hardware assistance. Specifically, the kernel can keep track of page accesses via page faults [2, 32, 44], scanning page tables [2, 14, 19, 43, 54], or both. Capturing each memory access for precise tracking can be expensive. Page fault-based tracking traps memory accesses to selected pages (i.e., whose page table entry permissions are set to `no access`) via hint (minor) page faults. Thus, it allows the kernel to accurately measure the *recency* and *frequency* of these pages. However, invoking a page fault on every memory access incurs high overhead on the critical path of program execution. On the other hand, page table (PT) scanning periodically checks the `access` bit in all page table entries (PTE) to determine recently accessed pages since the last scanning. Compared to page fault-based tracking, which tracks every access on selected pages, PT scanning has to make a tradeoff between scanning overhead and tracking accuracy by choosing an appropriate scanning interval [37].

Linux adopts a *lazy* PT scanning mechanism to track hot pages, which lays the foundation for its tiered memory management. Linux maintains two LRU lists for a memory node: an *active* list to store hot pages and an *inactive* list for cold pages. By default, all new pages go to the inactive list and will be promoted to the active list according to two flags, `PG_referenced` and `PG_active`, in the per-page struct `page`. `PG_reference` is set when the `access` bit in the corresponding PTE is set upon a PTE check and `PG_active` is set after `PG_reference` is set for two consecutive times. A page is promoted to the active list when its `PG_active` flag is set. For file-backed pages, their accesses are handled by the OS through the file system interface, e.g., `read()` and `write()`. Therefore, their two flags are updated each time they are accessed. For anonymous pages, e.g., application memory allocated through `malloc`, since page accesses are directly handled by the MMU hardware and bypass the OS kernel, the updates to their reference flags and LRU list management are only performed during memory reclamation. Under memory pressure, the swapping daemon `kswapd` scans the inactive list and the corresponding PTEs to update inactive pages' flags, and reclaims/swaps out those with `PG_reference` unset. Additionally, `kswapd` promotes hot pages (i.e., those with `PG_active` set) to the active list. This lazy scanning mechanism delays access tracking until it is necessary to reduce the tracking overhead, but undermines tracking accuracy.

TPP [44] leverages Linux's PT scanning to track hot pages and employs page fault-based tracking to decide whether to promote pages from slow memory. Specifically, TPP sets all pages residing in slow memory (e.g., CXL memory) as `inaccessible`, and any user access to these pages will trigger a minor page fault, during which TPP decides whether to promote the faulting page. If the faulting page is on the active list, it is migrated (promoted) to the fast tier. Page demotion occurs when fast memory is under pressure and `kswapd` migrates pages from the inactive list to slow memory.

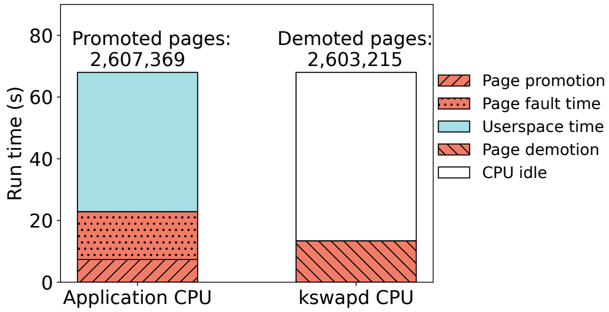

Figure 2: Time breakdown in the execution of *TPP in progress*: Synchronous page migration and page fault handling account for a significant portion of the runtime.

Accurate and lightweight memory access tracking can be achieved with hardware support, e.g., by adding a PTE *count field* in hardware that records the number of memory accesses [45]. However, hardware-based tracking can increase the complexity and require extensive hardware changes in mainstream architectures (e.g., x86). In practice, the hardware-assisted sampling, such as via Processor Event-Based Sampling (PEBS) [24, 37] on Intel platforms, has been employed to record page access (virtual address) information from sampled hardware events (e.g., LLC misses or store instructions). However, PEBS-based profiling also requires a careful balance between the frequency of sampling and the accuracy of profiling. We observed that the PEBS-based approach [37], with a sampling rate optimized for minimizing overhead, remains coarse-grained and fails to capture many hot pages. Further, the sampling-based approach may not accurately measure access recency, thus limiting its ability to make timely migration decisions.

Page migration between memory tiers involves a complex procedure: ① The system must trap to the kernel (e.g., via page faults) to handle migration; ② The PTE of a migrating page must be locked to prevent others from accessing the page during migration and be `ummapped` from the page table; ③ A translation lookaside buffer (TLB) shootdown must be issued to each processor (via inter-processor interrupts (IPIs)) that may have cached copies of the stale PTE; ④ The content of the page is copied between tiers; ⑤ Finally, the PTE must be `remapped` to point to the new location. Page migration can be done *synchronously* or *asynchronously*. Synchronous migration, e.g., page promotion in TPP, is on-demand triggered by user access to a page and on the critical path of program execution. During migration, the user program is blocked until migration is completed. Asynchronous migration, e.g., page demotion in TPP, is handled by a kernel thread (i.e., `kswapd`), oftentimes off programs' critical path, when certain criteria are met. Synchronous migration is costly not only because pages are inaccessible during migration but also may involve a large number of page faults.

Figure 2 shows the run time breakdown of the aforementioned benchmark while TPP is actively relocating pages between the two memory tiers. Since page promotion is synchronous, page fault handling and page content copying (i.e., promotion) are executed on the same CPU as the application thread. Page demotion is done through `kswapd` and uses a different core. As shown in Figure 2, synchronous promotion together with page fault handling incurs significant overhead on the application core. In contrast, the demotion core remains largely idle and does not present a bottleneck. As will be discussed in Section 3.1, userspace run time can also be prolonged due to repeated minor page faults (as many as 15) to successfully promote one page. This overhead analysis explains the poor performance of TPP observed in Figure 1.

2.3 Related Work

A long line of pioneering work has explored a wide range of tiered storage/memory systems, built upon SSDs and HDDs [12, 15, 22, 26, 33, 41, 49, 52, 57], DRAM and disks [21, 25, 29, 46], HBM and DRAMs [23, 45, 48], NUMA memory [2, 3], PM and DRAM [13, 14, 40, 43], local and far memory [19, 27, 34, 35, 47], DRAM and CXL memory [37, 38, 44], and multiple tiers [32, 36, 40, 51, 54]. We focus on tiered memory systems consisting of DRAM and the emerging byte-addressable memory devices, e.g., CXL memory and PM. NOMAD also applies to other tiered memory systems such as HBM/DRAM and DRAM/PM.

Lightweight memory access tracking. To mitigate software overhead associated with memory access tracking, Hotbox [19] employs two separate scanners for fast and slow tiers to scan the slow tier at a fixed rate while the fast tier at an adaptive rate, configurable based on the local memory pressure. Memtis [37] adjusts its PEBS-based sampling rate to ensure its overhead is under control (e.g., $< 3\%$). TMTS [24] also adopts a periodic scanning mechanism to detect frequency along with hardware sampling to more timely detect newly hot pages. While these approaches balance scanning/sampling overhead and tracking accuracy, an "always-on" profiling component does not seem practical, especially for high-pressure workloads. Instead, thermostat [14] samples a small fraction of pages, while DAMON [3] monitors memory access at a coarser-grained granularity (i.e., region). Although both can effectively reduce the scanning overhead, coarse granularity leads to lower accuracy regarding page access patterns. On the other hand, to reduce the overhead associated with frequent hint page faults like AutoNUMA [2], TPP [44] enables the page-fault based detection only for CXL memory (i.e., the slow tier) and tries to promote a page promptly via synchronous migration; prompt page promotion avoids subsequent page faults on the same page.

Inspired by existing lightweight tracking systems, such as Linux's active and inactive lists and hint page faults, NOMAD advances them by incorporating more recency information with *no* additional CPU overhead. Unlike hardware-assisted approaches [24, 37, 42], NOMAD does not require any additional hardware support.

Page migration optimizations. To hide reclamation overhead from applications, TPP [44] decouples page allocation and reclamation; however, page migration remains in the critical path, incurring significant slowdowns. Nimble [54] focuses on mitigating page migration overhead with new migration mechanisms, including transparent huge page migration and concurrent multi-page migration. Memtis [37] further moves page migration out of the critical path using a kernel thread to promote/demote pages in the background. TMTS [24] leverage a user/kernel collaborative approach to control page migration. In contrast, NOMAD aims to achieve prompt, on-demand page migration while moving page migration off the critical path. It is orthogonal to and can benefit from existing page migration optimizations. The most related work is [20], which leverages hardware support to pin data in caches, enabling access to pages during migration. Again, NOMAD does not need additional hardware support.

3 NOMAD Design and Implementation

NOMAD is a new page management mechanism for tiered memory that features *non-exclusive memory tiering* and *transactional page migration*. The goal of NOMAD design is to enable the processor to freely access pages from both fast and slow memory tiers and move the cost of page migration off the critical path of users' data access. Note that NOMAD does not make page migration decisions and relies on the existing memory access tracking in the OS to determine page temperature. Furthermore, NOMAD does not impact the initial memory allocation in the OS and assumes a standard page placement policy. Pages are allocated from the fast tier whenever possible and are placed in the slower tier only when there is an insufficient number of free pages in the fast tier, or attempts to reclaim memory in the fast tier have failed. After the initial page placement, NOMAD gradually migrates hot pages to the fast tier and cold pages to the slow tier. NOMAD seeks to address two key issues: 1) *how to minimize the cost of page migration?* 2) *how to minimize the number of migrations?*

Overview. Inspired by multi-level cache management in modern processors, which do not employ a purely inclusive or exclusive caching policy between tiers [16] to facilitate the sharing of or avoid the eviction of certain cache lines, NOMAD embraces a *non-exclusive* memory tiering policy to prevent memory thrashing when under memory pressure. Unlike the existing page management schemes that move pages between tiers and require that a page is only present in one tier, NOMAD instead copies pages from the slow tier to the fast tier and keeps a shadow copy of the migrated pages at the slow tier. The non-exclusive tiering policy maintains shadow copies

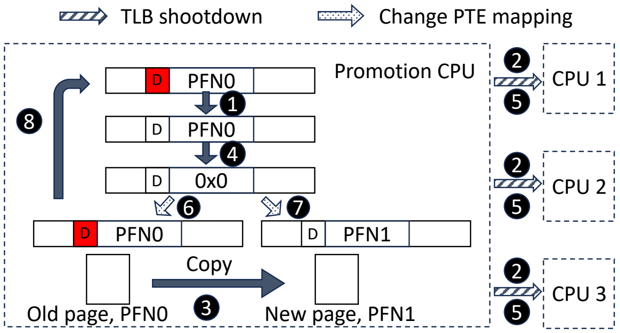

Figure 3: The workflow of transactional page migration. PFN is the page frame number and D is the dirty bit in PTE. The page is only inaccessible by user programs during step 4 when the page is remapped in the page table.

only for pages that have been promoted to the fast tier, thereby not an inclusive policy. The advantage of the non-exclusive policy is that the demotion of clean, cold pages can be simplified to remapping the page table entry (PTE) without the need to copy the cold page to the slower tier.

The building block of NOMAD is a new *transactional page migration* (TPM) mechanism to reduce the cost of page migrations. Unlike the existing unmap-copy-remap 3-step page migration, TPM opportunistically copies a page without unmapping it from the page table. During the page copy, the page is not locked and can be accessed by a user program. After the copy is completed, TPM checks if the page has been dirtied during the copy. If not, TPM locks the page and remaps it in the PTE to the faster tier. Otherwise, the migration is aborted and will be tried at a later time. TPM not only minimizes the duration during which a page is inaccessible but also makes page migration asynchronous, thereby removing it from the critical path of users' data access.

Without loss of generality, we describe NOMAD design in the context of Linux. We start with transactional page migration and then delve into page shadowing – an essential mechanism that enables non-exclusive memory tiering.

3.1 Transactional Page Migration

The motivation to develop TPM is to make page migration entirely asynchronous and decoupled from users' access to the page. As discussed in Section 2.2, the current page migration in Linux is synchronous and on the critical path of users' data access. For example, the default tiered memory management in Linux, TPP, attempts to migrate a page from the slow tier whenever a user program accesses the page. Since the page is in `inaccessible` mode, the access triggers a minor page fault, leading TPP to attempt the migration. The user program is blocked and makes no progress until the minor page fault is handled and the page is remapped to the fast tier, which can be a time-consuming process. Worse, if the migration fails, the OS remains in function `migrate_pages` and retries the aforementioned migration until it is successful or reaching a maximum of 10 attempts.

TPM decouples page migration from the critical path of user programs by making the migrating page accessible during migration. Therefore, users will access the migrating page from the slow tier before the migration is complete. While accessing a hot page from the slow tier may lead to sub-optimal memory performance, it avoids blocking user access due to the migration, thereby leading to superior user-perceived performance. Figure 3 shows the workflow of TPM. Before migration commences, TPM clears the protection bit of the page frame and adds the page to a migration pending queue. Since the page is no longer protected and not yet unmapped from the page table, following accesses to the page will not trigger additional page faults.

TPM starts a migration transaction by clearing the dirty bit of the page (step ❶) and checks the dirty bit after the page is copied to the fast tier to determine whether the transaction was successful. After changing the dirty bit in PTE, TPM issues a TLB shootdown to all cores that ever accessed this page (step ❷). This is to ensure that subsequent writes to the page can be recorded on the PTE. After the TLB shootdown is completed, TPM starts copying the page from the slow tier to the fast tier (step ❸). To commit the transaction, TPM checks the dirty bit by loading the entire PTE using atomic instruction `get_and_clear` (step ❹). Clearing the PTE is equivalent to unmapping the page and thus another TLB shootdown is needed (step ❺). Note that after unmapping the page from PTE, it becomes inaccessible by users. TPM checks whether the page was dirtied during the page copy (step ❻) and either commits the transaction by remapping the page to the fast tier if the page is clean (step ❼) or otherwise aborts the transaction (step ❽). If the migration is aborted, the original PTE is restored and waits for the next time when TPM is rescheduled to retry the migration. The duration in which the page is inaccessible is between ❹ and ❼/ ❽, significantly shorter than that in TPP (possibly multiple attempts between ❶ and ❼).

Page migration is a complex procedure that involves memory tracing and updates to the page table for page remapping. The state-of-the-art page fault-based migration approaches, e.g., TPP in Linux [44], employ synchronous page migration, a mechanism in the Linux kernel for moving pages between NUMA nodes. In addition to the extended migration time affecting the critical path of user programs, this mechanism causes excessive page faults when integrated with the existing LRU-based memory tracing. TPP makes *per-page* migration decisions based on whether the page is on the *active* LRU list. Nevertheless, in Linux, memory tracing adds pages from the inactive to the active LRU list in batches of 15 requests [2], aiming to minimize the queue management overhead. Due to synchronous page migration, TPP may submit multiple requests (up to 15 if the request queue is empty) for a page to

[2] The 15 requests could be repeated requests for promoting the same page to the active LRU list

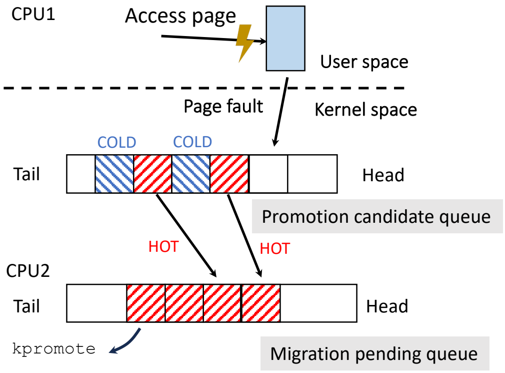

Figure 4: TPM uses a two-queue design to enable asynchronous page migration.

be promoted to the active LRU list to initiate the migration process. In the worst case, migrating one page may generate as many as 15 minor page faults.

TPM provides a mechanism to enable **asynchronous page migration** but requires additional effort to interface with memory tracing in Linux to minimize the number of page faults needed for page migration. As shown in Figure 4, in addition to the inactive and active LRU lists in memory tracing, TPM maintains a separate *promotion candidate* queue (PCQ) for pages that 1) have been tried for migration but 2) not yet promoted to the active LRU list. Upon each time a minor (hint) page fault occurs and the faulting page is added to PCQ, TPM checks if there are any hot pages in PCQ that have both the `active` and `accessed` bits set. These hot pages are then inserted to a *migration pending queue*, from where they will be tried for asynchronous, transactional migration by a background kernel thread `kpromote`. Note that TPM does not change how Linux determines the temperature of a page. For example, in Linux, all pages in the active LRU list, which are eligible for migration, have the two memory tracing bits set. However, not all pages with these bits set are in the active list due to LRU list management. TPM bypasses the LRU list management and provides a more efficient method to initiate page migration. If all transactional migrations were successful, TPM guarantees that only one page fault is needed per migration in the presence of LRU list management.

3.2 Page Shadowing

To enable non-exclusive memory tiering, NOMAD introduces a one-way *page shadowing* mechanism to allow a subset of pages resident in the performance tier to have a shadow copy in the capacity tier. Only pages promoted from the slow tier have shadow copies in the slow tier. Shadow copies are the original pages residing on the slow tier before they are unmapped in the page table and migrated to the fast tier. Shadow pages play a crucial role in minimizing the overhead of page migration during periods of memory pressure. Instead of swapping hot and cold pages between memory tiers, page shadowing enables efficient page demotion through page table remapping. This would eliminate half of the page migration overhead, i.e., page demotion, during memory thrashing.

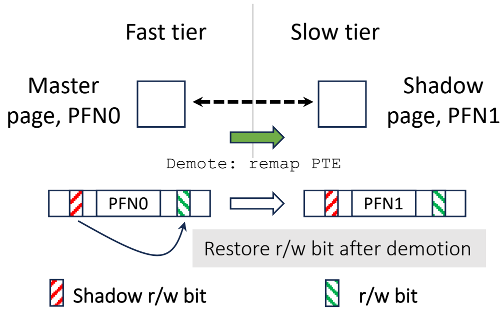

Figure 5: Shadow page management using `shadow r/w` bit.

Indexing shadow pages. Inspired by the indexing of file-based data in the Linux page cache, NOMAD builds an XArray for indexing shadow pages. An XArray is a radix-tree like, cache-efficient data structure that acts as a key-value store, mapping from the physical address of a fast tier page to the physical address of its shadow copy on the slow tier. Upon successfully completing a page migration, NOMAD inserts the addresses of both the new and old pages into the XArray. Additionally, it adds a new `shadow` flag to the `struct page` of the new page, indicating that shadowing is on for this page.

Shadow page management. The purpose of maintaining shadow pages is to assist with page demotion. Fast or efficient page demotion is possible via page remapping if the master page, i.e., the one on the fast tier, is clean and consistent with the shadow copy. Otherwise, the shadow copy should be discarded. To track inconsistency between the master and shadow copies, NOMAD sets the master page as `read-only` and a write to the page causes a page fault. To simplify system design and avoid additional cross-tier traffic, NOMAD discards the shadow page if the master page is dirtied.

However, tracking updates to the master page poses a significant challenge. Page management in Linux relies heavily on the read-write permission to perform various operations on a page, such as copy-on-write (CoW). While setting master pages as `read-only` effectively captures all writes, it may affect how these master pages are managed in the kernel. To address this issue, NOMAD introduces a procedure called *shadow page fault*. It still designates all master pages as `read-only` but preserves the original read-write permission in an unused software bit on the page's PTE (as shown in Figure 5). We refer to this software bit as `shadow r/w`. Upon a write to a master page, a page fault occurs. Unlike an ordinary page fault that handles write violation, the shadow page fault, which is invoked if the page's `shadow` flag is set in its `struct page`, restores the read-write permission of the faulting page according to the `shadow r/w` bit and discards/frees the shadow page. The write may proceed once the shadow page fault returns and reinstates the page to be writable. For `read-only` pages, tracking shadow pages does not impose additional overhead; for writable pages, it requires one additional shadow page fault to restore their write permission.

Reclaiming shadow pages. Non-exclusive memory tiering introduces space overhead due to the storage of shadow pages. If shadow pages are not timely reclaimed when the system is under memory pressure, applications may encounter out-of-memory (OOM) errors, which would not occur under exclusive memory tiering. There are two scenarios in which shadow pages should be reclaimed. First, the Linux kernel periodically checks the availability of free pages and if free memory falls below `low_water_mark`, kernel daemon `kswapd` is invoked to reclaim memory. NOMAD instructs `kswapd` to prioritize the reclamation of shadow pages. Second, upon a memory allocation failure, NOMAD also tries to free shadow pages. To avoid OOM errors, the number of freed shadow pages should exceed the number of requested pages. However, frequent memory allocation failures could negatively affect system performance. NOMAD employs a straightforward heuristic to reclaim shadow pages, targeting 10 times the number of requested pages or until all shadow pages are freed. While excessive reclamation may have a negative impact on NOMAD's performance, it is crucial to prevent Out-of-Memory (OOM) errors. Experiments in Section 4 demonstrate the robustness of NOMAD even under extreme circumstances.

3.3 Limitations

NOMAD relies on two rounds of TLB shootdown to effectively track updates to a migrating page during transactional page migration. When a page is used by multiple processes or mapped by multiple page tables, its migration involves multiple TLB shootdowns, per each mapping, that need to happen simultaneously. The overhead of handling multiple IPIs could outweigh the benefit of asynchronous page copy. Hence, NOMAD deactivates transactional page migration for multi-mapped pages and resorts to the default synchronous page migration mechanism in Linux. As high-latency TLB shootdowns based on IPIs continue to be a performance concern, modern processors, such as ARM, future AMD, and Intel x86 processors, are equipped with ISA extensions for faster broadcast-based [17, 18] or micro-coded RPC-like [28] TLB shootdowns. These emerging lightweight TLB shootdown methods will greatly reduce the overhead of TLB coherence in tiered memory systems with expanded memory capacity. NOMAD will also benefit from the emerging hardware and can be extended to scenarios where more intensive TLB shootdowns are necessary.

4 Evaluation

This section presents a thorough evaluation of NOMAD, focusing on its performance, overhead, and robustness. Our primary goal is to understand tiered memory management by comparing NOMAD with existing representative approaches to reveal the benefits and potential limitations of current page management approaches for emerging tiered memory.

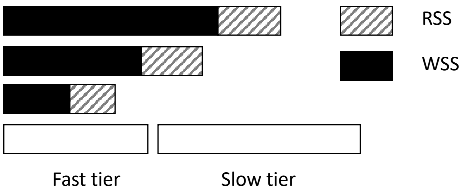

Figure 6: The three memory provisioning schemes used in the evaluation. From bottom to top concerning fast memory: over-provisioning, approaching capacity, and under-provisioning.

We analyze two types of memory footprints: 1) resident set size (RSS) – the total size of memory occupied by a program, and 2) working set size (WSS) – the amount of memory a program actively uses during execution. RSS determines the initial page placement, while WSS dictates the number of pages that should be migrated to the fast tier. Since we focus on in-memory computing, WSS is typically smaller than RSS. Figure 6 illustrates the three scenarios we study with the WSS size smaller than, close to, and larger than fast memory size.

Testbeds. We conducted experiments on *four* platforms with different configurations in CPU, local DRAM, CXL memory, and persistent memory, as detailed in Table 1.

- *Platform A* was built with commercial off-the-shelf (COTS) Intel Sapphire Rapids processors and a 16 GB Agilex-7 FPGA-based CXL memory device [6].
- *Platform B* featured an engineering sample of the Intel Sapphire Rapids processors with the same FPGA-based CXL memory device. The prototype processors have engineering tweaks that have the potential to enhance the performance of CXL memory, which were not available on platform A.
- *Platform C* included an Intel Cascade Lake processor and six 256 GB 100 series Intel Optane Persistent Memory. This platform enabled the full capability of PEBS-based memory tracking and allowed for a comprehensive comparison between page fault- and sampling-based page migration.
- *Platform D* had an AMD Genoa 9634 processor and four 256 GB Micron's (pre-market) CXL memory modules. This platform allowed us to evaluate NOMAD with more realistic CXL memory configurations.

Since the FPGA-based CXL memory device had only 16 GB of memory, we configured local DRAM to 16 GB for all platforms [3]. Note that platform C was equipped with DDR4 DRAM as fast memory while the other platforms used DDR5

[3] Although platform C and D have larger PM or CXL memory sizes, we configured them with 16 GB slow memory consistent with platform A and B for a fair comparison in micro-benchmarks.This limit was lifted when testing real applications.

	Platform A	Platform B (engineering sample)	Platform C	Platform D
CPU	4th Gen Xeon Gold 2.1GHz	4th Gen Xeon Platinum 3.5GHz	2nd Gen Xeon Gold 3.9GHz	AMD Genoa 3.7GHz
Performance tier (DRAM)	16 GB DDR5	16 GB DDR5	16 GB DDR4	16GB DDR5
Capacity tier (CXL or PM Memory)	Agilex 7 16 GB DDR4	Agilex 7 16 GB DDR4	Optane 100 256 GB DDR-T ×6	Micron CXL memory 256GB ×4
Performance tier read latency	316 cycles	226 cycles	249 cycles	391 cycles

DRAM. We evaluated both CXL memory and persistent memory (PM) as slow memory. Table 1 lists the performance characteristics of the four platforms for single-threaded and peak (multi-threaded) performance. While CXL memory and PM have distinct characteristics, including persistence, concurrent performance, and read/write asymmetry, they achieve comparable performance within 2-3x of DRAM and provide a similar programming interface as a CPUless memory node. To ensure a fair comparison, we only enabled one socket on each of the four platforms. Intel platforms were configured with 32 cores while the AMD platform had 84 cores.

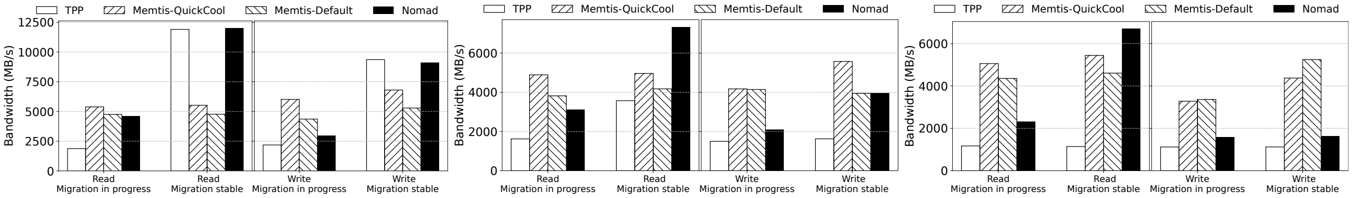
Baselines for comparison. We compared NOMAD with two state-of-the-art tired memory systems: TPP [44] and Memtis [37]. We evaluated both TPP and Nomad on Linux kernel v5.13-rc6 and ran Memtis on kernel v5.15.19, the kernel version upon which Memtis was built and released. We tested two versions of Memtis – Memtis-Default and Memtis-QuickCool – with different data cooling speeds (i.e., the number of samples collected before halving a page's access count). Specifically, Memtis-Default used the default cooling period of 2,000k samples, while Memtis-QuickCool used a period of 2k samples. A shorter cooling period encourages more frequent page migration between the memory tiers.

Memtis relies on Intel's Processor Event-Based Sampling (PEBS) to track memory access patterns. It samples various hardware events, including LLC misses, TLB misses, and retired store instructions, to infer accessed page addresses and build frequency-based histograms to aid in making migration decisions. Memtis currently only supports Intel-based systems, though it can be ported to AMD processors with Instruction-based Sampling (IBS). Thus, Memtis was not evaluated on platform D. Memtis works slightly differently on CXL-memory systems (platforms A and B) and the PM system (platform C). LLC misses to CXL memory are regarded as *uncore* events on Intel platforms and thus cannot be captured by PEBS. Therefore, Memtis relies solely on TLB misses and retired store instructions to infer page temperature on platforms A and B.

4.1 Micro-benchmarks

To evaluate the performance of NOMAD's transactional page migration and shadowing mechanisms, we developed a micro-benchmark to precisely assess NOMAD in a controlled manner. This micro-benchmark involves 1) allocating data to specific segments of the tiered memory; 2) running tests with various working set sizes (WSS) and resident set sizes (RSS); and 3) generating memory accesses to the WSS data that mimic real-world memory access patterns with a Zipfian distribution. We created three scenarios representing small, medium, and large WSS, as illustrated in Figure 6, to evaluate tiered memory management under different memory pressures. As platform B behaved similarly to platform A in micro-benchmarks, it is excluded from the discussion.

Small WSS. We began with a scenario with a small WSS of 10 GB and a total RSS of 20 GB. Initially, we filled the first 10 GB of local DRAM with the first half of the RSS data. Subsequently, we allocated 10 GB of WSS data as the



(a) Small working set size

(b) Medium working set size

(c) Large working set size

Figure 7: Performance comparison between TPP, Memtis-Default, Memtis-QuickCool, and NOMAD on platform A.

second half of the RSS – 6 GB on the local DRAM and 4 GB on CXL memory (platforms A and D) and the PM (platform C). The micro-benchmark continuously performed memory reads or writes (following a Zipfian distribution) to this 10 GB WSS data, spread across both the local DRAM and CXL memory or PM. The frequently accessed, or "hot" data, was uniformly distributed along the 10 GB WSS. In TPP and NOMAD, accessing data on CXL memory or PM triggered page migration to the local DRAM, with TPP performing this migration synchronously and NOMAD asynchronously. In contrast, Memtis used a background thread to migrate hot data from CXL memory or PM to the local DRAM. Due to page migration, the 4 GB WSS data, initially allocated to CXL memory or PM, was gradually moved to the local DRAM. Since the WSS was small (i.e., 10 GB), it could be completely stored in the fast tier (i.e., local DRAM) after the micro-benchmark reached a *stable* state.

Figures 7 (a), 8 (a), and 9 (a) show that in the *transient* phase, during which page migration was conducted intensively (i.e., *migration in progress*), both NOMAD and Memtis demonstrated similar performance regarding memory bandwidth for reads. Although page-fault-based page migration in NOMAD could incur more overhead than the PEBS-based approach in Memtis, when the WSS can fit in fast memory and no memory thrashing occurs, the benefit of migration outweighs its overhead. For writes, e.g., on platform A, NOMAD incurred noticeable performance degradation compared to Memtis due to possibly aborted migrations and the maintenance of shadow pages. Note that NOMAD's overhead varies across platforms depending on the performance difference between fast and slow memory. In contrast, Nomad consistently outperformed TPP for both read and write, except for the slightly worse performance on platform C, highlighting the advantage of asynchronous page migration in NOMAD.

In the *stable* phase (i.e., *migration stable*), when most of the WSS data had been migrated from CXL memory or PM to the local DRAM, both NOMAD and TPP achieved similar read/write bandwidth. This was because memory accesses were primarily served by the local DRAM with few page migrations, as shown in Table 2. Memtis performed the worst, achieving as low as 40% of the performance of the other two approaches. We make two observations regarding Memtis's weaknesses. First, its stable phase performance is not drastically different from the transient phase. The migration statistics in Table 2 show that Memtis performed significantly fewer page migrations. This explains its sub-optimal performance in the stable phase as most memory accesses were still served from slow memory. Second, a shorter cooling period in Memtis, which incentivizes more frequent migrations, led to better performance. This also suggests that sampling-based memory access tracking may not accurately identify and timely migrate hot pages to fast memory.

Medium WSS. We increased the size of WSS and RSS to 13.5 GB and 27 GB, respectively. Similarly, we placed the first half of the RSS (13.5 GB) at the start of the local DRAM, followed by 2.5 GB of the WSS on the local DRAM, with the remaining 11 GB residing on CXL memory or PM. However, as the system (e.g., the OS kernel) required approximately 3-4 GB of memory, the WSS could barely fit in the fast tier, resulting in occasional and substantial migrations even during the stable phase. Accurately identifying hot pages and avoiding thrashing is crucial to achieving high performance for this medium-sized benchmark.

Unlike the small WSS case, Figures 7 (b), 8 (b), and 9 (b) show that during the transient phase, NOMAD and TPP generally achieved lower performance for both read and write compared to Memtis. This is because, under the medium WSS, the system experienced higher memory pressure than in the small WSS case, causing NOMAD and TPP to conduct more page migrations (2x - 6x) and incur higher overhead than Memtis, as shown in Table 2. Many of such migrations were futile during thrashing. Conversely, Memtis performed significantly fewer page migrations and avoided the waste. However, there was no evidence that Memtis effectively detected thrashing and throttled migration. The coarse-grained sampling was unable to accurately determine page temperature in a volatile situation and inadvertently sustained high performance under high memory pressure.

In the stable phase, NOMAD significantly outperformed TPP in all cases, especially on platform D. These results show the benefit of NOMAD's transactional page migration and non-exclusive memory tiering compared to TPP's synchronous page migration and exclusive tiering. On platform D, which was equipped with an application-specific integrated circuit (ASIC)-based CXL memory implementation, the performance gap between fast and slow memory narrows. Thus, the software overhead associated with synchronous page migration was exacerbated and NOMAD offered more pronounced per-

formance gains. Similarly, NOMAD achieved substantially higher performance in reads than Memtis and comparable performance in writes. Unlike in the small WSS case, in which asynchronous and transactional page migration in NOMAD contributed most to its performance benefit, the advantage of page shadowing played a critical role in alleviating thrashing in the medium WSS case. Under memory thrashing, most demoted pages, which were recently promoted from the slow tier, can be simply discarded without migration. However, for write-intensive workloads, page shadowing requires one additional page fault for each write to restore a page's original read-write permission. This explains NOMAD's inferior write performance in the stable phase compared to Memtis.

Large WSS. We scaled up the WSS and RSS both to 27 GB and fully populated local DRAM with the first 16 GB of the WSS. The remaining WSS spilled onto CXL memory or PM. Unlike the medium WSS that incurred intermittent memory thrashing, this workload caused continuous and severe thrashing as the size of hot data greatly exceeded the capacity of fast memory. Figures 7 (c), 8 (c), and 9 (c) present the performance results in both the *transient* phase and the *stable* phase. Compared to the tests with the medium-sized workload in which NOMAD could outperform Memtis for read-only benchmarks, especially in the stable phase, both NOMAD and TPP performed worse than Memtis in almost all scenarios. It suggests that page fault-based tiered memory management, which makes per-page migration decisions upon access to a page, inevitably incurs high overhead during severe memory thrashing. Nevertheless, NOMAD consistently and significantly outperformed TPP thanks to asynchronous, transactional page migration and page shadowing.

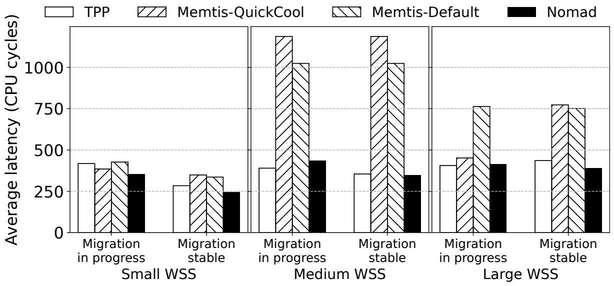

Figure 10: The average cache line access latency on platform C. The benchmark is a point-chasing workload optimized for PEBS-based memory access tracking.

Limitations of PEBS-based approaches. Our evaluation revealed several issues with PEBS-based memory access tracking. While Memtis prevented excessive migrations during thrashing, it achieved sub-optimal performance and failed to migrate all hot data to fast memory even when the WSS could fit in the fast tier. Due to the lack of hardware support for hot page tracking, PEBS-based approaches employ indirect metrics, such as LLC and TLB misses to sample recently accessed addresses to infer page temperature. Sampling-based memory tracking has two fundamental limitations. First, there is a difficult tradeoff between sampling rate and tracking accuracy. Second and most importantly, cache misses may not effectively capture hot pages. For most frequently accessed pages that always hit the caches, Memtis fails to collect enough (cache miss) samples to build the histogram. If such pages are evicted from the caches, e.g., due to conflict or coherence misses, they will be falsely regarded as "cold" pages.

To demonstrate these limitations, we created a favorable

RSS	23GB	25GB	27GB	29GB
Total shadow page size	3.93GB	2.68GB	2.2GB	0.58GB

Table 3: Shadow memory size as RSS changes on platform B. The size of tiered memory (DRAM+CXL) is 30.7 GB.

scenario where Memtis can capture every page access. We used a pointer-chasing benchmark that repeatedly accesses multiple fixed-sized (1 GB) memory blocks. Within each 1 GB block, the benchmark randomly accesses all cache lines belonging to a block while accesses across blocks follow a Zipfian distribution. The number of blocks determines the WSS. Since the block size exceeds the LLC size in our testbeds, every access generates an LLC miss that can be captured by Memtis. Effective memory access tracking should identify hot blocks and place them in fast memory.

Figure 10 shows the average latency to access a cache line in this benchmark on platform C. Note that platform C with PM was the only testbed on which Memtis has full tracking capability and can capture all the PEBS events. According to Table 1, a latency closer to DRAM performance (∼250 cycles) indicates more effective page placement. As shown in Figure 10, when the WSS exceeds fast tier capacity, Memtis achieved latency close to slow memory performance, suggesting that most hot pages still resided in the slow tier. In comparison, page fault-based approaches, e.g., NOMAD and TPP, can timely migrate hot pages and achieve low latency.

Robustness. Page shadowing can potentially increase memory usage and in the worst case can cause OOM errors if shadow pages are not timely reclaimed. In this test, we evaluated NOMAD's shadow page reclamation. We measured the total memory usage and the size of shadow memory using a micro-benchmark that sequentially scans a predefined RSS area. Table 3 shows the change of shadow pages as we varied the RSS. The results suggest that NOMAD effectively reclaimed shadow pages to reduce shadow memory usage as RSS increased and approached memory capacity.

4.2 Real-world Applications

We continued the evaluation of NOMAD using three representative real-world applications with unique memory access patterns: Redis [10], PageRank [9], and Liblinear [5]. We ran these three applications on four platforms (as shown in Table 1) with two configurations: 1) a small RSS (under 32 GB) working with all platforms and 2) a large RSS (over 32 GB) only on platform C and D with large PM or CXL memory. In addition, we include results from a "no migration" baseline which disables page migrations to show whether tiered memory management is necessary.

Key-value store. We first conducted experiments on a *latency-sensitive* key-value database, Redis [10]. The workload was generated from YCSB [11], using its *update-heavy* workload A, with a 50/50 distribution of read and write operations. We crafted three cases with different RSS and total operations.

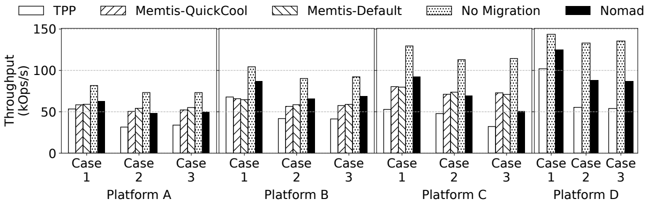

Figure 11: Performance comparisons using Redis and YCSB between TPP, Memtis-Default, Memtis-QuickCool, NOMAD, and "no migration".

Note that the parameters of YCSB were set as default unless otherwise specified. Case 1: We set *recordcount* to 6 million and *operationcount* to 8 million. After pre-loading the dataset, we used a customized tool to demote all memory pages to the slow tier before starting the experiment. The RSS of this case was 13GB. Case 2: We increased the RSS by setting *recordcount* to 10 million and *operationcount* to 12 million. We demoted all the memory pages to the slow tier in the same way. The RSS of this case was 24GB. Case 3: We kept the same total operations and RSS as Case 2. However, after preloading the dataset, we did *not* demote any memory pages.

Consistent with the micro-benchmarking results, Figure 11 shows that NOMAD delivered superior performance (in terms of operations per second) compared to TPP across all platforms in all cases. In addition, NOMAD outperformed Memtis when the WSS was small (i.e., in case 1), but suffered more performance degradation as the WSS increased (i.e., in case 2 and 3) due to an increased number of page migrations and additional overhead. Finally, all the page migration approaches underperformed compared to the "no migration" baseline. It is because the memory accesses generated by the YCSB workload were mostly "random", rendering migrating pages to the fast tier less effective, as those pages were unlikely to be accessed again. It indicates once again that page migration could incur nontrivial overhead, and a strategy to dynamically switch it on/off is needed.

We further increased the RSS of the database and operations of YCSB by setting the *recordcount* to 20 million and *operationcount* to 30 million. The RSS for this case was 36.5GB, exceeding the total size of the tiered memory on platforms A and B. Thus, the large RSS test was only performed on platforms C and D. We tested two initial memory placement strategies for the database – 1) *thrashing* that allocated all pages first to the slow tier and immediately invoked intensive page migrations, and 2) *normal* that prioritized page allocation to fast memory and triggered page migration only under memory pressure. As shown in Figure 14, NOMAD outperformed TPP due to its graceful performance degradation during thrashing but fell short of matching Memtis's performance. The initial placement strategy did not substantially affect the results and performance under different placements eventually converged.

Graph-based computation. We used PageRank [9], an ap-

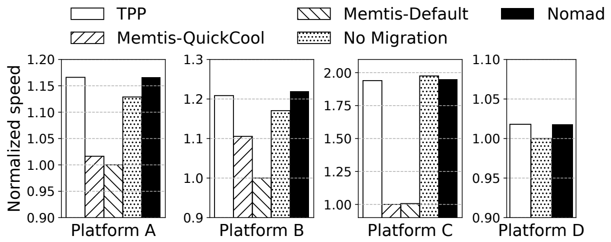

Figure 12: Performance comparisons of PageRank between non-migration, TPP, Memtis, and NOMAD. Performance is normalized to the approach with the lowest speed.

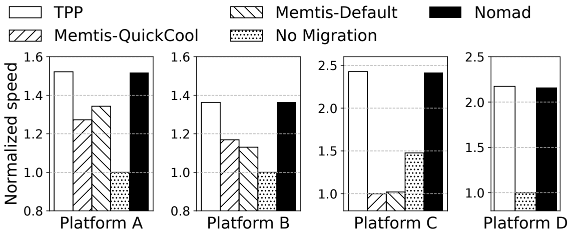

Figure 13: Performance comparisons of Liblinear between non-migration, TPP, Memtis, and NOMAD. Performance is normalized to the approach with the lowest speed.

plication used to rank web pages. It involves iterative computations to determine the rank of each page, based on the link structures of the entire web. As the size of the dataset increases, the computational complexity also increases, making it both memory-intensive and compute-intensive. We used a benchmark suite [8] to generate a synthetic uniform-random graph comprising 2^{26} vertices, each with an average of 20 edges. The RSS in this experiment was 22 GB, indicating that the memory pages were distributed at both the local DRAM and remote CXL memory or PM.

Figure 12 illustrates that there was negligible variance in performance between scenarios with page migrations (using NOMAD and TPP) and without page migrations (no migration). The results suggest that: 1) For *non-latency-sensitive* applications, such as PageRank, using CXL memory can significantly expand the local DRAM capacity without adversely impacting application-level performance. 2) In such scenarios, page migration appears to be unnecessary. These findings also reveal that the overhead associated with NOMAD's page migration minimally influences PageRank's performance. Additionally, it was observed that among all evaluated scenarios, Memtis exhibited the least efficient performance.

Figure 15 shows the case when we scaled the RSS to a very large scale on platforms C & D. When the PageRank program started, it first used up to 100GB memory, then its RSS size dropped to 45GB to 50GB. NOMAD achieved 2x the performance of TPP (both platforms) and slightly better than Memtis (platform C), due to more frequent page migrations – the local DRAM (16 GB) was not large enough to accommodate the WSS in this case.

Workload type	Success : Aborted
Liblinear (large RSS) on platform C	1:1.9
Liblinear (large RSS) on platform D	2.6:1
Redis (large RSS) on platform C	153:1
Redis (large RSS) on platform D	278.2:1

Table 4: The Success rate of transactional migration.

Machine learning. Our final evaluation of NOMAD involved using the machine learning library Liblinear [5], known for its large-scale linear classification capabilities. We executed Liblinear with an L1 regularized logistic regression workload with an RSS of 10 GB. Prior to each execution, we used our tool to demote all memory pages associated with the Liblinear workload to the slower memory tier.

Figure 13 demonstrates that both NOMAD and TPP significantly outperformed "no migration" and Memtis across all platforms, with performance improvement ranging from 20% to 150%. This result further illustrates that when the WSS is smaller than the local DRAM, NOMAD and TPP can substantially enhance application performance by timely migrating hot pages to the faster memory tier. Figure 16 shows that with a much larger model and RSS when running Liblinear, NOMAD consistently achieved high performance across all cases. In contrast, TPP's performance significantly declined, likely due to inefficiency issues, as frequent, high bursts in kernel CPU time were observed during TPP execution.

Migration success rate. As stated in Section 3.1, NOMAD's transactional page migration may be aborted due to updates to the migrating page, resulting in wasted memory bandwidth and CPU cycles. Subsequent retries could also fail. A low success rate could negatively affect application performance. Table 4 shows NOMAD's migration success rate for Liblinear and Redis on platforms C and D. We chose a large RSS for both applications and ensured there were sufficient cross-tier migrations. We observed a low success rate for Liblinear while Redis had a high success rate. Interestingly, this contrasted with NOMAD's performance – it was excellent with Liblinear but poor with Redis with large RSS. This suggests that a high success rate in page migrations does not necessarily lead to high performance. A low success rate indicates that the pages being migrated by NOMAD are also being modified by other processes, implying their "hotness". Timely migration of such pages can benefit ongoing and future accesses.

Summary. The results from micro-benchmarks and applications indicate that when the WSS was smaller than the performance tier, NOMAD enabled workloads to maintain higher performance than Memtis through asynchronous, transactional page migrations. However, when the WSS was comparable to or exceeded the performance tier capacity, leading to memory thrashing, the page-fault-based migration in NOMAD became detrimental to workload performance, underperforming Memtis in write operations. Notably, NOMAD's page shadowing feature preserved the efficiency of read opera-

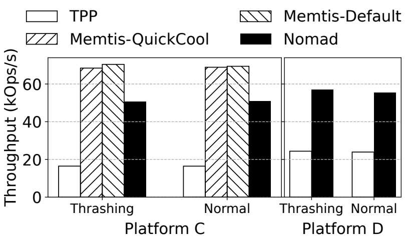

Figure 14: Redis (large RSS).

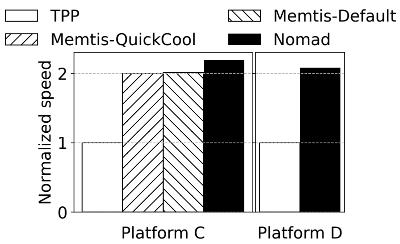

Figure 15: Page ranking (large RSS).

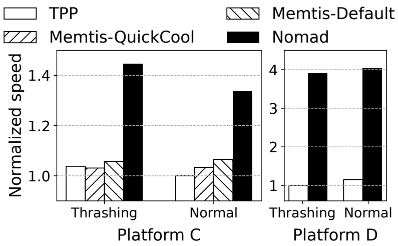

Figure 16: Liblinear (large RSS).

tions even under severe memory thrashing, often maintaining comparable or superior performance to Memtis. In all test scenarios, NOMAD significantly outperformed the state-of-the-art page-fault-based migration approach, TPP.

The evaluation results across four different platforms reveal the following observations: First, NOMAD generally performed better on platform D, which was equipped with faster and larger CXL memory, compared to other platforms. Additionally, the reduced performance gap between fast and slow memory on platform D allowed NOMAD to achieve greater performance gains than TPP, as the performance overhead from TPP's synchronous page migration was more pronounced. Second, while platforms A and B showed similar behavior in micro-benchmarks, their application-level performance varied (slightly) across different applications, suggesting that specific CPU features (differing between the off-the-shelf Intel Sapphire Rapids CPU for platform A and the engineering sample for platform B) may affect the performance of page migration under more realistic workloads.

5 Discussions and Future Work

The key insight from NOMAD's evaluation is that page migration, especially under memory pressure, has a detrimental impact on overall application performance. While NOMAD achieved graceful performance degradation and much higher performance than TPP, an approach based on synchronous page migration, its performance is sub-optimal compared to that without page migration. When the program's working set exceeds the capacity of the fast tier, the most effective strategy is to access pages directly from their initial placement, completely disabling page migration. It is straightforward to detect memory thrashing, e.g., frequent and equal number of page demotions and promotions, and disable page migrations. However, estimating the working set size to resume page migration becomes challenging, as the working set now spans multiple tiers. It requires global memory tracking, which could be prohibitively expensive, to identify the hot data set that can potentially be migrated to the fast tier. We plan to extend NOMAD to unilaterally throttle page promotions and monitor page demotions to effectively manage memory pressure on the fast tier. Note that this would require the development of a new page migration policy, which is orthogonal to the NOMAD page migration mechanisms proposed in this work.

Impact of Platform Characteristics: There exist difficult tradeoffs between page fault-based access tracking, such as TPP and NOMAD, and hardware performance counter-based memory access sampling like Memtis. While page fault-based tracking effectively captures access recency, it can be potentially expensive and on the critical path of program execution. In comparison, hardware-based access sampling is off the critical path and captures access frequency. However, it is not responsive to workload changes and its accuracy relies on the sampling rate. One advantage of NOMAD is that it is a page fault-based migration approach that is asynchronous and off the critical path. A potential future work is integrating NOMAD with hardware-based, access frequency tracking, such as Memtis, to enhance the current migration policy.

6 Conclusion

This paper introduces non-exclusive memory tiering as an alternative to the common exclusive memory tiering strategy, where each page is confined to either fast or slow memory. The proposed approach, implemented in NOMAD, leverages transactional page migration and page shadowing to enhance page management in Linux. Unlike traditional page migration, NOMAD ensures asynchronous migration and retains shadow copies of recently promoted pages. Through comprehensive evaluations, NOMAD demonstrates up to 6x performance improvement over existing methods, addressing critical performance degradation issues in exclusive memory tiering, especially under memory pressure. The paper calls for further research in tiered memory-aware memory allocation.

A Artifact Appendix

Abstract

The artifact contains the source code of NOMAD, TPP, and Memtis for reproducing the results and graphs presented in the paper. The code works on platforms with Persistent Memory, Intel Agilex CXL memory, and/or Micron CXL memory. To facilitate the reproduction, we have provided a collection of scripts for compiling and installing these approaches, executing the experiments, collecting logs, and creating graphs. More details are available in the "README.md" file.

Scope

This artifact demonstrates NOMAD's strengths and weaknesses over TPP and Memtis across various scenarios and platforms, as elaborated in the Evaluation section.

It is open-source and can be used for further research, development, or other purposes by the community.

Contents

NOMAD, TPP and Memtis implementation. We provide two separate patches to enable NOMAD and TPP to work with the upstream kernel version v5.13-rc6. In particular, the TPP patch comes from the Linux community email discussions. Memtis, on the other hand, is directly incorporated from its original artifact, with a few minor bugs fixed.

Documentation The "Reproducing Paper Results" section of "README.md" provides a step-by-step guide for reproducing the results in the paper. This guide includes instructions for compiling the three implementations (i.e., NOMAD, TPP, and Memtis), running the experiments, and generating the graphs as presented in the paper.

Hosting

Artifact link: https://github.com/lingfenghsiang/Nomad
Artifact license: GNU GPL V3.0
Artifact version tag: v0.0

Requirements

To reproduce the results in the paper, the system under test requires one NUMA node with a CPU and another CPU-less NUMA node. If the system has more NUMA nodes, the operating system might encounter unexpected errors. Additionally, Memtis is only fully functional on platforms with Optane Persistent Memory. More details are included in the "Prerequisites" section of "README.md".

Managing Memory Tiers with CXL in Virtualized Environments

Abstract

Cloud providers seek to deploy CXL-based memory to increase aggregate memory capacity, reduce costs, and lower carbon emissions. However, CXL accesses incur higher latency than local DRAM. Existing systems use software to manage data placement across memory tiers at page granularity. Cloud providers are reluctant to deploy software-based tiering due to high overheads in virtualized environments. Hardware-based memory tiering could place data at cacheline granularity, mitigating these drawbacks. However, hardware is oblivious to application-level performance.

We propose combining hardware-managed tiering with software-managed performance isolation to overcome the pitfalls of either approach. We introduce *Intel® Flat Memory Mode*, the first hardware-managed tiering system for CXL. Our evaluation on a full-system prototype demonstrates that it provides performance close to regular DRAM, with no more than 5% degradation for more than 82% of workloads. Despite such small slowdowns, we identify two challenges that can still degrade performance by up to 34% for "outlier" workloads: (1) memory contention across tenants, and (2) intra-tenant contention due to conflicting access patterns.

To address these challenges, we introduce *Memstrata*, a lightweight multi-tenant memory allocator. Memstrata employs page coloring to eliminate inter-VM contention. It improves performance for VMs with access patterns that are sensitive to hardware tiering by allocating them more local DRAM using an online slowdown estimator. In multi-VM experiments on prototype hardware, Memstrata is able to identify performance outliers and reduce their degradation from above 30% to below 6%, providing consistent performance across a wide range of workloads.

1 Introduction

Memory tiering is a promising approach to scale memory capacity and reduce the total cost of ownership (TCO) in datacenters. In public clouds, virtual machine (VM) memory sizes are increasing, with typical configurations of 4–32GB per virtual CPU [6, 7, 12]. However, the DRAM capacity accessible via DDR channels is lagging the rapid growth in available cores, due to physical limitations associated with scaling the capacity of DDR DIMMs [73, 91, 92]. To this end, cloud providers are increasingly adding a *capacity memory tier* to augment regular locally-accessed DRAM, which we refer to as the *performance tier* [61, 72, 78, 84, 99].

The recent Compute Express Link (CXL) standard [8, 91] offers a new mechanism to access DRAM or non-volatile memory (NVM) over the PCIe bus, potentially expanding memory capacity significantly. In addition, CXL can reduce TCO and carbon emissions [83, 98] by provisioning it with decommissioned DRAM or NVM. This has led to broad investment in CXL memory by dozens of vendors [9, 10, 15, 25, 27, 28, 37]. The CXL standard envisions a variety of configurations. In this paper, we focus on the basic use case where a CXL memory device is locally attached and dedicated to a single host [91, 98]. This use case is deployable today, and extends to future memory pools [46, 77, 78].

Most prior work on memory tiering assumes software (e.g., the hypervisor or the OS) has full control over data placement, i.e., whether a particular page resides in the capacity tier or the performance tier [45, 61, 70, 74, 78, 84, 89, 90, 99, 100]. We term this *software-managed memory tiering*. Software-managed tiering needs to track memory accesses to identify frequently-accessed data to place in the performance tier. Since the hypervisor/OS is not involved in most memory accesses, it must rely on page table operations management (e.g., scanning access bits [61, 84, 100] or PTE poisoning [45, 70, 84]) or instruction sampling (e.g., Intel PEBS sampling [61, 74, 89] and AMD IBS [4]) to track memory accesses.

However, in our experience at Microsoft Azure, these approaches face severe limitations in virtualized environments (§2). For example, instruction sampling is not supported for VMs and has privacy implications. Fine-grained page table operations consume excessive host CPU cycles [44, 79]. In addition, with software-managed tiering, the hypervisor/OS can only manage memory at page granularity. This leads to suboptimal decisions [76] for the common case where a mix of hot and cold data resides on the same page. This is particularly problematic for hypervisors that use larger page sizes (e.g., 2 MB and 1 GB) to reduce overheads. All of these drawbacks make deploying software-based memory tiering techniques unattractive in general-purpose cloud environments.

This paper addresses these issues by introducing a hardware-managed memory tiering solution for CXL and a system that combines hardware-managed tiering with software-managed multi-tenant isolation. We introduce *Intel® Flat Memory Mode* as the first cache-line granular, hardware-managed memory tiering solution for CXL. Intel® Flat Memory Mode transparently manages data placement between the two tiers at cache-line granularity within the processor memory controller (MC). It exposes the aggregate capacity of both local DRAM and CXL memory to software by placing data *exclusively* at either of the tiers. The hardware promotes the most recently accessed lines to local DRAM by "swapping" them with the lines that used to occupy local DRAM.

To reduce the performance degradation of CXL memory, Intel® Flat Memory Mode supports a *mixed mode* which reserves a certain number of *dedicated* pages that are guaranteed to reside in local memory, while cache lines associated with the remaining pages may be placed in either local or CXL memory, based on whether they were recently accessed.

Intel® Flat Memory Mode should not be confused with the hardware-managed memory tiering solution for Intel® Optane™ NVDIMMs, known as *2LM* or *memory mode* [18, 65]. Such systems employ DRAM as an *inclusive* cache for non-volatile memory, which means the performance tier does not add capacity visible to software. The inclusive cache design makes them less useful for expanding memory capacity and reducing TCO. Additionally, 2LM only supports non-volatile memory, not CXL.

We describe Intel® Flat Memory Mode's design and evaluate it on a real CXL hardware prototype with a set of 115 workloads, comparing it to running fully on local DRAM. We find that 82% of workloads experience small (no more than 5%) slowdown in mixed mode. The remaining "outlier" workloads experience slowdowns up to 34%. We also observe that when VMs are co-located naïvely on the same server, they may interfere by "stealing" local DRAM from each other.

To address these challenges, we implement *Memstrata*, the first multi-tenant memory management software stack for hardware-managed tiered memory. Memstrata prevents inter-VM interference by identifying pages with conflicting cache lines, allocating them to the same VM using *page coloring*. In addition, Memstrata leverages a lightweight online slowdown estimator to assess the overhead incurred by tiered memory misses for each VM. It dynamically allocates dedicated local memory pages across VMs to improve the performance of those that are most sensitive to memory latency. Intel® Flat Memory Mode will be available in the Intel® Xeon® 6 Processor. We open source Memstrata at https://bitbucket.org/yuhong_zhong/memstrata.

We implement a full system prototype on a preproduction Intel® Xeon® 6 Processor that supports Intel® Flat Memory Mode. Memstrata is implemented within the Linux/KVM hypervisor and a new user-space management process. Our evaluation covers common workload and VM mixes observed in production at Azure. We find that Memstrata effectively prevents cross-VM interference and mitigates the tail in all scenarios. Specifically, the worst-case performance slowdown is reduced from 35% to less than 6% in realistic multi-VM experiments. Across all experiments, the maximum CPU overhead of Memstrata is 4% of a single core, which is less than 1% of a single core per VM.

We make the following contributions:

1. We introduce Intel® Flat Memory Mode, the first hardware-managed memory tiering mechanism for CXL. We evaluate it on a real CXL system, and show that for most applications it exhibits small slowdowns.
2. We design Memstrata, the first software multi-tenant management system for hardware-managed CXL that ensures performance isolation and minimizes VM slowdowns.
3. We study a wide range of workloads, and demonstrate that Intel® Flat Memory Mode combined with Memstrata eliminates almost all performance outliers, exhibiting minimal performance degradation compared to regular DRAM.

2 Background and Motivation

This section motivates hardware-managed memory tiering for CXL in virtualized environments.

2.1 Memory Tiering in Public Clouds

Current compute servers, which host customer VMs, use locally-attached DDR5 memory. With CPU core counts of 60-96 [66, 94] and Simultaneous Multithreading (SMT), achieving at least 4-8GB per virtual core requires 8-12 expensive dual-rank DIMMs (e.g., 64GB or 96GB). These DIMMs are the single biggest contributor to server cost [78, 99]. For large-memory VM sizes [6] or 128-288 core-count-CPUs [2, 14, 57], cloud providers need to use DIMMs with 3D stacking, which adds a multiplicative factor to per-GB memory cost [32]. Additionally, DIMMs make up 41% of a server's embodied carbon at Azure [49, 63, 83, 87, 98].

A second tier of memory can effectively reduce this cost. In modern servers, this second tier will use CXL [8, 91] to expand server memory capacity and bandwidth. This saves cost because cloud providers can use multiple smaller and cheaper DIMMs. Cost can be further reduced by *reusing memory from decomissioned servers*. Without CXL, DDR4 memory would be incompatible with modern servers. Instead of discarding DDR4 DIMMs, they can be repurposed for CXL memory. DDR4 reuse is supported today and has significant industry momentum [3, 26, 49, 83, 98]. This pattern can continue in future generations of DRAM, e.g., when DDR6 will be deployed, DDR5 can be reused with CXL. A third option is denser memory media [17, 38]. Both reusing old memory and using denser memory significantly cuts costs and carbon emissions. For example, attaching 40% of memory by reusing DDR4 can save over 20% of server embodied carbon emissions [83]. In this paper, we focus on this use case.

The downside of CXL memory is its latency overhead. CXL.mem customizes the PCIe link and transaction layers for low latency [91]. CPUs can natively access CXL memory via cacheable loads and stores, without involving page faults or DMAs. While an order of magnitude faster than RDMA, CXL is still slower than local DRAM as it essentially converts a parallel bus into a serial one. Depending on the specific memory controller, we measure that CXL memory has 2.02× the load-to-use latency of local DDR5 on the 5th Gen Intel® Xeon® Processor. A bidirectional ×8-CXL port at a typical 2:1 read:write-ratio matches a DDR5-4800 channel. In practice we use at least four ×8 ports.

2.2 Cloud Workload and Design Goals

Azure and other large cloud providers virtualize all workloads. VMs are generally small. For example, in a typical compute cluster at Azure, 40% of VMs use no more than two cores and 86% of VMs use no more than eight cores. Most modern hosts thus run dozens of VMs at any given time. Production cluster schedulers [47, 64, 97] increase utilization by mixing different workloads with no (or few) co-location constraints. Some constraints force similar workloads to be run across many hosts and racks, e.g., for fault tolerance. This leads to typical hosts running heterogeneous sets of workloads representing many different workload behaviors.

We derive the following four first-order design goals:

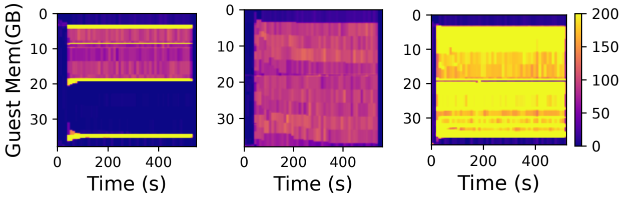
1. Compatibility with unmodified virtual machines. Do not assume guest cooperation.
2. Low host resource overheads. Cloud providers seek to sell almost all cores [44, 79]. Hosts typically use large 2 MB or 1 GB page sizes to reduce overhead.
3. No additional sources of cross-VM interference compared to running entirely on local memory.
4. Performance close to local memory for all workloads. Limit slowdown to about 5%, similar to prior work [78].

As observed in prior work, CXL slowdowns can be high for many workloads [78, 84]. This motivates managing data placement in tiered memory, either in software or in hardware.

2.3 Software-Managed Tiering

Software-managed tiering usually represents tiers as NUMA nodes [61, 78, 84]. Software explicitly allocates memory from a NUMA node and migrates pages between nodes. The hypervisor/OS typically tracks memory hotness to promote hot capacity-tier pages to the performance tier and demote cold pages to the capacity tier [61, 84, 89, 100]. Hotness tracking often relies on page table operations such as scanning PTE access bits [61, 84, 100] or temporarily unmapping entries to trigger minor page faults when they are accessed [45, 70, 84]. Other software tiering systems use instruction sampling (e.g., Intel PEBS [61, 74, 89] or AMD IBS [4]) to sample memory requests along with their associated memory addresses.

Problem 1: High host CPU cost. Tracking hotness at fine granularity is challenging in a cloud environment. Instruction sampling is typically unfeasible due to security and privacy concerns. Thus, cloud platforms need to rely on page-table-based approaches. We find that they can consume excessive host CPU cycles, which runs counter to design goal #2.



(a) Fresh VM (b) Randomized (c) Warm VM

Figure 1: Memory access distribution of `bc-web` measured using DAMON in (a) a fresh VM, (b) a VM that enables free page randomization, and (c) a warm VM that has already run the workload 50 times. The right-hand y-axis represents the number of accesses captured by DAMON.

We measure the CPU overhead of TPP [84], a state-of-the-art software tiering system for guest kernels. We start a VM with 7.5 GB of local DRAM and 2.5 GB of second-tier memory. The VM runs YCSB A on FASTER [54], a production in-memory key-value store. FASTER consumes 8.3 GB memory in total, which means its memory cannot fit entirely in local DRAM. TPP devotes nearly an entire core to track memory accesses and migrate pages. This is caused by the frequent scanning of access bits in `kswapd`, which is used by TPP to demote cold pages. Without frequent access-bit scanning, TPP is unable to leave enough free space in local DRAM to promote hot pages. Scaling to larger systems and multiple VMs requires proportionally more CPU cycles.

The CPU overhead of page-table-based approaches can be reduced by exploiting spatial locality [11]. Unfortunately, spatial locality is limited in virtualized systems, which employ an additional layer of page table indirection. Additionally, a guest's free pages may be randomized for security [21]. We run the `bc-web` workload from the GAP benchmark suite [48] in a fresh VM, a VM with free page randomization enabled, and a warm VM that has already run the same workload 50 times. Figure 1 shows the memory access distribution measured using DAMON in the three VMs. While there is spatial locality in a fresh VM, locality disappears in both the VM with free page randomization and the warm VM. Approaches that scan guest page tables [90] may overcome fragmentation but run counter to goals #1 and #2.

Problem 2: Coarse-grained data placement. Software tiering moves entire pages, making a strong assumption about access locality. Many applications have spatially-sparse access patterns and thus perform poorly on software-managed tiering systems [53, 76]. Commonly, only a fraction of each page's cachelines are hot; moving such pages to the performance tier would be wasteful. This problem is exacerbated as cloud platforms use larger 2 MB and 1 GB page sizes to reduce page table depth and TLB misses [1, 34, 43, 45, 50].

To study how page size affects application performance, we

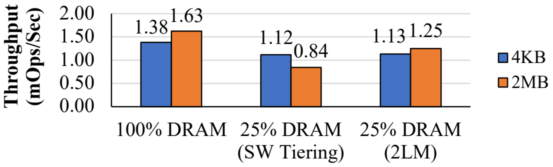


Figure 2: Throughput of FASTER on YCSB A with a varying DRAM ratio and different page sizes. The performance tier is DRAM and the second tier is Intel® Optane™ NVM.

run a VM with FASTER using the YCSB A workload. Since FASTER has a simple and predictable memory access pattern when running YCSB A, we analytically compute the popularity of each of its pages and always place the most popular pages in DRAM. Figure 2 shows that when FASTER's resident set can fit into DRAM, using 2 MB instead of 4 KB as the page size improves the throughput of FASTER by 18% thanks to the reduced page table depth and TLB misses. However, when only 25% of the resident set can fit into DRAM, a 2 MB page size degrades throughput by 25% due to the coarser data placement by software tiering. Google also reports that huge pages make cold page identification and demotion more challenging in their tiered memory production clusters [61].

2.4 Hardware-Managed Tiering

There are multiple variants of hardware memory tiering [68, 75, 85, 103]. They are typically implemented within the MC on the CPU SoC and behave similar to on-die CPU caches. Different memory tiers are typically invisible to software (no NUMA node) and fine-grained cache operations are visible only to the MC.

A well-known implementation of hardware tiering is "2LM" or "memory mode" for Intel® Optane™ NVDIMMs in the 2nd and the 3rd Gen Intel® Xeon® Scalable Processors [18, 65]. 2LM configures DRAM as a direct-mapped cache at cacheline granularity. It thus has no hotness tracking overhead and excels at managing workloads with limited locality [76], regardless of the page size (Figure 2). A major downside of using 2LM in the context of CXL is that the second tier is inclusive of the performance tier. This is wasteful, especially for the case of cloud providers who seek high performance and thus provision a large first memory tier. For example, provisioning 600 GB of DDR5 and 1000 GB of CXL memory means that only 1000 GB of overall memory is available, wasting 60% of CXL capacity.

3 Intel® Flat Memory Mode

In this section, we describe the hardware design of Intel® Flat Memory Mode and present a performance study on a wide range of applications.

3.1 Hardware Design

Intel® Flat Memory Mode overcomes the drawbacks of software-managed memory tiering by implementing the data placement within the MC. This allows it to manage data placement at cacheline granularity without involving host CPU. This design is especially useful in virtualized environments because the data placement is independent of the page size, and almost all the host CPU cores can be used to run VMs.

CXL memory ratio. To ensure minimal slowdown compared to local memory[1] (design goal #4), we assume a 1:1 ratio between the local memory and the CXL memory capacities. Other tiered memory deployments in industry also use small capacity-tier ratios to minimize slowdown: 33% at Meta [84] and 25% at Google [61]. With a 1:1 ratio, we can reduce the amount of local memory provisioned by 50%, which already significantly reduces memory cost. A higher CXL memory percentage may lead to higher slowdowns [78].

Exclusive placement. The amount of physical memory exposed to software is the aggregate capacity of both local DRAM and CXL memory. This is in contrast to 2LM, where the physical memory capacity is only as large as the size of the capacity tier (i.e., non-volatile memory). This design fully utilizes the capacity of both local DRAM and CXL memory by placing data *exclusively* at either of them, but not both. For example, once a cacheline is moved to local DRAM, it will no longer occupy any space in CXL memory.

Associativity. The associativity between physical memory and local memory is direct-mapped, which means each line in the physical memory address space can only be cached at one location in local memory. While direct-mapped associativity may lead to more conflict misses, this effect happens only after all the processor set-associative caches have missed. In addition, a straightforward implementation of set associativity would read multiple local DRAM lines to serve one main memory access, causing substantial bandwidth amplification.

Mixed mode. To further reduce local memory misses and improve the performance of workloads with cache-unfriendly memory access patterns, Intel® Flat Memory Mode supports adding dedicated local DRAM that is not hardware-tiered as a separate range in the physical memory address space. This dedicated local memory is exposed as a second NUMA node alongside the first NUMA node which contains the hardware-tiered memory. This dedicated NUMA node can be used for workloads suffering from severe local memory misses, as implemented in Memstrata (§4). We denote configurations where both hardware-tiered and dedicated NUMA nodes are present as *mixed mode*.

Mapping physical and local memory. In the hardware-tiered NUMA node, the ratio between local DRAM and the total physical memory capacity is 1:2. Thus, each line in local DRAM has 2 physical memory lines that map to it. This means that each 64 B line in the physical address space may be at one of two locations: either in local memory or in CXL memory. We use a modulo operation as the mapping function between the physical memory and local DRAM with the size of local DRAM (L GB) as the modulus. Figure 3 shows

[1] We use "local memory" and "local DRAM" interchangeably.

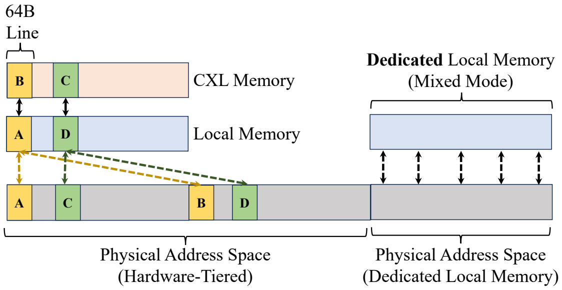

Figure 3: Intel® Flat Memory Mode is a hardware tiering solution at cache line granularity between local and CXL memory. It supports a mixed mode option where part of the address space is not hardware managed and entirely backed by local memory for better performance. In the actively-managed region, cache lines A and B are mapped to the same local memory line, as are C and D. Only the most recently-accessed lines remain in local memory.

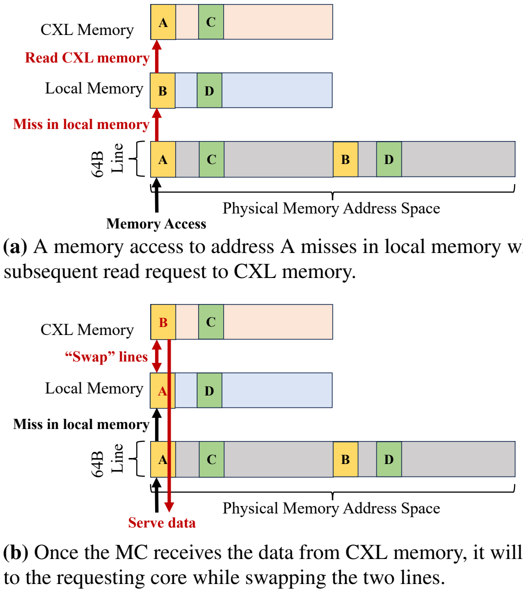

(a) A memory access to address A misses in local memory which leads to a subsequent read request to CXL memory.

(b) Once the MC receives the data from CXL memory, it will serve the data to the requesting core while swapping the two lines.

Figure 4: Main memory requests may miss in local memory. This triggers a cache line swap. Subsequent accesses to the same cache line hit local memory.

the mapping between the physical address space and local memory. This mapping halves the hardware-tiered physical memory, where the top half conflicts with the bottom half. For example, to hold physical memory addresses $[0\ GB, 1\ GB]$ in local DRAM, the hardware needs to evict $[L\ GB, L+1\ GB]$ to CXL memory.

Read and write operations. A memory access (i.e., Last Level Cache (LLC) miss) for a cache line in the hardware-tiered NUMA node may result in a "hit" or a "miss". The MC first reads local memory and determines if the requested line is in local memory. As only two physical memory lines can be cached at a given local memory line, the hardware only needs to maintain a single-bit tag to distinguish between them. If the tag matches the read request, the data is sent to the core that requested the line.

Otherwise, the requested line was a miss in local memory. Figure 4 shows how the MC handles a miss. The MC first fetches the data from CXL memory, and then sends the data to the core that requested the line. Meanwhile, the MC swaps the cache lines. Specifically, the MC writes the other line that used to occupy local memory to CXL memory. The MC writes the newly requested line to local memory.

When the MC receives a write request, just like the read flow, it needs to first locate and read the line into the processor caches. When the write is evicted from the processor caches (since writes are posted), the data is written to local memory.

Request interleaving. To achieve maximum bandwidth, we interleave local memory requests across memory channels and interleave CXL memory requests across CXL devices at cache line granularity within the same NUMA node.

3.2 Application Performance

Adding CXL memory capacity can provide clear performance benefits to memory-hungry applications, due to reduced paging to disk, and higher page-cache hit rates. However, these benefits depends heavily on the specific workloads and the total amount of memory available to them. To conservatively evaluate Intel® Flat Memory Mode, we compare it with X local memory and Y CXL memory to a baseline configured with $X+Y$ local memory. We evaluate the performance using a wide range of applications on a prototype CPU that supports Intel® Flat Memory Mode. The detailed hardware setup is described in §6. We use 115 workloads in total, including:

- **Web**: DaCapo [51], Renaissance [88], Ruby YJIT [39], and DeathStarBench benchmarks [62]
- **Database**: TPC-C [41] on Silo [96] and TPC-H [42] on PostgreSQL [33]
- **Machine learning (ML)**: DLRM benchmark [67, 86]
- **Key-value (KV) store**: YCSB [58] on FASTER [54], Redis [36], and memcached [23]
- **Big data**: HiBench [13] on Spark [104]
- **Graph processing**: GAP benchmark [48]
- **Scientific computing**: SPEC CPU 2017 [40]

We measure the performance of each workload running inside a VM on Linux/KVM. The VM memory size is chosen by rounding up the workload's peak resident set size to the nearest common VM memory size on public cloud platforms (2 GB, 4 GB, 8 GB, 16 GB, 32 GB, and 64 GB) [6, 7, 12]. We run each workload in four different settings: (1) local DRAM only, (2) CXL memory only, (3) hardware-tiered memory only, and (4) a mixed mode with 33% dedicated local DRAM and 67% hardware-tiered memory.

When allocating hardware-tiered memory pages to a VM, we allocate pairs of conflicting pages so that half of the allocation can be cached in local DRAM. As a result, our mixed mode configuration consists of 67% local DRAM (33% dedicated + half of 67% hardware-tiered) and 33% CXL memory. We conservatively choose 67% as the percentage of hardware-tiered memory as this configuration can already reduce the

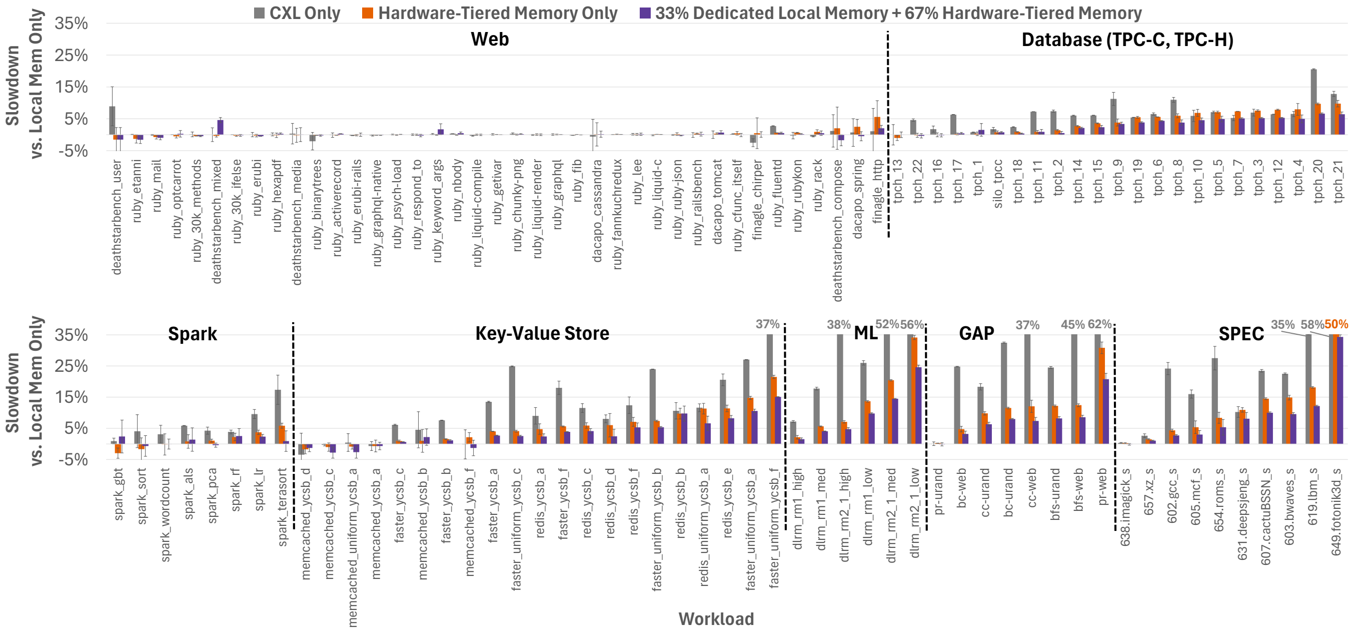

Figure 5: Slowdowns of 115 workloads when using only CXL memory, 100% hardware-tiered memory, or a mixed mode with 33% dedicated memory and 67% hardware-tiered memory. The error bars represent the standard deviations of slowdowns across three runs.

provisioned local memory by 33%. We randomly assign the dedicated local pages across a VM's address space. Each VM sees a uniform address space, as this is the default configuration on cloud platforms.

Figure 5 presents the results, categorizing workloads by their types, and ordering them by their relative slowdowns of hardware tiering. We refer to applications that experience slowdowns above 5% (see goal #4 in §2.2) as *outliers*. Web workloads experience negligible slowdowns even with CXL memory only, indicating their insensitivity to main memory latency. In contrast, database and Spark workloads have some outliers with slowdowns of up to 20% when using only CXL memory. Hardware tiering reduces the slowdowns for most outliers to close to or lower than 5%, although a few outliers still exhibit around 10% degradation. Other categories have more outliers with CXL memory only, with slowdowns of up to 58%. Hardware tiering significantly alleviates the performance degradation for these outliers. For example, the slowdown of FASTER with uniform YCSB C is reduced from 25% to 4%. However, even with reduced degradation, some outliers still experience slowdowns of up to 50% with hardware-tiered memory due to cache-unfriendly memory access patterns and the associated high local memory miss ratios. The most severe outlier, `649.fotonik3d_s`, suffers from a 41% miss ratio due to its large working set and scan-like memory access pattern.

The mixed mode with 33% dedicated local memory improves the performance of these outliers thanks to the reduction in the number of pages that conflict on local DRAM. Overall, with only hardware-tiered memory, 73% of the workloads experience no more than 5% slowdown, and 86% experience no more than 10% slowdown. In the mixed mode, the percentage of workloads with no more than 5% slowdown increases to 82%, and 95% of the workloads experience no more than 10% slowdown. These results are encouraging: despite the non-negligible slowdown of CXL compared to local DRAM, most applications have small slowdowns in the mixed mode. However, even in the mixed mode, some applications experience non-trivial degradation of up to 34%. This observation motivates the use of software to dynamically allocate dedicated memory pages across VMs to consistently achieve minimal slowdown, because the hardware is oblivious to which VMs suffer from local memory misses.

3.3 Noisy Neighbors

In Intel® Flat Memory Mode, two conflicting physical memory lines compete for the same local DRAM line, and only the most recently accessed one can be cached in local DRAM. Therefore, when conflicting pages are allocated to different VMs, they may contend for local memory, resulting in performance interference.

We study this inter-VM interference due to local DRAM conflicts by running two VMs: a normal VM and a *noisy neighbor* VM. In the normal VM, we run one of the workloads from our workload set, while in the noisy-neighbor VM, we always run a 6-thread Intel® Memory Latency Checker (MLC) [19], which scans its memory in a busy loop. We always scale MLC to have the same memory size as the normal VM. We configure MLC to use only 6 threads so that neither the local DRAM bandwidth nor the CXL memory bandwidth is saturated. Running MLC as the workload in the noisy neighbor VM allows us to estimate the worst-case interference, as MLC is optimized to be memory intensive.

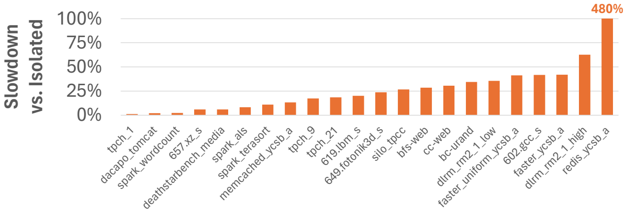

Figure 6: Slowdown caused by the noisy neighbor due to local DRAM conflicts.

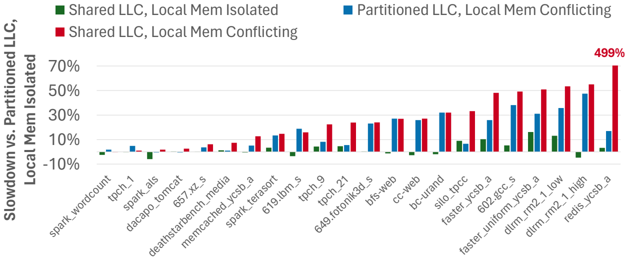

Figure 7: Inter-VM interference caused by LLC contention and local DRAM contention.

The experiments are conducted in two settings:

1. **Isolated.** Allocate conflicting pages to the same VM to ensure each VM only conflicts with itself.
2. **Conflicting.** Allocate conflicting pages to different VMs. This setting measures the worst-case interference since the noisy neighbor VM might monopolize local DRAM.

Figure 6 shows the slowdown of conflicting compared to isolated with a sampled set of representative workloads from each category. 73% of the workloads experience more than 10% slowdown because of local DRAM conflicts. The massive slowdown of Redis is because we use p95 latency as its performance metric. Redis always has some requests with extreme latency (4× higher than the median), and the contention causes the percentage of these requests to exceed 5%, which translates to a 480% slowdown in p95 latency. The results indicate that without any software management to isolate local DRAM conflicts, VMs running on the same host could cause significant performance interference to each other.

Besides local DRAM contention, other sources of interference in multi-tenant environments include contention in the LLC and power. We also study how LLC contention compares to local memory contention in Intel® Flat Memory Mode. We again use a normal VM and a noisy neighbor VM to measure interference. Besides configuring how the two VMs conflict with each other in local memory, we configure the LLC in two settings: (1) sharing LLC across two VMs, or (2) partitioning LLC evenly between two VMs. We use Intel's Cache Allocation Technology [20] to partition the LLC.

When the LLC is partitioned and local DRAM conflicts are isolated, there will be no interference caused by either LLC or local memory contention. When the LLC is shared but local DRAM conflicts are still isolated, we will only observe LLC interference. Similarly, we can only observe local memory interference if the LLC is partitioned and the two VMs are conflicting in local DRAM. Finally, to measure both LLC and local memory interference, we can share the LLC and also let the two VMs are conflicting in local memory.

Figure 7 shows the slowdowns caused by either LLC or local memory interference, as well as the slowdowns when both types of interference exist. Compared to LLC interference, local memory interference is typically larger. In addition, the workloads that suffer from LLC interference also suffer from local memory interference. When both LLC and local memory interference exist, those workloads experience higher slowdowns than when there is a single source of interference. These results again indicate that we should isolate local DRAM conflicts to achieve design goal #3.

4 Memstrata

Memstrata leaves the heavy lifting of fine-grained memory management to the hardware-managed tiering layer at the MC. It provides consistent performance by integrating a lightweight software stack with the virtualization host. This achieves the first two design goals (§2.2).

To provide performance isolation (design goal #3), Memstrata adapts page coloring [69, 105], a classic technique for partitioning CPU caches, to the CXL setting. Memstrata identifies all conflicting pages and allocates conflicting pairs to the same VM, ensuring no inter-VM conflicts (§4.1).

To improve the performance of outliers (design goal #4), Memstrata dynamically allocates dedicated local memory pages across VMs to reduce the outliers' local memory miss rates. Our key insight is that many workloads exhibit low slowdowns even without any dedicated local memory. Therefore, if the hypervisor can identify outlier VMs and move dedicated local memory pages to them, it can limit their slowdowns.

However, the hypervisor has limited visibility into the workloads running inside VMs, making it challenging to identify outliers. Although monitoring local DRAM miss rates seems attractive for detecting outliers, we cannot directly measure per-core or per-VM miss rates because data placement is implemented in the MC, so hardware performance counters can report only the system-wide local memory miss rate.

To tackle these challenges, we analyze numerous performance events measured during our application performance study (§3.2) and propose a proxy to estimate per-VM miss rates. By combining the estimated miss rate with other performance metrics, we can accurately predict the slowdown of a VM using a simple online ML model (§4.2). This model is used by a dynamic page allocator to migrate dedicated local memory pages across VMs, minimizing slowdowns across all workloads with negligible CPU overhead (§4.3). Figure 8 shows an overview and the workflow of Memstrata.

4.1 Page Coloring

Page coloring is a software technique that has been widely used to partition shared processor caches (e.g., the LLC) in a modern CPU [80, 93, 95, 102, 105]. CPU caches are commonly

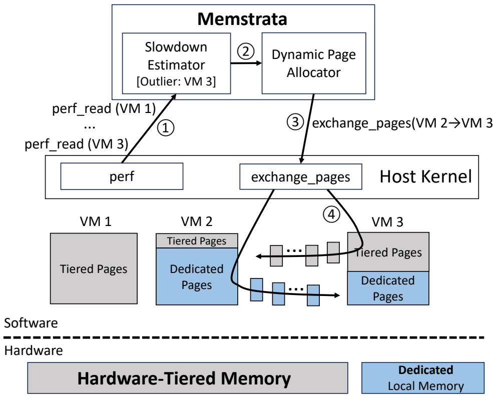

Figure 8: Overview of Memstrata. ①: Memstrata reads the performance events of each VM and runs the slowdown estimator. ②: Slowdown estimations are used to decide the allocation of dedicated pages. ③: The dynamic page allocator uses the `exchange_pages` syscall to migrate dedicated pages to an outlier. ④: The hardware-tiered pages of the outlier are exchanged with the dedicated pages of a non-outlier VM.

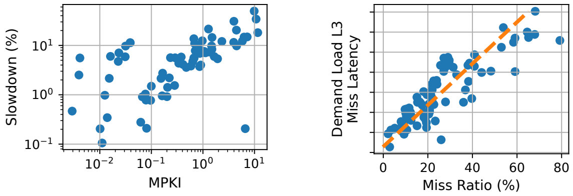
organized in a set-associative (or direct-mapped) manner, in which each physical memory address is mapped to the index of a single set in the cache. If the indexing function is known, then software can determine the subset of cache indices associated with a given memory page, referred to as its *page color*. Since main memory is much larger than the cache, many memory pages have the same color, which means that they compete for the same limited cache space.

System software can control the amount of cache space that may be used by different applications by allocating pages to them with particular colors. For example, a hypervisor can allocate host-physical pages so that each VM uses distinct colors that are disjoint from other VMs.

Similar to shared processor caches, in Intel® Flat Memory Mode, local memory is shared among all VMs within the same NUMA node.[2] Physical memory lines that are mapped to the same local memory line compete for the same local memory space, which will contain the one accessed most recently. Therefore, we can adopt page coloring to partition local memory pages across different VMs to avoid inter-VM local memory conflicts.

We implement page coloring in the context of a virtualized system configured with Intel® Flat Memory Mode. The implementation consists of changing the free-page management logic and the page allocator in the host Linux kernel. We modify Linux's free-page management to group the physical pages that map to the same local DRAM page.

To avoid performance interference due to inter-VM conflicts, the page allocator always allocates the physical pages that map to the same local memory page to the same VM. This isolates each VM, ensuring that it can conflict only with itself, eliminating the possibility of conflicts with other VMs. Isolating local memory conflicts within VMs also prevents their use as inter-VM side channels, similar to those exploited in other caching systems to leak memory access patterns and to exfiltrate data across trust boundaries [71, 81, 82].



(a) MPKI vs. slowdown **(b)** Miss ratio vs. L3 miss latency

Figure 9: Correlation between performance metrics.

While one might expect this to cause poor performance, there are, in fact, many cold or unused cache lines. This means that we actually observe relatively low local memory miss rates (§3.2).

4.2 Identifying Outliers

To improve the performance of outlier workloads, we first need to determine which VMs suffer from high slowdowns because of local DRAM misses. Since the workloads running inside VMs are opaque to the hypervisor, we cannot rely on application-level performance metrics for outlier detection.

Fortunately, modern processors provide performance counters that can be used to infer VM performance characteristics with low overhead [5, 16, 31, 35, 101]. Our prototype CPU also supports various performance events. In our large-scale performance study of Intel® Flat Memory Mode using 115 workloads (§3.2), we configured the CPU to count all performance events for each workload by time-multiplexing them, yielding 151 performance metrics based on raw event counts.

MPKI and its proxy. Among all the performance metrics, local memory miss rate seems promising for detecting outliers, since the local memory is treated as a cache. Specifically, we examine MPKI, which measures the number of local memory misses per thousand instructions. Figure 9a shows that MPKI is correlated ($r^2 = 0.73$) with application slowdown.

Estimating slowdown for a single VM requires per-VM miss rates. As each VM is pinned to a set of exclusive CPU cores, this suggests aggregating the miss rates across its associated cores to compute the VM-level miss rate. Unfortunately, since cacheline promotions and demotions are handled in the MC, it is not easy to track per-core misses, and the system-wide miss rate is insufficient for outlier detection. Although future hardware may support measuring per-core miss rates, this is not implemented in the current prototype.

To work around this limitation, we analyze other performance metrics that can be tracked with per-core granularity to find a proxy for the per-core miss rate. As shown in Figure 9b, we find that the L3 miss latency[3] of demand loads event has a strong linear correlation ($r^2 = 0.87$) with the local

[2] For clarity, we only discuss the hardware-tiered memory *without* dedicated local memory in this subsection. Dedicated local memory is contained in a distinct NUMA node from the local memory associated with the hardware-tiered memory.

[3] Figure 9b omits the y-axis latency scale for confidentiality.

memory miss ratio (not MPKI), defined as the percentage of main memory requests that miss in local memory. This is not surprising, as Intel® Flat Memory Mode exhibits stable hit and miss latencies unless the memory bandwidth is saturated. We leverage this observation by fitting a linear model to estimate the local memory miss ratio from demand load L3 miss latency. The estimated miss ratio is translated to MPKI by multiplying it with the main memory request count and then dividing by the instruction count. We use this estimated MPKI as a proxy for the actual MPKI.

A limitation of this approach is that demand loads represent only a portion of main memory requests. Other sources include read-for-ownership (RFO) requests, non-temporal stores, CPU cache writebacks, and CPU cache prefetches. However, we find that the estimated MPKI works well in practice. When combined with other metrics, it can be used to predict VM slowdown accurately.

Using a model to detect outliers. Although MPKI strongly correlates with application slowdown, we find that MPKI alone is not sufficient to identify outliers because applications can have different sensitivities to memory latency. Therefore we use an online random forest binary classifier [52] to determine whether a VM will experience more than 5% slowdown. We choose a random forest classifier because it performs well with low-level performance metrics [78], is lightweight, and does not require a GPU. The input to the classifier includes the estimated MPKI along with four additional per-VM metrics that also exhibit useful correlations, selected by computing the relative importance of features during classifier training: (a) L3 miss latency of demand loads, (b) L2 miss latency of demand loads, (c) data TLB load miss latency, and (d) L2 MPKI of demand loads. We evenly split the workloads into training and validation sets, and configure the random forest with 100 decision-tree estimators. The classifier achieves 100% accuracy on the training set and 88% accuracy on the validation set, demonstrating the ability to detect outliers across a diverse set of workloads. In contrast, using MPKI as the only feature achieves only 63% accuracy on the validation set.

4.3 Dynamic Page Allocator

The Memstrata dynamic page allocator manages how dedicated local memory pages are allocated across VMs. It uses the ML model to detect outlier VMs, and migrates dedicated local memory pages accordingly to achieve minimum slowdown across all workloads. Within each VM, the page allocator assigns dedicated local memory pages to guest physical pages randomly. We also implemented an alternative hotness-based approach that prioritizes popular guest physical pages, but found that its overhead typically exceeds its benefit.

Inter-VM page allocation. The dynamic page allocator allocates dedicated pages to each VM based on its performance events and slowdown predictions from the ML model. It starts by measuring the events needed by the ML model for a given time interval (10 seconds, by default), and runs the model to predict if the slowdown for each VM is greater than 5%. The 10-second interval enables the page allocator to react quickly to changes, while averaging out noise associated with low-level event counts. To reduce the effect of short-term variations, we employ an exponentially weighted moving average (EWMA) to smooth the performance metrics derived from the event counts (EWMA constant $\alpha = 0.2$, by default).

```
def comparator(vm1, vm2):
  if vm1.isOutlier != vm2.isOutlier:
    return vm2.isOutlier
  return vm1.avgMissCount < vm2.avgMissCount

def migrate(vms, timeInterval, ewma, stepRatio):
  while systemIsRunning():
    sleep(timeInterval)
    updatePerfMetrics(vms, ewma)
    predictSlowdown(vms)
    sort(vms, comparator)
    donor = 0
    for borrower in range(len(vms) - 1, 0, -1):
      if not vms[borrower].isOutlier:
        break
      toBorrow = vms[borrower].pages * stepRatio
      while donor < borrower and toBorrow > 0:
        toDonate = (vms[donor].pages * stepRatio
                    - vms[donor].donated)
        toMigrate = min(toBorrow, toDonate)
        doMigrate(borrower, donor, toMigrate)
        toBorrow -= toMigrate
        vms[donor].donated += toMigrate
        if toDonate == toMigrate:
          donor += 1
```

Listing 1: Inter-VM page migration algorithm.

Once the page allocator obtains the performance metrics and slowdown prediction for each VM, it decides how dedicated local memory pages should be migrated across VMs. Listing 1 presents the page migration algorithm. The page allocator first ranks the VMs based on their predicted slowdowns and the average number of local DRAM misses per allocated hardware-tiered page. The average miss count is computed by multiplying the estimated miss ratio with the main memory request count, and dividing the result by the number of hardware-tiered pages assigned to the VM. The VMs predicted to have less than 5% slowdown receive lower ranks than the outlier VMs. VMs that have the same slowdown prediction are ordered based on their average miss count. The intuition is that prioritizing VMs with higher average miss counts minimizes system-wide local memory misses, since they benefit more from a fixed amount of dedicated local memory pages compared to others [56].

After the VMs are sorted according to their ranks, the allocator repeatedly migrates dedicated pages from the VM with the lowest rank to the VM with the highest rank. To prevent large performance fluctuations, it never migrates more than a fraction `stepRatio` of each VM's pages (10%, by default) during each step. Only VMs predicted to be outliers can receive dedicated local memory pages from others.

To migrate dedicated local memory pages from VM 1 to

VM 2, the page allocator first selects a given number of dedicated pages from VM 1 and the same amount of hardware-tiered pages from VM 2. It then exchanges the selected pages between the two VMs. To avoid introducing inter-VM local DRAM conflicts, conflicting pages are always migrated together. After one round of page migrations, the page allocator stops migrating and measures performance events over the next `timeInterval` before the next round of migration.

Launching and terminating VMs. In cloud environments, running VMs may be terminated and new VMs may be launched at any time. To avoid disruptions, the page allocator first removes a terminating VM from the list of active VMs that participate in page migration. The terminating VM can then be shut down, causing its pages to be returned to the free page pool maintained by the host kernel.

When a new VM is launched, its initial allocation consists of existing free pages from the host kernel, which could be any mix of hardware-tiered pages and dedicated local memory pages. Since the dynamic page allocator does not have any prior information about the new VM, once it is added to the active VM list, the allocator migrates pages so that the new VM contains the same percentage of dedicated pages as the entire system. For example, if the overall system has a total of 33% dedicated local memory and 67% hardware-tiered memory, the new VM will also have 33% dedicated pages. This initial migration is performed by taking (or giving) dedicated pages to (or from) other existing VMs, each of which contributes (or receives) the same number of dedicated pages.

Assigning dedicated memory. By default, the dynamic page allocator assigns dedicated local memory pages to guest physical pages randomly within each VM. We also experimented with an alternative hotness-based page allocation option, which prioritizes popular guest physical pages when allocating dedicated pages. To identify popular guest physical pages, we employ DAMON [11], a low-overhead memory access tracking subsystem integrated into the mainstream Linux kernel. We use DAMON's default settings, but configure its aggregation period to match the `timeInterval` used by the allocator. After finishing inter-VM page migration, the allocator checks the per-region access counts reported by DAMON. Using simple thresholds (cold = 0, hot $\geq$ 20, by default), it exchanges any hardware-tiered pages in hot regions with dedicated pages in cold regions. To avoid large performance fluctuations, such intra-VM migrations are limited to a small fraction (2%, by default) of the VM memory size.

However, we found that the overhead of this hotness-based approach exceeds it benefit (§6.2). Similar to software-managed tiering, it consumes significant CPU cycles to track memory accesses (§2.3). Therefore, by default, Memstrata simply assigns dedicated local pages randomly.

5 Memstrata Implementation

Memstrata's implementation consists of implementing page coloring and the page-exchange system call in the host Linux kernel (v5.19, 2729 LOC), modifying QEMU (v6.2, 60 LOC) to preallocate guest memory for VMs, and building the main functionality of Memstrata as a privileged userspace process that runs on the host (2190 LOC, C++). Like QEMU, Memstrata uses 2 MB as the page size at the host level.

The page-exchange system call `exchange_pages(pid_1, pid_2, page_arr_1, page_arr_2, num_pages)` accepts the PIDs of two processes, an array of linear addresses for each process, and the number of pages to exchange. One can exchange pages within a single process by specifying the same value for `pid_1` and `pid_2`. The syscall is implemented in the host kernel based on the `migrate_pages()` function. To exchange two physical pages, the kernel initially moves the first page to a temporary physical page, then transfers the second page to occupy the first page's original location, and finally relocates the temporary page to the second page's initial position. It uses a Linux MMU notifier [24] to synchronize the secondary page table used by the VM and the QEMU host-level page table.

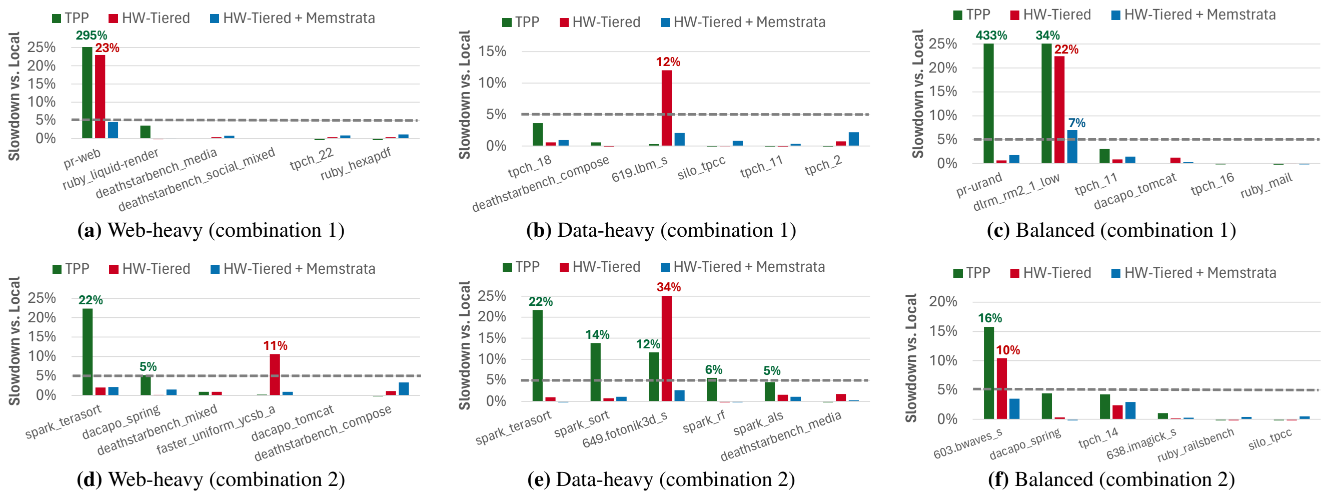
We implement only the necessary mechanisms (i.e., page coloring and page exchange) in the host kernel and run Memstrata as a privileged userspace process, facilitating debugging and extensions. The userspace process configures and reads performance events via the `perf` interface exposed by the host Linux kernel. It uses the custom page-exchange syscall to exchange pages between two VMs, or within a single VM. We use ONNX [60] to run the ML model in the userspace process. To synchronize Memstrata with VM launching and termination, we use POSIX message queues to let the VM scheduler communicate with Memstrata.

6 Evaluation

In this section we seek to answer the following questions:

1. How does Intel® Flat Memory Mode compare to software-managed tiering? (§6.1)
2. Can Memstrata improve the performance of outliers without impacting other applications? (§6.1)
3. How does dedicated memory page allocation affect application performance? (§6.2)
4. Is Memstrata sensitive to its parameters? (§6.3)

Experimental setup. We use a pre-production Intel® Xeon® 6 Processor that implements Intel® Flat Memory Mode. Our test server contains a single socket with 128GB DDR5 local memory and 128GB DDR5 CXL memory. The CXL memory is attached via three CXL cards, which each hold two DDR5-4800 DIMMs and offer an x16 PCIe5 CXL connection. We use a preproduction Astera Labs Leo CXL Smart Memory Controller [22]. The idle latency of the CXL memory is roughly 200-220% the latency of the local memory, and the max bandwidth per CXL card is around 50 GB/s [91]. Although we use DDR5-4800 DIMMs in the CXL cards, we believe the results are transferable to DDR4 DIMMs because the actual CXL bandwidth usage is always below the limit



(a) Web-heavy (combination 1)

(b) Data-heavy (combination 1)

(c) Balanced (combination 1)

(d) Web-heavy (combination 2)

(e) Data-heavy (combination 2)

(f) Balanced (combination 2)

Figure 10: Application slowdown of TPP and hardware tiering with and without Memstrata using different workload combinations.

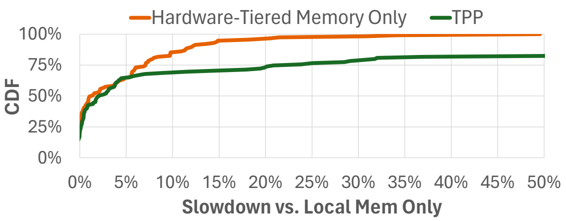


Figure 11: Slowdown distribution of hardware-tiered memory and TPP. TPP is configured with 50% local memory to match the local memory ratio of hardware-tiered memory.

of DDR4 DIMMs. Since the CPU is pre-production, the core count, frequency, and CPU cache sizes may not reflect those of the final product. For confidentiality, we cannot share the detailed technical specification. Similarly, these CXL cards are pre-production and future versions may be faster.

We focus on end-to-end application performance to demonstrate the performance benefits of Memstrata. Our software stack comprises Ubuntu 22.04, modified Linux 5.19, and QEMU/KVM 6.2. Hyperthreading and CPU frequency scaling are disabled. We pin each VM's virtual cores to physical cores in a 1:1 manner. We set the VM memory size of each workload by rounding up its peak resident set size to the next largest VM memory size offered on public cloud platforms.

We do not use public or Azure VM traces since they do not label workloads for VMs. This is because public cloud providers are not generally aware of workloads running inside VMs. Therefore, we rely on analyses of the composition of 188 internal workloads over 100,000 VMs at Azure [98], which reveal that web (31%), big data (32%), and ML (11%) workloads constitute most of the VMs. The remaining workload categories include DevOps and real-time communication workloads, which are challenging to run and have few open-source representatives. Therefore, we focus on the web, big data, and ML workload categories and reuse the set of workloads from §3.2 to match this composition. We exclude the workloads that have unstable performance. With the prototype system only offering 128 GB local memory, we also exclude workloads that require more than 32 GB of memory, so that we can measure a multi-VM local-only baseline.

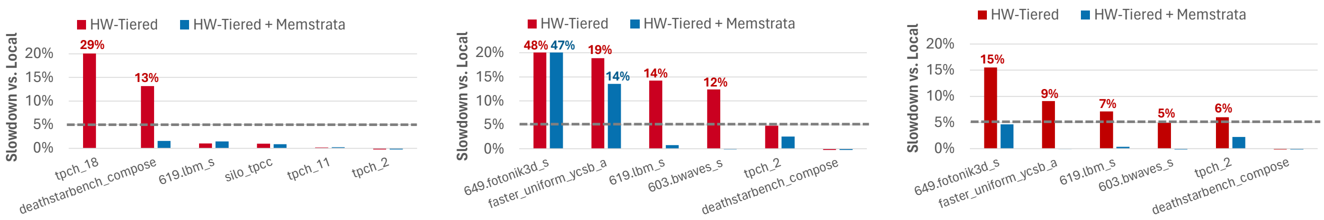
We compare Intel® Flat Memory Mode without and with Memstrata (referred to in the figures as "HW-Tiered" and "HW-Tiered + Memstrata", respectively). To emulate a setting without Memstrata, we use a static allocation scheme in which the percentage of dedicated pages in each VM remains constant over time. In contrast, Memstrata dynamically migrates dedicated pages across VMs to minimize slowdown. All settings use page coloring to avoid inter-VM conflicts.

We also compare hardware tiering without Memstrata to TPP [84], a state-of-the-art software-tiering approach. Since TPP does not support virtualization, we run it within each one of the isolated VMs, with a 2:1 ratio of local DRAM to CXL memory, matching the default setting of hardware tiering. Similar to hardware tiering without Memstrata, TPP does not move memory across VMs. The open-sourced TPP has an issue that wastes some local memory because it allocates local memory only from the `NORMAL` memory zone [30]. We have fixed this issue to enable TPP to perform better.

6.1 Performance Benefits

We assume a workload mix with about $\frac{1}{6}$ of workloads being outliers with hardware tiering, as our results show that 20% of the web, big data, and ML workloads experience more than 5% slowdown with hardware tiering (§3.2). As our prototype offers only 128 GB local memory, we must scale down the set of workloads typical for a large server. We scale to six VMs, typically with a single outlier workload[4]. We also consider the less likely scenarios of 2/6 and 4/6 outliers, as well as

[4] If compute servers indeed were to only host six VMs, scenarios with multiple outliers would be common. However, we seek to represent a scaled-down typical compute server with large VM counts (§2.2). Due to large-number effects most servers will thus have a $\frac{1}{6}$ ratio of outlier workloads. One can also integrate our slowdown estimator (§4.2) into the VM scheduler to explicitly prevent colocating many outliers (§7).



(a) 2 outliers with 33% dedicated local memory **(b)** 4 outliers with 33% dedicated local memory **(c)** 4 outliers with 67% dedicated local memory

Figure 12: Application slowdown when the workload combination contains 2 or 4 outliers.

dynamic VM arrivals. We start each VM with 33% dedicated local memory pages and 67% hardware-tiered pages.

Common cases. As web and data workloads are the dominant workload categories at Azure [98], we choose the following workload mixes to evaluate Memstrata:

1. **Web-heavy**: 4 web, 1 data, and 1 outlier.
2. **Data-heavy**: 1 web, 4 data, and 1 outlier.
3. **Balanced**: 2 web, 2 data, 1 others, and 1 outlier.

For each workload mix, we generate two workload combinations from our workload set. Each combination starts the six workloads simultaneously at the beginning.

Figure 10 shows the slowdown across the entire run. Under TPP, there are significantly more outliers than with hardware tiering, despite TPP having an unfair advantage: TPP has visibility inside the VM, and knows which pages are being used at the 4 KB granularity. Consequently, TPP can place the entire working set into local DRAM if its size does not exceed the local DRAM size. Such visibility assumes guest cooperation and is not compatible with design goal #1 (§2.2).

Interestingly, TPP and hardware tiering sometimes have different outliers. We observe that TPP achieves minimal slowdown whenever the working set can fit into local memory (e.g., SPEC's `619.lbm_s` and FASTER with uniform YCSB A), which is the target use case of TPP [84]. However, if the working set is too large, TPP experiences severe thrashing, causing massive TLB invalidations and page faults due to frequent page migration. For example, in an extreme case where TPP causes `pr-web` to have a 295% slowdown (Figure 10a), TPP migrates memory at 22 GB/s in a 32 GB VM.

This thrashing issue arises because TPP uses NUMA balancing hints [29] to choose promotion candidates and is not aware of the global memory access distribution. We repeat the single-application performance study in §3.2 with TPP. The results show that 17% of the workloads experience more than 50% slowdown with TPP because of thrashing (Figure 11). Although software tiering can measure the global access distribution and only migrate pages when the distribution is skewed to avoid thrashing, the CPU overhead of such global telemetry is prohibitive without guest cooperation, due to the lack of spatial locality in the guest physical memory address space (§2.3). In addition, even with global telemetry, the larger page sizes used with virtualization still make software tiering less effective, as they may average out the skewness in memory access distribution (§2.3).

In summary, the comparison with TPP matches the results of recent work [76] indicating that hardware-based memory tiering's low overhead and cacheline-level granularity typically provide superior performance to software-based tiering. Therefore, in the rest of our experiments we focus on comparing Intel® Flat Memory Mode with and without Memstrata.

For all six experiments in Figure 10 Memstrata is able to significantly reduce the slowdown experienced by the outlier application to near 5% or less, with minimal impact to the other non-memory-sensitive applications. The max CPU overhead of Memstrata across all workload combinations is 4% of a single core, including running the ML model. The max memory overhead of Memstrata is 110 MB. The results show that Memstrata can accurately identify the outlier VM and migrate dedicated local memory pages to reduce its slowdown, without affecting the performance of other VMs.

Higher outlier ratio. To understand the limits of Memstrata, we consider a server that hosts a disproportionate ratio of outlier workloads. We consider two combinations: one with two outliers (Figure 12a), and another with four outliers (Figure 12b). In both experiments, Memstrata significantly improves outlier performance. However, is not able to reduce the slowdown for all outliers to below 5% when four outliers exist. This is because 33% of dedicated local DRAM (i.e., 26.4 GB) is insufficient to accommodate the memory needs of four outlier VMs (56 GB). We verify this by repeating the experiment with 67% dedicated local DRAM. In this configuration Memstrata removes all the outliers (Figure 12c).

Dynamic VM arrivals. We evaluate Memstrata in a more complex setting where VMs are continuously launched and terminated. We again use the three workload combinations described above. Whenever a workload of one type finishes, we start a new VM with a workload selected from the same type. The experiment keeps running until all the workloads have been run at least once. We measure the application performance with and without Memstrata. For the workloads that have finished multiple times, we report its average performance across all the completed runs.

Figure 13 shows that Memstrata can significantly reduce the slowdown of the outliers in such dynamic environments under all three workload mixes. The results demonstrate that Memstrata's online outlier detection can identify the outliers on-the-fly and dynamically migrate dedicated local memory pages to reduce their slowdown. We conclude that a combi-

nation of Intel® Flat Memory Mode and Memstrata enables server memory capacity to be expanded by 1.5× using CXL at a minimal performance impact to applications.

6.2 Dedicated Memory Page Allocation

To understand how the allocation of dedicated local memory pages within a VM affects performance, we compare random page allocation (the default) with a hotness-based approach. We study a representative set of 22 workloads from different categories. With random allocation, the 33% of dedicated pages are randomly allocated to the VM when it is launched. With the hotness-based approach, the dedicated pages are also allocated randomly at launch, but Memstrata's dynamic allocator migrates them to hot guest physical regions based on the information provided by DAMON [11]. To measure the best-case performance of the hotness-based approach, we preserve the guest memory's spatial locality by always starting in a fresh VM.

Figure 14 shows the slowdown of both random and hotness-based page allocation. The hotness-based approach provides only marginal benefits and even causes worse slowdowns for some workloads because of its overhead. Figure 15 presents the hotness information recorded by DAMON and how the page allocator moves dedicated pages within the guest physical address space for `619.lbm_s`. Although it migrates dedicated pages to the hot regions identified by DAMON, the improvement is still limited. This is because to track memory accesses, DAMON must clear PTE access bits, resulting in expensive TLB shootdowns that offset its benefits.

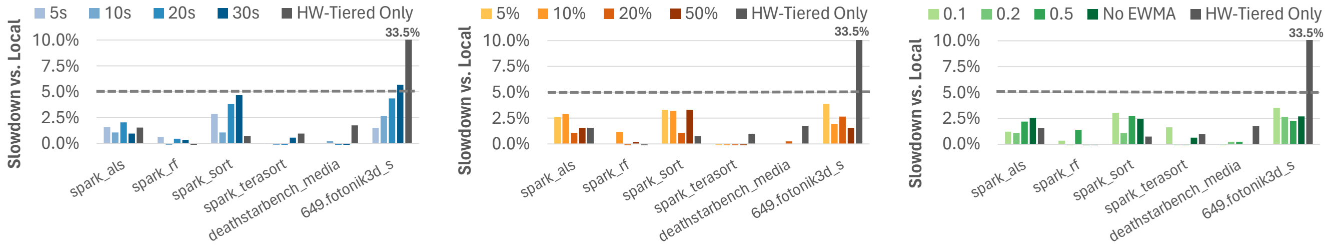
6.3 Sensitivity Analyses

Memstrata has three parameters: `timeInterval` and `stepRatio`, which control the aggressiveness of page migration, and the EWMA constant, which smoothes short-term variations of performance metrics. Figure 16 plots Memstrata's sensitivity to the three parameters using the same workloads as Figure 10e. With a lower `timeInterval` or a higher `stepRatio`, Memstrata migrates dedicated local memory pages to the outlier VM more quickly and achieves lower slowdowns (Figure 16a and Figure 16b). The default parameters (i.e., 10 s `timeInterval` and 10% `stepRatio`) have performance similar to the optimal one in this experiment, but are less aggressive and can avoid large performance fluctuations. Memstrata is not sensitive to the EWMA constant (Figure 16c).

7 Discussion

Non-virtualized environments. Most of Memstrata's components can be readily applied to non-virtualized environments. For example, per-process performance event tracking is already supported by Linux, and page migration mechanisms for both VMs and normal processes are also supported.

However, the page coloring implementation needs to be modified for non-virtualized settings. Unlike VMs, whose memory sizes do not typically change during their lifetimes, processes commonly have dynamic memory footprints. Memstrata statically allocates a fixed number of colors during VM creation, which is insufficient for processes with dynamic memory demands. Therefore, we need to augment the page coloring mechanism to support on-demand color allocation. In addition, as a process continuously allocates and frees memory, allocated colors may have numerous unused pages (e.g.,



(a) `timeInterval` (s) **(b)** `stepRatio` (%) **(c)** EWMA constant (α)

Figure 16: Sensitivity analyses of Memstrata under a data-heavy workload combination.

if a process allocates a large amount of memory but then frees half of it later). Such fragmentation can lead to insufficient free colors for new memory allocations. We therefore need to implement a compaction mechanism to reclaim colors from processes exhibiting significant fragmentation.

Intel® Flat Memory Mode with other memory ratios. In principle, Intel® Flat Memory Mode could support other ratios between local memory and CXL memory such as 1:2 or 1:4. We are not prepared to discuss whether such ratios will be available in a future version. There are also associated costs such as requiring more tag bits for bookkeeping.

Detecting outliers at the VM scheduler. Similar to Pond [78], the VM scheduler can correlate historical performance event measurements with a new VM allocation request by matching the customer ID, VM type, and location. Based on the historical information, the scheduler can perform an initial outlier detection to decide the memory type for the new VM. Additionally, the VM scheduler can also run online outlier detection after the VM is allocated and can live migrate the VM if the initial outlier detection proves to be inaccurate.

Adapting to other slowdown thresholds. Adapting to slowdown thresholds other than 5% requires retraining the random forest model using the performance events and the corresponding slowdowns of various workloads. Since the random forest model is lightweight and does not require any GPU, retraining the model incurs only minimal overhead and can be completed within a few seconds.

8 Related Work

Most prior work relies on software to place data across memory tiers [45, 70, 99, 100, 100], whereas Memstrata combines hardware tiering with a lightweight software layer. HeMem [89] and MEMTIS [74] are recent systems that use Intel PEBS to track memory accesses. Unfortunately, PEBS is not compatible with virtualized environments. In addition, unlike MEMTIS, which balances the TLB benefits of huge pages with the granularity of data placement by dynamically splitting huge pages, Memstrata achieves both low TLB cost and fine-grained data placement without sacrificing either. TPP [84] relies on LRU and NUMA balancing hints [29] to track memory accesses, but incurs high slowdowns (§6.1) and significant CPU overhead (§2.3).

Three prior systems explore software-managed tiered memory in multi-tenant environments. Unfortunately, they are not available for comparison. TMTS [61] is a memory tiering system deployed in Google's datacenters. We believe TMTS is overly conservative and requires large amounts of local memory. Pond [78] statically places VMs into a CXL-based memory pool based on predictions of slowdowns. Pond uses VM live migration to mitigate outliers, which impacts VM performance and thus must be applied conservatively. vTMM [90] is a dynamic software tiering memory management system for VMs. We believe vTMM suffers from overheads similar to other software-based systems (§2.3). Memstrata differs from all three systems due to its unique combination of hardware and software tiering in the same system.

2LM is a hardware-managed tiered memory system for Intel® Optane™ NVM, using DRAM as an inclusive direct-mapped cache of NVM. In contrast, Intel® Flat Memory Mode uses exclusive caching, and 2LM lacks the cross-VM isolation provided by Memstrata. Other hardware approaches have been proposed for DRAM and high-bandwidth memory [68, 75, 85, 103]; some Intel processors support a hardware-managed "cache mode" that uses HBM as a cache for DRAM [55, 59].

9 Conclusions

We presented a new hardware-based CXL tiering system, Intel® Flat Memory Mode, combined with a software stack, Memstrata. The combination provides performance similar to local DRAM across a wide range of workloads. Consequently, they enable expanding server memory capacity by 1.5× with minimal impact to performance. We believe there remain many open research challenges in deploying CXL in virtualized environments, including fairness in inter-VM resource allocation policies, guest cooperation for tiered memory, and using device-side hotness tracking to reduce page conflicts.

Acknowledgments

Abstract

Memory-bound stalls account for a significant portion of CPU cycles in datacenter workloads, which makes harvesting them to execute other useful work highly valuable. However, mainstream implementations of the hardware harvesting mechanism, simultaneous multithreading (SMT), are unsatisfactory. They incur high latency overhead and do not offer fine-grained configurability of the trade-off between latency and harvesting throughput, which hinders wide adoption for latency-critical services; and they support only limited degrees of concurrency, which prevents full harvesting of memory stall cycles.

We present MSH, the first system that transparently and efficiently harvests memory-bound stall cycles in software. MSH makes full use of stall cycles with concurrency scaling, while incurring minimal and configurable latency overhead. MSH achieves these with a novel co-design of profiling, program analysis, binary instrumentation and runtime scheduling. Our evaluation shows that MSH achieves up to 72% harvesting throughput of SMT for latency SLOs under which SMT has to be disabled, and that strategically combining MSH with SMT leads to higher throughput than SMT due to MSH's capability to fully harvest memory-bound stall cycles.

1 Introduction

CPU cores are valuable resources in datacenter infrastructure. To meet the ever-growing computation demand, there have been extensive software efforts in *harvesting* idle CPU cycles and keeping cores fully utilized [7,43,52,88,94]. While differing in mechanisms, these works share a similar harvesting scheme: "scavenger" instances (*e.g.,* spot VMs, batch jobs) temporarily run on cores that primary instances are not actively using. Their common performance goal is to have scavenger instances fully utilize the idle cycles without slowing down primary instances. Minimizing negative performance impacts is particularly important for latency-critical services as their increased latencies directly affect user experience.

Unlike prior efforts that harvest cores that are idle for a relatively long period of time, *e.g.,* allocated but unused cores of the primary VM, we focus on memory-bound CPU *stall* cycles. These are cycles that cores transiently stall while waiting for memory accesses to finish. Although each lasts only a few hundred nanoseconds, memory-bound stalls can happen frequently and account for a significant portion of CPU cycles [10,23,45,78]: more than 60% for some widely-used modern applications, which implies substantial benefits harvesting these stall cycles. However, the current hardware harvesting mechanism, simultaneous multithreading (SMT), is unsatisfactory. First, SMT is known to likely lead to significantly *increased latencies*, as it focuses solely on multiplexing instruction streams to best utilize core resources [37, 74, 83, 84]. Moreover, SMT does not allow fine-grained *control* over the tradeoff between primary latency and scavenger throughput, which is needed to maximize CPU utilization under a latency SLO. As a result, for latency-critical services, a common compromise is thus to avoid using SMT for better performance, at the cost of wasting stall cycles [18,19,55,69]. Lastly, there are cases where SMT can not *fully harvest* memory-bound stall cycles: modern CPUs often support only limited degrees of concurrency (*e.g.,* 2 threads per physical core in the case of Intel's Hyperthreading), which are insufficient when concurrent threads frequently incur cache misses [44,45,72].

In view of the significance of memory-bound CPU stalls and the drawbacks of SMT as the hardware harvesting mechanism, our goal is to design a system that harvests these stall cycles in software. This system should meet several requirements. First, it should be *transparent* to applications and require no additional rewriting efforts from developers. As a result, it will resemble SMT in terms of being conveniently applicable to any code, including legacy code. The other requirements then demand improving upon the drawbacks of SMT. Specifically, it should *efficiently* and *fully* harvest the memory-bound stall cycles, and it should do so while introducing *minimal* latency overhead to the primary instance.

A recent proposal [57] discusses the possibility of transparently hiding the latency of cache misses in software with the combination of light-weight coroutines [25,28,64,79] and sample-based profiling [17,47,82]. The former allows interleaving of primary and scavenger coroutines with a switching overhead much smaller than traditional threads of executions like processes and kernel threads; whereas the latter makes it possible to do it transparently, as we could identify likely locations of cache misses via profiling. This is a key realization that our work builds upon. However, there remains to be a set of challenges toward building a software system that harvests memory-bound CPU stall cycles and meets the aforementioned requirements. First, to improve harvesting efficiency, we have to minimize the amount of register savings and restorations for each yield, while ensuring the correctness of program executions. Second, to introduce minimal latency overhead, scavengers need to yield back the core soon after they have consumed enough stall cycles, which is challenging given that programs have complex and dynamic control flows. Third, to fully harvest stall cycles, we need to detect when a higher degree of concurrency is needed and properly interleave the executions of multiple scavengers. Lastly, it is challenging to transparently interleave scavenger executions with a primary binary that has an internal threading structure.

To overcome these challenges, we present Memory Stall Software Harvester (MSH), the first system that transparently and efficiently harvests memory-bound CPU stall cycles in software. MSH makes full use of stall cycles while incurring only minimal latency overhead. MSH fulfills all the requirements with a novel co-design of *profiling, program analysis, binary instrumentation and runtime scheduling*. To use MSH, users simply provide unmodified primary binaries and a pool of scavenger threads, and MSH takes care of running scavenger threads with stall cycles of the primary binaries.

Internally, MSH operates in two logical steps. First, after profiling the primary and scavenger code, MSH statically instruments them at the binary level, by leveraging information obtained via profiling and program analysis. Specifically, for both primaries and scavengers, MSH inserts a prefetch instruction followed by yielding to either a primary or a scavenger coroutine (configured in runtime, discussed below), before selected load instructions that frequently incur cache misses according to profiled data. In addition, MSH places additional yields in scavengers to ensure that they timely relinquish their core. The first two of the aforementioned challenges are resolved in this step. For the primary binaries, MSH carries out various optimizations to reduce the amount of register savings and restorations for each yield by analyzing register usage and program structures. For the scavenger, MSH conducts a forward data flow analysis that also takes in profiled data to decide additional yield points, so that the distance between consecutive yields is bounded to a configurable threshold.

In the second logical step, when executing a primary binary, MSH sets up and dynamically assigns scavengers to active primary threads. The last two challenges regarding scavenger scheduling and concurrency scaling are tackled in this step. MSH intercepts function calls that change the status of primary threads and efficiently adjusts the scavenger assignment. This allows MSH to transparently schedule scavengers on top of the primary's threading structure. To support on-demand concurrency scaling, MSH performs two operations: assigning multiple scavengers to a primary thread and configuring scavengers so that they yield to the right target. For the former, MSH decides the number of scavengers assigned to a primary thread by estimating and bounding the likelihood of not full harvesting stall cycles. For the latter, MSH instruments yields in scavengers that are close to each other to yield to the next scavenger instead of the primary thread. MSH's runtime then takes care of correctly setting up the targets of these yields.

We implement MSH's offline parts on top of Bolt [67], an open-source binary optimizer built on the LLVM framework, and MSH's runtime as a user-level library[1]. We evaluate MSH with unmodified syntactic and real applications and show that MSH is general enough to harvest stall cycles from all of them. Compared with SMT, MSH offers superior harvesting performance in three aspects: first, MSH incurs minimal latency overhead and achieves up to 72% harvesting throughput of SMT, for latency SLOs under which SMT has to be disabled. Second, as a configurable software solution, MSH enables users to have fine-grained control over the tradeoff between primary latency and scavenger throughput. Third, MSH can fully harvest memory-bound stall cycles via concurrency scaling, achieving up to 2x higher throughput than SMT when scavengers frequently stall. Moreover, we show that by strategically combining MSH with SMT, one could achieve higher throughput than SMT due to MSH's ability to fully harvest memory-bound stall cycles. Lastly, we extensively evaluate MSH's main components and show that they play a vital role in achieving MSH's superior performance.

In summary, the contributions of this paper are: (i) a transparent and efficient approach to harvest memory-bound CPU stall cycles in software; (ii) the detailed design and implementation of a system (MSH) based on this approach, which involves a co-design of profiling, program analysis, binary instrumentation, and runtime scheduling; (iii) an evaluation with real applications showing that compared with SMT, MSH can deliver high scavenger throughput under stringent primary latency SLOs and fully harvest memory-bound stall cycles. In addition to presenting the design, implementation, and evaluation of MSH, we extensively discuss other related aspects in §8. These include isolation mechanisms that can be integrated with MSH to ensure memory safety, hardware support that can enhance MSH's performance and so on. Our hope here is to motivate greater efforts in delivering these critical aspects.

2 Background and Motivation

Memory-bound stalls: Memory-bound stalls, where cores stall and wait for memory accesses to finish, were reported to be a dominant source of CPU overhead for datacenter workloads. To see this, we perform a top-down analysis [90] on two latency-critical applications. This analysis classifies CPU pipeline slots into four categories: retiring, frontend-bound, bad speculation and backend-bound. The last three correspond to different overhead, and backend-bound stalls can be further divided into core-bound or memory-bound stalls. Our

[1] MSH is publicly available at https://github.com/sosson97/msh.

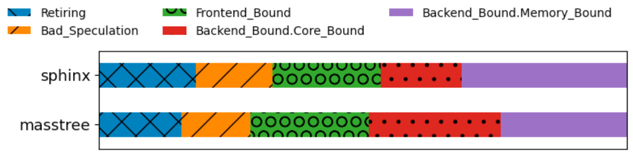

Figure 1: Top-down analysis of Sphinx and Masstree; memory stalls account for 25% and 31% of cycles respectively.

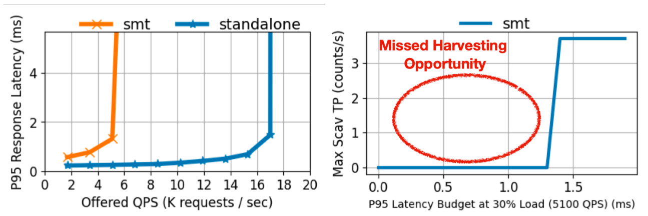

(a)

(b)

Figure 2: (a) P95 latency of Masstree when running by itself vs. co-locating with a Scan scavenger; (b) SMT is unable to harvest stall cycles under low latency SLOs.

analysis confirms the dominance of memory-bound stalls, as they account for 25% and 31% of total cycles for Masstree and Sphinx respectively (Figure 1). While there have been extensive efforts on *reducing* memory stalls, it is generally infeasible to eliminate them (§7). In this work, we focus on the alternative approach of *harvesting* these stall cycles to execute useful work, where simultaneous multithreading (SMT) is the representative hardware mechanism.

Drawbacks of SMT: However, SMT, as a harvesting mechanism, suffers from three main drawbacks[2] that we next show:

- **Latency overhead:** SMT focuses solely on multiplexing instruction streams to best utilize CPU cores. As a result, it significantly increases the primary latency if the scavenger creates notable *contention* on core resources. This is problematic as it is common to co-locate latency-critical tasks that have stringent latency SLOs, with best-effort tasks that are resource-hungry. To see the latency overhead of SMT, we measure the latency of Masstree while running a synthetic Scan scavenger on its sibling cores. Scan is a representative of contending scavengers: by iterating a 4MB array and computing the sum, it consumes L1/L2 caches and core resources like ALU. As shown in Figure 2-(a), compared with running on dedicated cores, harvesting stall cycles via SMT leads to 92x higher latency of Masstree at 40% load. Such a behavior is widely observed in prior studies, thus it is common to avoid using SMT for latency-critical services at the cost of wasting cycles.

- **Lack of Configurability:** Related to the large latency overhead, another drawback of SMT that hinders its uses for latency-critical services is the lack of fine-grained configurability. Given a latency SLO, what is needed to maximize CPU utilization is a knob that controls the *extent* of resource sharing and hence the tradeoff between primary latency and scavenger throughput. However, with SMT, one can only decide whether to turn it on or off, which is too coarse-grained to be useful. To see this, we compute the maximum achievable Scan scavenger throughput under different Masstree latency SLOs for the experiment above. Here we set the SLO to be the latency under 30% load. An ideal mechanism should gracefully harvest cycles proportional to the latency budget given. In contrast, as shown in Figure 2-(b), with SMT, one has to turn off SMT and effectively achieve zero scavenger throughput when the latency SLO is lower than SMT latency. Even after SMT is on, it can not harvest more cycles when looser latency SLOs are given. Neither of these two ends is desirable.

- **Incomplete harvesting:** Lastly, SMT often can not fully harvest memory-bound stall cycles, especially when concurrent threads frequently incur cache misses. This is because the mainstream 2-wide SMT does not have sufficient degrees of concurrency to harvest the bulk of memory stalls. Note that while increasing the width of SMT helps with this issue, it requires dedicating more hardware resources and worsens the already problematic latency overhead issue.

We aim to design a software system that harvests memory-bound stall cycles, is as generally applicable and convenient to use as SMT, and improves upon the drawbacks of SMT.

Software opportunities: There are two capabilities a software mechanism needs for harvesting memory stall cycles: (i) transparently detecting the presence of memory stalls and (ii) efficiently interleaving the executions of primaries and scavengers. The former is challenging, because cache misses are not exposed to software, and manually identifying stalls is burdensome and error-prone. The latter requires much smaller switching overhead than traditional threads of execution like kernel threads. A recent proposal [57] discusses the opportunity of enabling these two capabilities via a combination of light-weight coroutines and sample-based profiling:

- **Sample-based profiling:** By using hardware performance counters in modern CPUs, such as Intel's PEBS [3] and LBR [47], one could profile binaries with no special build and negligible run time overhead. Thanks to these merits, sample-based profiling has been widely used in production for profile-guided optimizations (PGO) [17, 30, 66–68].

- **Light-weight coroutines:** Context switches of coroutines are orders of magnitudes cheaper than traditional threads of execution. This is because as a user-space mechanism within a single process, coroutine context switch requires no system calls nor changes to virtual memory mappings.

Building on these two techniques, MSH is the first software system that transparently and efficiently harvests memory-bound stall cycles. Next, we present an overview of MSH.

[2] These drawbacks apply to SMT of most modern processors (*e.g.,* Intel's and AMD's), with IBM Power as an exception, discussed further in §7.

3 MSH Overview

In this section, we discuss MSH's overarching goals, deployment scenarios, high-level approach as well as overall flow.

Goal: Our goal is to transparently harvest memory-bound stall cycles from any application, while overcoming SMT's performance limitations. We thus distill four requirements that MSH as a software harvesting system should meet:

- **Transparent:** The system should be transparent to applications. It thus requires no rewriting effort from developers and is applicable to any code, including legacy code.
- **Efficient:** The system should efficiently utilize the stall cycles for scavenger executions, which demands extremely low overhead from the harvesting machinery.
- **Latency-aware:** The system should incur minimal latency overhead and allow fine-grained control over the trade-off between primary latency and scavenger throughput.
- **Full-harvesting:** The system should fully harvest stall cycles by interleaving sufficient scavenger executions, especially when scavengers also incur frequent cache misses.

Deployment scenario: System operators can use MSH to harvest stall cycles of any application written in compiled languages. MSH handles scavenger's offline instrumentations and runtime executions. MSH assumes that it is safe to run these scavengers alongside the primaries [92], *e.g.,* they are crash-free and access memory safely. Ensuring safety properties with techniques like verification and information flow control [14, 35, 62] is left to future work. MSH can be seamlessly integrated with existing profiling systems deployed for PGO [17, 30, 68]. MSH is well suited for when latency-critical and best-efforts tasks are co-located in the same machine, a common arrangement in production [27, 55, 61, 93]. In this case, latency-critical tasks serve as the primary, whose stall cycles are harvested for the best-effort tasks.

Approach: MSH uses a novel co-design of binary instrumentation, profiling, program analysis, and runtime scheduling, each of which plays a role in meeting the requirements above:

- **Binary instrumentation:** MSH instruments primaries and scavengers so that they are amenable to stall cycle harvesting. Operating at the binary level provides visibility of low-level information, *e.g.,* register usage and basic block control flows, which is needed by MSH's program analysis.
- **Profiling:** With sample-based profiling, MSH decides locations to harvest stall cycles without requiring efforts from developers. Profiling also allows MSH to use dynamic information, *e.g.,* basic block latency and branching probability, to achieve high accuracy in its program analysis.
- **Program analysis:** MSH leverages program analysis to achieve efficiency, full-harvesting and latency-awareness. For efficiency, MSH minimizes the amount of register savings and restorations for yields. For full-harvesting, MSH directs yields in scavengers that are close to each other to another scavenger. For latency-awareness, MSH bounds the latency between adjacent yields in scavengers.
- **Runtime scheduling:** MSH's runtime schedules scavenger executions on top of the primary's internal threading structure. It enables MSH to fully harvest stall cycles with available scavengers, by assigning multiple scavengers to a primary thread to scale up concurrency and migrating scavengers from blocked primary threads to active ones.

Overall Flow: MSH performs both offline and run-time operations (Figure 3). In the offline phase, MSH transforms the primary and scavenger binaries so that they are amenable to stall cycle harvesting. Specifically, MSH first profiles the binaries and obtains information needed by program analysis and later binary instrumentation: load instructions that incur cache misses, indicating where CPU stalls happen; basic block latencies and execution counts as well as branching probability, which are used by the primary and scavenger instrumentations. After profiling, MSH analyzes the binaries and extracts information that later guides the instrumentations. For each yield site, where a yield is inserted to harvest stall cycles of a delinquent load, MSH identifies a minimal amount of register savings and restorations that still ensures program correctness, by analyzing register usage and program structures. For scavengers, MSH conducts a data flow analysis to decide the locations of additional yields, so that the expected inter-yield latency is bounded. Most of the analysis is designed to be intra-procedural, the complexity of which thus scales only sublinearly with program sizes. Lastly, based on the analysis results, MSH instruments the binaries.

The instrumented primary binaries contain so-called "primary" yields to expose CPU stalls: each primary yield is inserted before a selected load instruction and prefetches the cache line before yielding to a scavenger. As for instrumented scavengers, they also contain primary yields before selected load instructions, with default yield targets being a primary thread. The special case is when primary yields are close to each other: the target of these "special" primary yields is set to another scavenger to scale up concurrency. Scavengers also contain so-called "scavenger" yields, which are placed to ensure that scavengers relinquish their cores in a timely manner. We present the design of primary and scavenger instrumentations in §4.1 and §4.2.

At runtime, MSH interleaves the executions of instrumented primaries and scavengers by dynamically assigning scavengers to active primary threads, which means that MSH does not require pre-determined or static pairings of primaries and scavengers. To do that, MSH tracks the status of primary threads by intercepting relevant function calls and adjusts scavenger assignment accordingly. When a new thread is created, MSH either steals the scavengers of a blocked thread or fetches scavengers from the scavenger pool. If a thread is blocked or ended, MSH marks its scavengers as stealable.

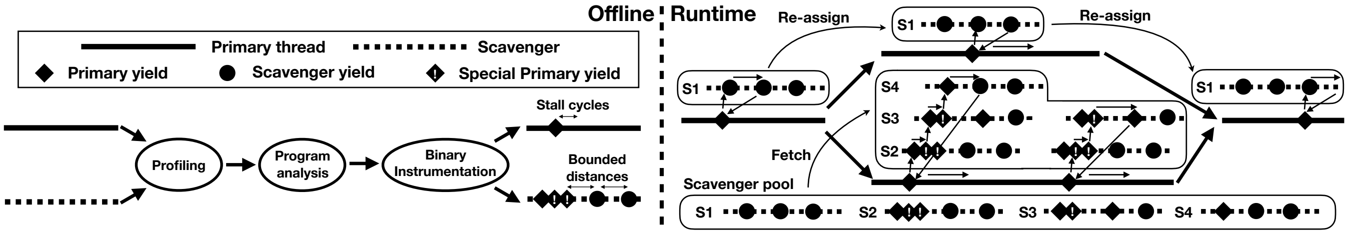

Figure 3: MSH system overview. Offline: MSH profiles and analyzes primaries and scavengers. It then instruments the primaries to yield control to scavengers at likely memory stall sites, with scavengers returning control to primaries within a bounded time. Runtime: MSH sets up a scavenger pool and dynamically assigns scavengers to each active primary thread.

When a thread later resumes, it will first attempt to reuse its previously assigned scavengers, before falling back to getting new scavengers like the thread creation case. Multiple scavengers could be assigned to a primary thread to scale up concurrency. MSH's runtime performs all these operations efficiently, and its design is later presented in §4.3.

4 Design

MSH consists of three components: primary instrumentation (§4.1), scavenger instrumentation (§4.2) and a runtime (§4.3).

4.1 Primary Instrumentation

Primary instrumentation allows MSH to prefetch and yield before load instructions that incur cache misses to expose stall cycles. This should be transparent – requiring no assistance from developers, and efficient – leaving most stall cycles for scavengers. MSH achieves transparency by selecting yield sites based on profiled data, and efficiency by minimizing register savings/restorations for each yield via program analysis.

Profile-guided yield instrumentation: MSH selects locations that both account for a significant portion of memory-bound stalls and have a high likelihood of L3 cache misses: the former indicates substantial stall cycles, and the latter allows less impact to the primary's latency. To support this, MSH obtains two pieces of information via profiling: load instructions with L2/L3 cache misses and execution counts of basic blocks.. MSH then adopts a two-step selection logic. First, MSH sorts load instructions whose cache miss rates are higher than a threshold by their frequencies. Second, MSH estimates the latency overhead for each load instruction by multiplying its frequency with its cache hit rate and the memory access latency. MSH then goes down the sorted list, includes a load instruction if the aggregate overhead falls below a provided bound, and skips otherwise. This selection logic maximizes harvesting opportunities by prioritizing frequent load instructions, while limiting the overall latency overhead. Both the cache miss threshold and overhead bound are configurable parameters that affect the tradeoff between primary latency and scavenger throughput (§6.4).

For each selected load instructions, MSH instruments a prefetch instruction for the same address, followed by a yield that consists of two parts: register savings/restorations and control passing. The former accounts for most of the yielding overhead, and as we will describe next, MSH minimizes it while ensuring correctness of program executions. For control passing, MSH instruments the primary to swap its instruction and stack pointer with the ones of an assigned scavenger that the primary reads from a per-thread data structure (§4.3). The instrumented code also reads a flag that indicates whether to bypass the yield and directly resumes. This allows the runtime to turn off stall cycle harvesting for instrumented primaries and avoid the latency overhead of scavenger executions.

Yield cost minimization: Minimizing the yield cost is important for two reasons. First, it improves harvesting efficiency: the less cycles spent on the yielding machinery, the more cycles available for executing scavengers while the primary stalls. Moreover, it reduces the latency impacts to the primary, especially when an instrumented load instruction results in a cache hit and only stalls for a short amount of time.

Register savings and restorations are the dominant cost for yields. MSH thus performs various optimizations to reduce them while ensuring correctness of the program executions. To avoid preserving every register, MSH first leverages register liveness analysis [71], a form of data-flow analysis that determines for each program point the set of "live" registers whose values will likely be used later. Given that register liveness is conservative, meaning that a register will be identified as live as long as there is any potential program path that may read its current value, by preserving live registers at the yield site, we are guaranteed to not violate the program correctness.

While saving only live registers reduces the yielding overhead, the cost saving is small for functions with non-trivial control flows, where most registers are considered live. To further reduce the cost, MSH builds on an observation: besides *what* registers to preserve, *where* these register savings and restorations take place also plays an important role in the yielding overhead. In particular, the naive approach of placing register savings and restorations at yield sites leads to *unnecessary* overhead. This is because there can be multiple yields between a definition of a register and its corresponding uses that repeatedly save and restore the register's value as the register is indeed live. To fix this, the key insight is to *align* register savings/restorations with register definitions/uses. Intuitively, if we were to save/restore the register at

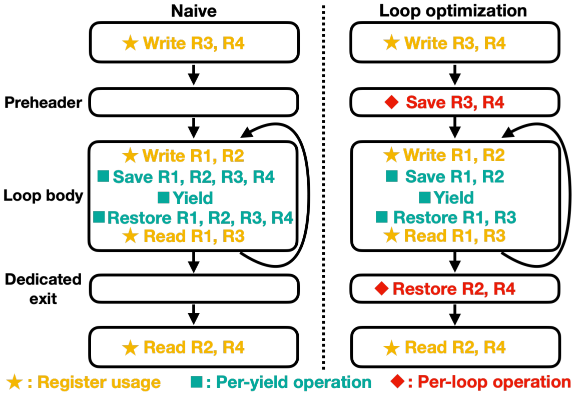

Figure 4: Loop optimization in primary instrumentation.

its definition/use sites, we can remove the redundancy due to having multiple yields in between the definition-use pairs, while still correctly preserving program semantics.

However, placing register savings/restorations at its definition/use sites for arbitrary program structures is highly complicated and potentially undesirable. Specifically, for correctness, one needs to identify all the definition sites, whose definitions are likely to reach the yielding point, as well as all the use sites that likely read these definitions. Instrumenting at all these scattered locations requires a substantial amount of work. Moreover, it is inevitable that some definition-use pairs have paths that do not go through the yield point. This means that there is register saving/restoring overhead even when the function does not yield, which could lead to overall increased overhead, if these cases happen frequently.

Instead of handling arbitrary program structures, MSH focuses on *loops*: it is often the case that a large portion of yields reside in loops, which make them valuable targets for optimizations. More importantly, the unique structure of loops allows MSH to perform *per-loop* register savings or restorations. As shown in Figure 4, most loops can be restructured to have a preheader and some dedicated exits: the former dominates the loop body whereas the latter post-dominate it. As a result, any paths traversing the loop will enter the preheader and leave one of the exits. MSH can thus simply place register savings and restorations at the preheader and exits, respectively, to ensure correctness for yields within the loop. Moreover, as long as more than one loop iteration goes through the yielding point, such a placement leads to strictly fewer register savings and restorations than the yield-site placement. In practice, this improvement is significant as the operation now happens once per loop instead of once per iteration. For registers that only have either uses or definitions within the loop body (R2 and R3 in Figure 4), MSH adopts a hybrid approach that places either saving or storing at the preheader/exit and the other at the yield site. To enable such loop optimizations, besides register liveness analysis, MSH performs reaching definition analysis to track the relevant definitions and uses for live registers, as well as loop simplification to transform feasible loops.

Besides when there are yields directly within a loop, MSH optimizes for another common case, where a function called within loops contains a single yield point. In particular, for a function that has unused callee-saved registers, we need to preserve values of these registers at the function boundary to abide by the calling convention. However, when such functions are called in loops, they incur redundant overhead due to per-iteration saving and restoration. To address this issue, MSH performs an optimization that we call “pseudo-inlining”: MSH effectively inlines the target function by creating a copy of the function, for which the values of unused callee-saved registers are not preserved, and redirecting calls in loops towards this copy. MSH then leverages its loop optimization technique to save and restore the values of these unused callee-saved registers at the loop granularity as much as possible. MSH ensures that the original copy complies with the calling convention, so that other calls to the function take place correctly. Pseudo-inlining thus enables loop optimizations as if the function were inlined, while being easy to implement and creating minimal code expansion since the copy is shared.

In summary, MSH is strategic about what registers to preserve and where operations take place. It achieves the former by identifying live registers and the latter by exploiting per-loop operations. This reduced yield cost then leads to lower primary latency and higher harvesting efficiency (§6.4).

4.2 Scavenger Instrumentation

Scavenger instrumentation allows full stall cycle harvesting, while incurring minimal latency overheads. To minimize latency overhead, MSH places scavenger yields to bound inter-yield distances. To fully harvest stall cycles, primary yields that are too close to each other are directed to another scavenger. Next, we describe the mechanism in detail.

Primary yields: MSH instruments yields for stalling load instructions within scavengers in the same way as primary instrumentation: identifying yield sites via profiling and adopting optimizations to reduce yield costs. By default, these primary yields relinquish the core back to the primary. The special case is when some yields are too close to each other to fully harvest stall cycles (*e.g.,* yields within tight loops). These special primary yields will continue to the next scavenger. To support this, the per-thread data structure managed by runtime contains two targets (*i.e.,* primary thread and next scavenger) for each scavenger (§4.3). Normal and special primary yields are thus instructed to read different targets.

Scavenger yields: With only primary yields, it could take arbitrarily long for scavengers to yield back. MSH thus bounds inter-yield distances via a data-flow analysis that (i) calculates the average distances between a basic block and the current set of scavenger yields and (ii) inserts yields if some distance is over the bound. Note that the accuracy of bounding inter-yield distances affects the latency overhead, but not the correctness of the primary's execution. We next describe the state, transfer function and join operation of the analysis:

- **State:** The state of our analysis is a list of yields and their average *uninstrumented* distances (in terms of time/cycles) to the current program point. If the scavenger were to yield here, these are the expected amount of time the scavenger has consumed before relinquishing the core since the previous yield points. Note that only yields with paths to the current program point that do not contain any other yield are included in the list. Input and output states of a basic block thus represent the uninstrumented distances before and after the basic block execution. MSH focuses on these states as they directly allow bounding inter-yield distances.
- **Transfer function:** This determines how the output state of a basic block is calculated based on its input state. If no new yields are added, the output state is simply the input incremented by the average latency of the basic block. This average latency can be computed with latency samples from profiling, or estimated as the product of the number of instructions and the scavenger's CPI. If any of the incremented distance is larger than the bound, MSH looks for a subset of its incoming edges to instrument yields. As described below, this will change the input (and consequently output) state of the basic block to contain new yield points and hopefully keep all the distances in the output within bound. If no such subset can be found, MSH inserts a yield at the end of the basic block and sets the output state to have only this yield point with zero distance.
- **Join operation:** This determines how the input state of a basic block is calculated based on the output states of its predecessors. For predecessors whose incoming edges are not instrumented, yields in their output states are all included in the basic block's input state, with distances being weighted averages of the corresponding distances in predecessors' output states. The weights are proportional to hotness of incoming edges, obtained via profiling. For instrumented incoming edges, the predecessor's output state will not propagate, instead the inserted yield is added to the basic block's input state with zero distance.

For the analysis, MSH ignores back edges (loops are handled later) and sorts basic blocks topologically, so that output states of predecessors are available before a basic block's turn. MSH sets the input state of the entry basic block to be a pseudo-yield named "function-start" with zero distance. MSH then iteratively computes all the states with the transfer function and join operation. Here, there are two aspects that require careful treatments – loops and function calls:

- **Loops:** For each loop, MSH computes the expected uninstrumented distance as a weighted average of the distances of all uninstrumented paths from the header basic block to the latch basic block, where weights correspond to path hotness. If the distance is zero (*i.e.,* all paths have yields), no loop instrumentation is needed. Otherwise, MSH instruments the back edge so that it yields every bound divided by distance iterations. To do this, MSH uses an induction register if available; otherwise MSH maintains a counter with unused registers or in per-thread data structures.
- **Function calls:** One aspect omitted so far is the treatment of function calls. For calls whose callee are unknown or external, MSH treats them as normal instructions. For uninstrumented external library calls that are known to be expensive, we adopt the standard practice of instrumenting right before and after the calls [13, 58]. Instead, for calls to local functions, MSH considers whether there are uninstrumented paths (*i.e.,* from entry to exits) in the callee – if yes, distances in the basic block's output state are incremented by the average uninstrumented latency of the callee; otherwise, since previous yields will be terminated in this call, MSH resets the output state to have only a pseudo-yield for the call with zero distance. The uninstrumented latency of a callee is computed with the distances for the function-start entry in the output states of its exit basic blocks. To use callee's analysis results, MSH builds a function call graph, ignores some calls to break loops, and analyzes functions in a topological order.

In summary, MSH can scale up concurrency to fully harvest stall cycles (§6.2) and manage latency impacts by enforcing inter-yield distance bounds via data-flow analysis (§6.4).

4.3 MSH Runtime

MSH intercepts function calls and assigns scavengers to active primary threads with minimal runtime overhead using tailored data structures. Next, we present the runtime design.

Function interception: MSH intercepts three types of functions: (i) functions starting a thread: *e.g.,* pthread_create, (ii) functions (likely) blocking a thread, *e.g.,* pthread_mutex_lock, and (iii) functions terminating a thread, *e.g.,* returning from the thread's start routine. Note that if there are unintercepted function calls that alter thread status, MSH's correctness is unaffected: *e.g.,* if a thread gets blocked silently (from the view of MSH), its scavengers will stay with the blocked thread, and harvestings will continue normally once the thread resumes.

Runtime operations: MSH performs different operations before/after intercepted calls to adjust scavenger assignment:

- **Scavenger initialization:** MSH initializes a new scavenger before assigning it to a primary thread, which includes loading the scavenger code, allocating its stack space and setting the return address for MSH to track when it finishes.
- **Scavenger assignment:** MSH assigns scavengers to a primary thread by configuring yield targets. The target for primary threads is a scavenger, and the target for scavengers is a primary thread by default, or another scavenger for special yields. MSH assigns more scavengers to a thread until the product of special yield ratios for scavengers is below a threshold or the scavenger number reaches a maximum.
- **Scavenger stealing:** When a primary thread needs scavengers, MSH first attempts to "steal" existing scavengers.

```
bool steal_scavengers(per_thread_ctx *t) {
    for (per_thread_ctx *it: thread_list) {
        if (CAS(it->stealable, true, false)) {
            it->stolen = migrate_scavengers(t, it);
            it->stealable = true;
            if(!need_more_scavengers(t))
                return true;
        }
    }
    return false;
}
void get_scavengers(per_thread_ctx *t) {
    if(!steal_scavengers(t)) {
        fetch_scavengers_from_pool(t);
    }
}
void enter_blockable_call(per_thread_ctx *t) {
    t->stealable = true;
}
void exit_blockable_call(per_thread_ctx *t) {
    while (!CAS(t->stealable, true, false)) {}
    if (t->stolen) {
        get_scavengers(t);
        update_yield_targets(t->yield_contexts);
        t->stolen = false;
    }
}
```

Listing 1: Pseudocode for key functions of MSH's runtime.

MSH ensures that each scavenger is assigned to at most one active thread at any time, by marking the scavengers of a thread as stealable before the thread gets blocked or terminated and only re-assigning stealable scavengers.

- **Scavenger fetching:** When there are no stealable scavengers, MSH fetches new scavengers from a pool. These scavengers should be initialized before getting assigned.

For functions starting a thread, MSH obtains scavengers via stealing or fetching and initializes them if necessary before assigning them to the thread. For functions (potentially) blocking a thread, MSH marks the thread's scavengers as stealable before the function call. After the call, MSH first attempts to reuse the scavengers previously assigned to this thread. If some scavengers were stolen, MSH obtains new scavengers with the same logic as the one for thread creation functions. Having "sticky scavengers" is good for cache locality, as scavengers mostly remain in the same core unless the primary thread gets migrated by the kernel. Lastly, for functions terminating a thread, before the thread destruction, MSH marks its scavengers as stealable.

Data structures: MSH tailors its data structures to prioritize critical events that are short but take place frequently, as overhead added to them likely leads to performance degradation. We identify two critical events: (i) primary and scavenger yielding and (ii) primary threads quickly resuming after blocking calls. (i) requires primaries and scavengers to quickly check their yield targets. (ii) occurs because a likely blocking function may not block after all (*e.g.,* synchronization calls).

MSH's data structures are shown in Figure 5. For event (i), the goal is allowing primaries and scavengers to quickly check their yield targets. A naive design is to have a per-application data structure that stores the context for each primary thread and scavenger. Such a context includes its stack and instruction pointers, and a runtime allocated stack in the case of a scavenger. Each primary thread has a per-thread data structure that stores pointers to contexts. Such a design, while intuitive, adds indirection overhead for yields: each primary thread or scavenger first reads its pointer in the per-thread data structure, in order to read its target's stack and instruction pointers (in a different cache line) from the per-application structure. Given the high frequency and small time budgets of yields, such a design is undesirable.

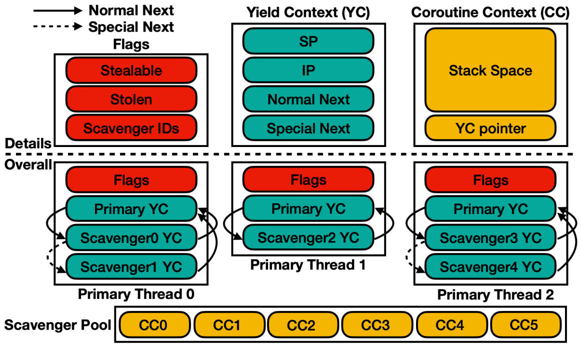

Figure 5: Data structures managed by MSH runtime. Some fields are omitted due to space constraints.

In contrast, MSH adopts a design that effectively removes the indirection overhead for yields. MSH divides a scavenger context into two parts: a "yield context", containing information needed for yielding to the scavenger, *i.e.,* its stack and instruction pointers; and a "coroutine context", containing other relevant information, *e.g.,* the scavenger stack and a pointer to the yield context. The coroutine context of each scavenger is stored in a per-application data structure, as it is in the naive design. As for the yield context, it is augmented with indexes of its targets (so effectively pointers), and the augmented yield contexts of the primary thread and its scavengers are stored contiguously on the primary's per-thread data structure. With this arrangement, each primary thread or scavenger yields by reading two yield contexts, one of itself and the other of its target. MSH minimizes the size of yield contexts, so that these two yield contexts often reside in the same cache line, resulting in little overhead. Moreover, since scavenger stacks reside in the shared data structure, MSH can easily migrate scavengers by setting up the targets in the per-thread data structures, without having to copy their stacks.

For event (ii), MSH strives to minimize the overhead for when a primary thread quickly resumes with no blocking and no scavengers stolen. A naive design is to maintain the status of each scavenger, whether it is stealable or has been stolen, in a per-application data structure. This makes scavenger stealing simple by just looking for stealable scavengers and changing their status to stolen. However, such a design complicates the operations that a primary thread needs to perform before and after a (likely) blocking call, which includes reading and setting the status of all the assigned scavengers. This process is unnecessarily expensive when there is no blocking.

In contrast, MSH optimizes for this case by leveraging two per-thread flags: a "stealable" flag indicating whether this thread is blocked, and a "stolen" flag indicating whether some scavengers were stolen. As shown in Listing 1, before a primary thread enters a blocking function, it simply sets the stealable flag to be true. If it does not get blocked, it (i) waits for the stealable flag to become true (explained later), which will be immediate in this case, and (ii) resumes its execution if the stolen flag is false. As a result, a primary thread that quickly resumes at a blocking function only performs a read, a write, and a CAS operation on a single cache line, which is significantly less work than the baseline design.

To steal scavengers, a new thread attempts to compare-and-swap the stealable flags of other threads from true to false. If succeeded, this means that (i) that thread is blocked and (ii) no other thread is stealing from this thread. The new thread then steals the blocked thread's scavengers by looking at their yield contexts – if a scavenger's yield context is valid, it copies the yield context to its own per-thread structure before invalidating the context. The new thread ends its stealing by setting both the stolen and stealable flags of the blocked thread as true. Once the blocked thread resumes, it finds out that some of its scavengers get stolen via the stolen flag, which triggers the slow path of replacing its stolen scavengers with new ones. In essence, by using per-thread flags, MSH expedites the cases where the per-thread flags are untouched due to short or no blocking. The cost of more complex scavenger stealing is acceptable given that stealings happen infrequently.

To sum up, MSH is capable of dynamically assigning scavengers to primary threads for unmodified multi-threaded applications (§6.2) and does so with minimal overhead (§6.4).

5 Implementation

We prototype MSH's offline parts on top of Bolt [67], a binary optimizer, as well as perf [24], a sample-based profiler; and MSH's runtime as a user-level library. Next, we describe how the four main components are implemented:

Offline profiling: MSH adopts the same set of profiling practices as prior sample-based profiling works [17, 30, 31, 41, 66–68]: sampled inputs are used for profiling, and in the case of input changes leading to notable performance degradations, different profiling runs happen in the background. In practice, MSH's performance is observed to be consistent across different inputs. This is because programs often have a fixed set of delinquent load instructions that trigger cache misses, an insight that has been observed and exploited in cache prefetching works [11, 41, 54]. MSH parallelizes profile processing across multiple cores to speed up the process.

Primary instrumentation: There are three phases: a profiling phase, where we profile load instructions causing cache misses via PEBS and basic block execution counts via LBR, and parse profiled data; an analysis phase, where program analysis results (*e.g.,* what registers to save) are annotated in relevant program points (*e.g.,* load instructions, loops); and an instrumentation phase, where binaries are finally altered. We reuse register liveness and reaching definition analysis from Bolt, and implement loop optimizations and pseudo-inlining.

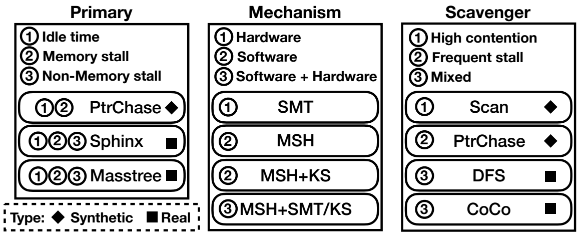

Figure 6: Primaries, scavengers and mechanisms evaluated.

Scavenger instrumentation: This takes place in the same three phases. In the profiling phase, we obtain the basic block latency via LBR. Given that LBR reports the latency between different branching instructions, which does not always correspond to a basic block's latency, we implement a script to map LBR samples to basic blocks. In the analysis phase, we construct call graphs and implement the data-flow analysis.

MSH Runtime: We use the LD_PRELOAD dynamic linker feature [73] to override pthread functions, and implement in a shared library MSH's runtime operations before/after calling the original pthread functions. For per-thread data structures, the runtime sets their base addresses in the GS segment register upon thread creations, so that they can be accessed by primaries and scavengers via GS-based addressing [53].

6 Evaluation

In this section, we present our evaluation setup (§6.1) and investigate three key questions regarding MSH: (i) how well does MSH perform compared to SMT? (§6.2), (ii) how does MSH change the landscape of cycle harvesting? (§6.3) and (iii) how do different components of MSH contribute to its performance? (§6.4). We answer (i) and (ii) by evaluating different mechanisms with both synthetic workloads and real applications, (iii) by carefully testing the specific component.

6.1 Evaluation Setup

As shown in Figure 6, we carefully select primaries, scavengers and mechanisms to allow a comprehensive understanding of MSH's behaviors and the cycle harvesting landscape.

Harvestable cycles: To set up evaluations, it is important to realize that there are three main classes of harvestable cycles. The first class is idle time, which occurs at low loads when an application does not have enough work for its cores. Software mechanisms like kernel scheduling (KS) focus on harvesting these cycles. As the load increases, idle time reduces and CPU stalls become the main harvestable cycles. CPU stalls

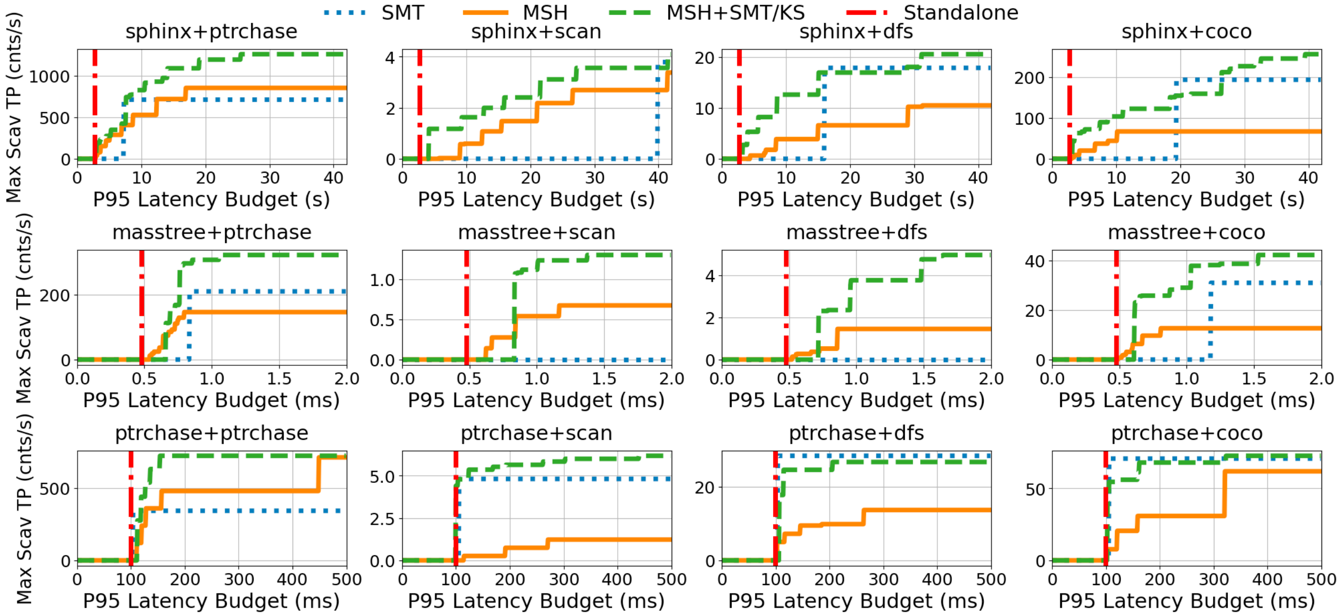

Figure 7: Maximum scavenger throughput vs. P95 Latency budget at 80% load. The red line denotes the standalone latency.

can be divided into either memory stalls, which often account for a significant portion of cycles (§2) and can be efficiently harvested by MSH, or non-memory stalls (*e.g.,* core-bound or frontend stalls), which remain to be private territory of SMT.

Primaries: For primaries, we include a synthetic pointer-chasing workload (PtrChase), which has most of its active cycles bounded by memory. It thus allows us to study how well MSH harvests memory stalls in comparison to SMT. We also have two real latency-critical applications: Masstree [59], an in-memory key-value store, and Sphinx [87], a speech recognition system. With these workloads, we evaluate harvesting mechanisms on realistic mixes of memory and non-memory stalls. Masstree and Sphinx are configured to use the same dataset as Tailbench [46] with 6 and 24 threads respectively. PtrChase has 8 threads, each iterating over its own 16MB array via random pointer chasing upon new requests.

Mechanisms: SMT harvests all three classes of harvestable cycles, but suffers from high latency overhead, lack of configurability, and incomplete harvesting (§2). MSH harvests memory-bound stalls and overcomes the drawbacks of SMT. Building on MSH's superior performance, we complement it with KS and SMT to also harvest idle time and non-memory stalls: KS adds little overhead to MSH but allows idle time harvesting; MSH+SMT/KS enables SMT with MSH if the primary latency meets the SLO, disables SMT and runs KS otherwise. This allows exploiting SMT's ability to harvest non-memory stalls, while managing its latency impacts.

SMT[3] runs scavengers on the sibling cores of the primary. MSH interleaves scavenger executions within the primary. MSH+KS schedules scavengers to run on the primary's logical cores with lower real-time priority, so that these scavengers run when the primary is idle. MSH+SMT/KS runs other scavengers on sibling cores when SMT is enabled.

Scavengers: SMT performs poorly for scavengers that contend for core resources or frequently stall, causing large latency overhead and incomplete harvesting respectively. We thus include synthetic workloads with such behaviors: Scan – creating contention by scanning a 4MB array and computing the sum; PtrChase – frequently stalling due to iterating through a 16MB array in random order via pointer chasing, to evaluate whether MSH can handle such challenging cases. We also include two graph analysis workloads: DFS and Connected Component (CoCo), from the CRONO benchmark [1] as representatives of scavengers with mixed behaviors.

Testbed and Metrics: We conduct experiments using a dual-socket server with 56-core Intel Xeon Platinum 8176 CPUs operating at 2.1 GHz[4]. We measure at different loads the 95 percentile primary latency as well the scavenger throughput in terms of the number of scavengers finished per second.

6.2 MSH performance

Summary: We extensively evaluate MSH and show that it provides three main performance benefits over SMT:

- MSH can harvest up to 72% scavenger throughput of SMT, for latency SLOs under which SMT has to be disabled.
- MSH can further trade off primary latency for higher scavenger throughput if looser latency SLOs are given.

[3] We focus on Intel's SMT implementation (*i.e.,* Hyper-threading) in our evaluation. As we will discuss in §7, drawbacks of SMT stem from the lack of (software-controllable) prioritizations and the limited degrees of concurrency, which are common among most commercial SMT implementations. We thus expect our results to be representative of common SMT behaviors.

[4] Applications use memory from the local node in our evaluation. Under a NUMA setup, MSH can be configured to efficiently harvest the longer stalls caused by remote accesses, *e.g.,* by using larger inter-yield distances (§6.2).

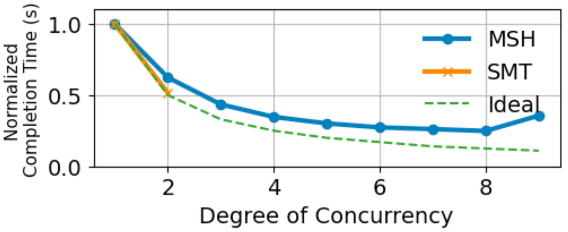

Figure 8: Time to completion for a fixed number of pointer-chasing jobs with different degrees of concurrency.

- Unlike SMT, MSH can fully harvest memory stalls when scavengers stall and achieve up to 2x higher throughput.

MSH provides these benefits with its capabilities like fine-grained configurability and concurrency scaling, which we will elaborate further on §6.4. Here we focus on presenting MSH's performance characteristics in comparison to SMT.

The whole picture: As shown in Figure 7, for each of the primary and scavenger combinations, we report the maximum achievable scavenger throughputs under different primary latency SLOs, which is defined as the latency budget at 80% loads. Note that, the comparisons among harvesting mechanisms remain unchanged for different latency metrics (e.g. average, 99 percentile) at other loads (other than 80%). As discussed below, MSH can be flexibly configured to achieve different scavenger throughputs depending on the primary latency budgets. These results thus allow us to have a holistic understanding of MSH's performance in comparison to SMT. Here one could make several key observations:

First, MSH harvests substantial stall cycles for latency SLOs under which SMT effectively achieves zero scavenger throughput (*i.e.,* disabled). This is especially valuable when contentious scavengers cause significant slowdown for SMT: *e.g.,* for Sphinx with Scan, MSH achieves up to 72% of SMT scavenger throughput with lower than SMT primary latency. Such behaviors exist for Sphinx and Masstree with all the evaluated scavengers, indicating the general usefulness of MSH as a harvesting mechanism under stringent latency SLOs.

Second, unlike SMT, which achieves the same scavenger throughput regardless of the latency SLO given, MSH can trade off primary latency for higher scavenger throughput. This capability, together with the aforementioned ability to harvest stall cycles under stringent latency SLOs, makes MSH a highly elastic harvesting mechanism that can be combined with other mechanisms, as we will describe in §6.3.

Lastly, MSH can fully harvest memory stalls even when scavengers frequently stall. Specifically, for the PtrChase scavenger, with both Sphinx and PtrChase primaries, MSH manages to achieve higher scavenger throughput than SMT without incurring much latency overhead. Given that SMT harvests both idle time and non-memory stalls, which MSH does not handle, this indicates that MSH can better harvest memory stalls with higher degrees of concurrency.

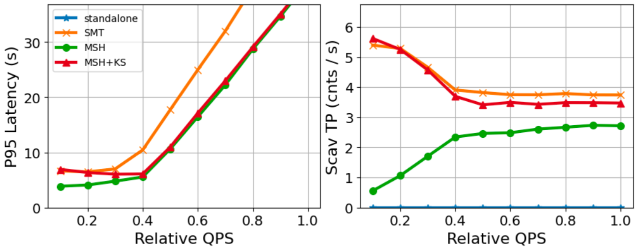

Figure 9: SMT, MSH and MSH+KS for Sphinx+Scan.

Full harvesting: To verify this, we conduct an experiment with a fixed number of jobs, where each job traverses a 128 MB array via random pointer chasing and thus frequently incurs memory stalls. We then measure the total completion time of these jobs with a single physical core. For SMT, we either run one job at a time or co-locate two concurrent jobs. For MSH, we interleave these jobs with various degrees of concurrency. The normalized completion times are shown in Figure 8. In the ideal case, the completion time is one over the concurrency degree. Although SMT-2 is close to ideal thanks to hardware efficiency, it does not have enough concurrency to further harvest memory stalls. In contrast, while having larger interleaving overhead, MSH reduces SMT's completion time by roughly a half (*i.e.,* 2x throughput) with a concurrency degree of eight. This shows that compared with SMT, MSH can harvest more memory stalls via concurrency scaling. When the degree of concurrency goes beyond eight, the completion time of MSH increases due to the aggregate yielding overhead outweighing the benefits of additional multiplexings.

6.3 Cycle Harvesting Landscape

With various desirable properties, MSH can be efficiently combined with other harvesting mechanisms to re-shape the CPU cycle harvesting landscape. To see this, we evaluate two compound mechanisms that leverage MSH for memory stalls: MSH+KS and MSH+SMT/KS, and compare that with SMT.

- **MSH+KS:** KS complements MSH with idle time harvesting. MSH+KS thus achieves much higher scavenger throughput than MSH at low loads, while adding small latency overhead (Figure 9). As the load increases, idle time reduces, and MSH+KS behaviors converge to MSH's. Note that MSH in this figure is only one configuration.

- **MSH+SMT/KS:** MSH+SMT/KS strives to utilize SMT's ability to harvest non-memory stalls, and falls back to KS if SMT incurs excessive latency overhead. As shown in Figure 7, MSH+SMT/KS delivers superior performance, with higher scavenger throughput than SMT under *almost all* latency SLOs. The reason is that: (i) for scavengers that frequently stall, SMT can be safely enabled with minimal latency overhead, the combination of SMT and MSH can harvest idle time, non-memory and memory stalls to the full extent; (ii) for contentious scavengers, the combination of KS and MSH then efficiently harvests both idle time and memory stalls for latency SLOs where SMT is disabled.

6.4 Performance Breakdown

Summary: We test MSH's configurability and performance of its components, the results of which are outlined below:

- **Configurability:** MSH offers fine-grained control over the latency-throughput trade-off via (i) yield site selections in primary instrumentation, (ii) inter-yield distances in scavenger instrumentation and (iii) concurrency degrees in runtime. Since the effects of concurrency scaling have been studied in Figure 8, we focus on the other two knobs. We measure the primary latency and scavenger throughput for Sphinx and Scan with different configurations, with results shown in Figure 10. For the primary, MSH estimates the overhead of each load instruction with its cache miss rate and bounds the aggregate overhead when selecting yield sites (§4.1). We increase this overhead bound from 5% to 15% and observe a clear latency-throughput trade-off as more yields are instrumented. For the scavenger, increasing the target inter-yield distance also leads to higher scavenger throughput at the cost of larger primary overhead. Besides the latency-throughput trade-off, such configurability allows MSH to mitigate some inherent issues of instruction interleaving, such as increased memory contention and effectively partitioned caches, by controlling the extent and locations of interleaving.

- **Primary instrumentation:** MSH reduces the yield cost by minimizing the amount of register savings and restorations per yield. To measure how this affects its harvesting performance, we conduct an experiment with Sphinx and Scan, where we measure Sphinx's latency for different inter-yield distances of Scan, with and without our optimizations. As shown in Figure 11, reduced yield costs do lead to up to 23% lower primary latency. Note that the improvement first increases with scavenger inter-yield distances before dropping, because (i) the larger yield cost (without optimizations) does not affect the primary latency until the duration of the interleaved scavenger execution (*i.e.,* inter-yield distance plus yield cost) exceeds the cache hit latency, and (ii) as the inter-yield distance further increases, yield cost plays a smaller part in the overall overhead.

- **Scavenger instrumentation:** MSH accurately enforces target inter-yield distances via its data-flow analysis (Figure 12-(a)). As for overhead, a unique source of overhead for scavengers is the loop instrumentation overhead – using an in-memory iteration counter is expensive for tight loops. MSH thus attempts to reuse induction registers or maintain a counter with unused registers before spilling to memory. This optimization reduces the overhead by 130% and 15% for CoCo and DFS respectively (Figure 12-(b)).

- **MSH runtime:** MSH harvests stall cycles via dynamic scavenger assignment. It does so with low overhead: 10 ns for thread resuming with unstolen scavengers, which does not cause noticeable impacts on our evaluated applications.

- **Profiling overhead:** Even with sample-based profiling using hardware performance counters, sampling events at high frequencies can still slow down the primary application. In MSH, we confirm that accurately capturing delinquent load instructions incurs minimal profiling overhead. Specifically, for Masstree, using the default sampling frequency and following the yield site selection logic (§4.1), MSH selects the *same* set of load instructions as if it were to sample 100x more frequently. As a result, while using a 100x higher sampling rate would slow down the application by 25%, the slowdown from MSH's profiling is negligible.

- **Analysis complexity:** MSH instruments only selective loads and performs mostly intra-procedural analysis, which finishes less than a minute for all the evaluated workloads.

7 Related Work

Reducing memory stalls: Orthogonal to harvesting efforts like MSH, there has been extensive research on reducing memory stalls. Beyond out-of-order executions, there are two lines of techniques based on *load slices*, *i.e.,* instructions that generate the address of a load instruction. One technique is prefetching [2, 4, 8, 12, 22, 39, 42, 56], where the cache line is prefetched after the end of its load slice; and the other technique is criticality-aware instruction scheduling [5, 6, 16, 77], where the processor prioritizes the executions of load slices, which requires hardware changes. For both techniques, there is a trade-off between capability and deployability. Simple techniques like stream prefetchers [39, 75] and prefetch insertion via static analysis [4, 20] have limited capability (*e.g.,* unable to handle complex access patterns); whereas advanced proposals like runahead prefetchers [26, 33] often have requirements that hinder wide adoptions (*e.g.,* excessive hardware complexity, source code modification). Moreover, a key requirement for both techniques to reduce stalls is that load slices end *sufficiently ahead* of the load instruction. As a result, for cases where load slices are close to the load instruction, neither technique can help. In contrast, MSH is easily deployable, requiring no hardware changes nor rewriting efforts, and harvests stall cycles for any access pattern.

SMT: For the three drawbacks of SMT (*i.e.,* latency overhead, lack of configurability and incomplete harvesting), the first two stem from the lack of prioritizations, whereas the last one is due to limited degrees of concurrency. Most modern processors from Intel and AMD have these two issues, which leads to unsatisfactory harvesting performance (§6.2). An exception is IBM Power processors [50, 63], as they (i) support assigning hardware threads with priorities that determine the ratio of physical core decode slots allotted to them, and (ii) have wider SMT with up to eight threads per core, at the cost of more complex and resource-consuming SMT design.

Given this context, the value of MSH is two fold. First,

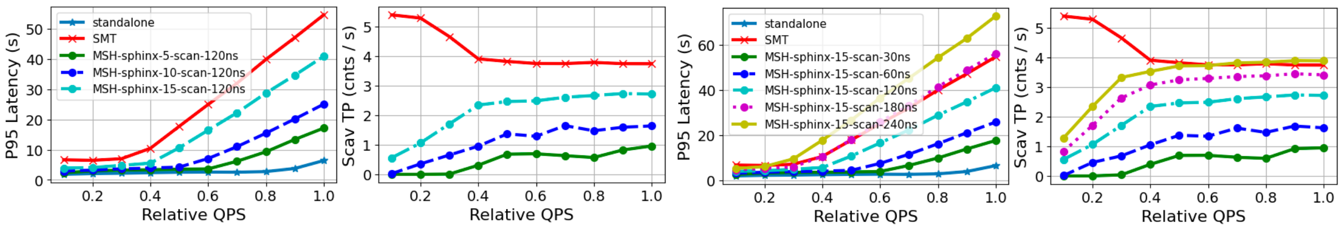

Figure 10: The effects of the aggregate yield overhead bound (left) and the scavenger inter-yield distance (right) on the primary latency and the scavenger throughput in Sphinx+Scan.

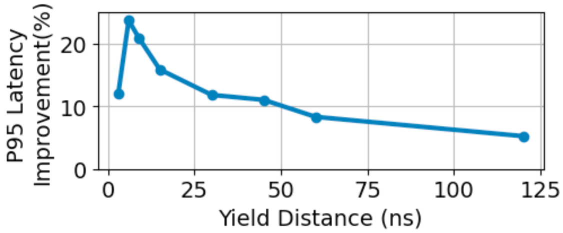

Figure 11: Latency improvement made by the yield cost optimizations in the primary instrumentation on Sphinx+Scan.

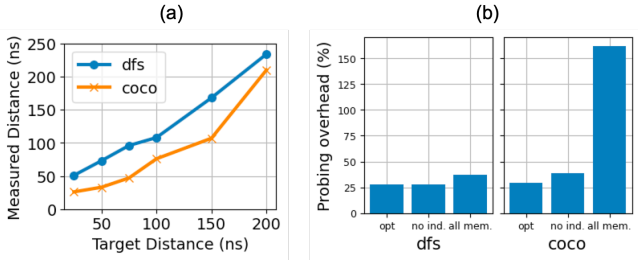

Figure 12: (a) Inter-yield distance of scavenger instrumentation; (b) overhead of loop instrumentation: *opt* uses induction registers and unused registers, *no ind.* uses only unused registers, and *all-mem* uses in-memory iteration counters.

for most modern processors, MSH allows harvesting memory stall cycles in software without the drawbacks of their SMT mechanisms. Second, for processors like IBM Power and Cray Threadstorm [48, 49] that support massive multithreading and fine-grained parallelism, MSH raises the question of whether certain functionality should be implemented in hardware or software, *e.g.,* concurrency scaling in MSH happens *on-demand*, without requiring dedicated thus likely wasted resources, such as die area and power.

Software efforts: Some work focuses on utilizing SMT with latency-critical services, by disabling it when high latency or resource interference is detected [29, 60, 70, 89]. However, they do not address SMT's high latency overhead and lack of configurability, and are thus unable to harvest stall cycles when SMT violates latency SLOs. As for software harvesting efforts, prior work shows that if done correctly, prefetching and yielding before load instructions can lead to increased throughput for memory-intensive workloads [21, 34, 44, 72]. However, they either require manual identification of yield sites and source code modification, or instrument every load instruction at the cost of high latency. Moreover, none of them can enforce low latency overhead and full harvesting from diverse scavengers, which MSH provides with scavenger instrumentation and runtime operations. In short, MSH is the first software system that enables transparent and general memory stall harvesting with competitive performance.

8 Discussion

Isolation mechanism: In MSH, the primary and its scavengers reside in the same process to benefit from fast yielding, which necessitates mechanisms other than hardware isolation to ensure memory safety under this setup. This turns out to be an extensively studied problem, with solutions falling into two main categories: (i) software-based fault isolation (SFI) [76, 81, 86], which establishes logical protection domains by inserting dynamic checks at the binary level; and (ii) language-based isolation, where a program is accepted in the form of a safe language (*e.g.,* WebAssembly [32, 36, 85], Rust [15, 51, 65, 92]) and validated by the type checker and compiler. Operating at the binary level, MSH easily coexists with either isolation mechanism: SFI can be a better fit as it is applicable to code written in different languages, including legacy code, which is a merit that MSH shares. Moreover, a recent work [91] shows lower runtime overhead with a lightweight SFI implementation than existing language-based solutions. Integrating MSH with some isolation mechanism and evaluating the resulting system is left for future work.

Further evaluation: In §6, we demonstrated and dissected the desirability of MSH as a harvesting mechanism. Next, we discuss directions for more thorough evaluation of MSH.

- **Additional workloads:** We focus on evaluating a set of representative workloads with distinct characteristics, *e.g.,* scavengers that either create large contentions, or frequently stall, or exhibit mixed behaviors. This appraoch allows us to interpret the performance differences caused by (i) the distinct characteristics of the primary-scavenger pairs and (ii) the differences in harvesting mechanisms. One could extend with more real workloads
- **Cache prefetching:** As discussed in §7, MSH can harvest memory stalls that are not hidden by cache prefetching, and prefetching techniques that are easy to deploy usually have limited capability. It will thus be interesting to evaluate the

effectiveness of MSH with software prefetching techniques used in production [40]. That being said, most delinquent loads in our evaluated workloads exhibit pointer-chasing behaviors, which are inherently challenging to prefetch.

- **Datacenter efficiency:** The effect of MSH on the overall CPU efficiency of a datacenter is hard to estimate, as it depends on various factors such as workload characteristics, colocation arrangements, and SLO policies. This necessitates large-scale evaluation and profiling [45].

Efficacy of profiling: In terms of profiling overhead, we have shown that MSH can capture delinquent load instructions with a low sampling rate (§6.4). The other natural question is whether profiling is consistently effective for the purpose of harvesting stall cycles in MSH. Similar to prior works that leverage profiling for cache prefetching [40, 41, 95], we show positive results with our evaluated workloads (§6.2). One conjecture is that, while whether a particular load invocation will trigger a cache miss is highly random, the two pieces of information MSH needs from profiling – namely, (i) the set of load instructions that account for a significant portion of memory stalls and (ii) their likelihoods of cache misses, are often stable across runs and inputs. Evaluating a wider range of applications can help further validate this conjecture.

Hardware support for MSH: We identify two aspects that MSH can benefit from hardware support. First, an overhead that MSH inevitably incurs is when an instrumented load causes cache hits. MSH mitigates this with the selection logic in primary instrumentation, which enforces a lower bound on cache miss rate and an upper bound on aggregate overhead (§4.1). To do better, what is needed is *dynamic visibility* of cache misses, *e.g.,* indicating if a cache line is in L2 cache. This allows yields to be conditional on whether cache misses actually happen. We expect conditional checking overhead to be on the scale of L2 cache latency, much faster than scavenger executions configured to harvest memory stalls.

Another aspect that hardware can offer support is reducing yield overhead. MSH minimizes the amount of register savings and restorations for each yield, which leads to lower latency overhead (§6.4). One useful hardware feature here is to save/restore multiple registers to/from memory with a single instruction for lower instruction fetch costs, which is already provided in ARM with LDM/STM instructions [9]. Prior works also propose hardware support for fast saving and restoration of process state during context switches [38, 80].

9 Conclusion

We presented MSH, a software system that transparently and efficiently harvests memory stall cycles. With a co-design of profiling, program analysis, binary instrumentation and runtime scheduling, MSH fully harvests stall cycles, while incurring minimal latency overhead and offering fine-grained control of the latency-throughput tradeoff. MSH is thus a preferable solution for harvesting memory stalls and brings valuable changes to the CPU cycle harvesting landscape.

Abstract

With rapid advances in network hardware, far memory has gained a great deal of traction due to its ability to break the memory capacity wall. Existing far memory systems fall into one of two data paths: one that uses the kernel's paging system to transparently access far memory at the page granularity, and a second that bypasses the kernel, fetching data at the object granularity. While it is generally believed that object fetching outperforms paging due to its fine-grained access, it requires significantly more compute resources to run object-level LRU and eviction.

We built Atlas, a hybrid data plane enabled by a runtime-kernel co-design that simultaneously enables accesses via these two data paths to provide high efficiency for real-world applications. Atlas uses *always-on* profiling to continuously measure page locality. For workloads already with good locality, paging is used to fetch data, whereas for those without, object fetching is employed. Object fetching moves objects that are accessed close in time to contiguous local space, dynamically improving locality and making the execution increasingly amenable to paging, which is much more resource-efficient. Our evaluation shows that Atlas improves the throughput (*e.g.*, by 1.5× and 3.2×) and reduces the tail latency (*e.g.*, by one and two orders of magnitude) when using remote memory, compared with AIFM and Fastswap, the state-of-the-art techniques respectively in the two categories.

1 Introduction

Today's datacenters commonly suffer from low memory utilization [21]; yet, datacenter applications are increasingly memory-constrained [19, 36, 42, 62] due to their need to hold large datasets in memory for quick data analytics [11, 76] or machine learning [8, 53]. Thanks to the high bandwidth and low latency provided by modern network fabrics such as InfiniBand, far memory techniques [9, 25, 57, 67–69] enable an abstraction of unlimited memory for applications by allowing them to use available memory on remote servers, thereby simultaneously improving application performance and datacenters' overall memory utilization.

Although techniques such as RDMA enable fast network accesses, each remote access is still at least an order of magnitude slower than a local access. As such, it is paramount to optimize the remote access data plane so that applications can benefit from increased memory capacity without suffering a significant performance hit. A major line of work for accessing remote memory is using the kernel's paging system, exemplified by techniques such as InfiniSwap [25], Fastswap [9], Canvas [68] and Hermit [55]. These techniques allow applications to transparently access far memory at the *page* granularity, using the kernel's swap system to swap pages in and out between local and remote memory.

While paging works well for applications that perform bulk data movement and exhibit clear (sequential or strided) access patterns, its coarse granularity incurs substantial *I/O amplification* (*i.e.*, pages loaded only contain a small amount of useful data) for applications that exhibit irregular (or random) access patterns, such as Memcached [5] and graph applications [34]. To reduce I/O amplification, a recent line of work exemplified by AIFM [57] and Kona [13] advocates to access data at a much finer (object) granularity using a user-space runtime system. Swapping objects, rather than pages, can significantly reduce the amount of useless data swapped, leading to higher efficiency. Furthermore, since objects are the data abstraction for developers to write programs, they carry semantics (*i.e.*, user intention) that can be exposed to and used by the runtime to perform additional optimizations, such as data-structure-based prefetching.

Fetching objects at runtime, however, comes at a cost. A drawback that was often overlooked by existing works is that object fetching requires *non-trivial compute resources* to profile object usage, identify patterns, and perform object-level LRU and eviction. For instance, running an object-level LRU algorithm is **one order of magnitude** more expensive than page-based LRU due to a huge number of objects to be processed and the lack of hardware support for tracking object accesses. This overhead is significantly more pronounced in real-world scenarios where CPUs are all busy with executing application threads—given a tight time budget, memory

[*] Contributed equally.

management threads cannot scan enough objects to make accurate LRU and eventually have to evict arbitrary objects.

As a result, the right access mechanism is essentially the result of a tradeoff between program locality (*i.e.*, how bad I/O amplification can be) and the amount of compute resources available (*i.e.*, how many cores can be dedicated to object-level memory management tasks). For programs with poor locality, the overhead of object-level memory management can be offset from the large gains of reducing I/O amplification. On the other hand, for programs with good locality and insignificant I/O amplification, the overhead of object fetching stands out, especially in an environment where applications have taken all compute resources (see §3).

There is a recent line of compiler-based techniques (as exemplified by Mira [26]) that profile a program *offline* to understand such a tradeoff, so that compiler can statically choose the mechanism for each data access when compiling the program. However, offline profiling hinges upon program input. For interactive applications such as Memcached, their input data comes from users and keeps changing, rendering a dry-run-based technique ineffective.

Major Insight. The main question we ask in this paper is: can we enable *always-on* profiling for an application to identify its access patterns and dynamically switch between paging and object fetching to adapt to the observed patterns? This approach, if implemented efficiently, has two advantages over the state-of-the-art techniques. First, its continuous profiling identifies patterns *on-the-fly* for different computation stages or parallel threads accessing different data structures, even if the program input keeps changing. As a result, it can quickly change the access path to use a more efficient fetching mechanism. Second, for programs with irregular patterns, object fetching moves objects that are accessed close in time into contiguous memory space, dynamically improving locality as the program executes. This makes it possible for the execution to *be increasingly amenable to paging*, which has higher resource efficiency (see §3).

Although promising, realizing this insight requires overcoming three major challenges, as elaborated below:

The *first challenge* is how to continuously and accurately profile an application with low overhead. Kernel-based page-level profiling, though efficient, does not provide sufficient information with respect to fine-grained data locality. For example, if one single hot object on a page keeps getting accessed but none of other objects do, the kernel-based profiling would identify the page as a hot page although the page clearly possesses poor locality and its accesses should go through object fetching, not paging.

To enable fine-grained profiling, Atlas divides a page into a set of *cards*, each of which is a unit for our locality measurement. We leverage the runtime (and in particular, a *read barrier*) to compute a *card access table (CAT)* (§4.3) for each page, which is a bitmap where each bit corresponds to a card (*i.e.*, consecutive 16 bytes) on the page and a set bit represents that the card has been accessed since the page was allocated or last swapped in. A page with a high *card access rate* (CAR, measured as the percentage of the set bits in its CAT) is deemed to possess good locality and should be accessed with paging, while a page with a low CAR has poor locality and should be accessed with object fetching.

The *second challenge* is how to dynamically switch access mechanisms. Atlas uses a read barrier at each smart pointer dereference. The barrier quickly checks a per-page *path selector flag* (PSF) for the remote page to be accessed. Each PSF is a 1-bit flag, set to either `runtime` or `paging`. `runtime` indicates that the runtime path should be used to fetch individual objects (like AIFM), while `paging` means that the paging path is taken to fetch an entire page. The PSF of a page is updated only when the page is evicted based upon the page's CAR—it is set to `runtime` if the page's CAR is low, indicating the page exhibits poor locality, and `paging` otherwise, indicating good locality.

Although Atlas supports both object fetching and paging at *ingress*, it evicts data only at the page granularity at *egress*, to reduce the high overhead associated with object-level profiling and LRU. While evicting pages may introduce I/O amplification for workloads with poor locality, this impact is insignificant under Atlas, because accesses in these workloads would likely go through the object fetching path, which improves locality by moving objects accessed close in time into contiguous local space. The enhanced locality effectively mitigates the negative impact of page-level eviction.

To reduce fragmentation resulting from dead objects, Atlas runs *concurrent evacuation* tasks that periodically move live objects into contiguous memory space. During each evacuation, Atlas groups recently-accessed objects into contiguous pages to further improve data locality.

The *third challenge* is how to synchronize the two access paths. Since the kernel and the runtime are not coordinated (*e.g.*, the kernel does not inform the runtime of the start or the completion of a page-fault handling), special care must be taken to prevent the two access paths from creating inconsistent data copies. In particular, correctness issues may arise from a set of ingress and egress events (*i.e.*, object-in, page-in, and page-out) that occur simultaneously. Atlas solves the problem with a synchronization protocol (see §4.2), implemented with a combination of runtime and kernel support.

Results. We have evaluated Atlas with a set of eight applications that cover a full range of memory access patterns: sequential, random, and mixed. Our results show that Atlas enables these applications running on remote memory to achieve an overall of 1.5× and 3.2× throughput improvement, compared with AIFM [57] and Fastswap [9], respectively. Atlas reduces the tail latency by one and two orders of magnitude when compared with AIFM and Fastswap. Atlas is available at https://github.com/wangchenxi7/Atlas.

2 Background on Object Fetching

Object fetching is motivated by two observations on the inefficiencies of paging. First, fetching data at the page granularity often leads to I/O amplification [13]. Second, managing data in the kernel space is agnostic to program semantics, resulting in missed optimization opportunities [57, 65, 67]. As such, work has been proposed to manage data with a language runtime at a finer-grained object (or cache-line) granularity [13, 43, 57, 66, 67, 69]. Unlike paging, the runtime can only manage objects in user space, which results in two consequences: (1) the runtime must change the virtual address of an object when moving it and hence must change all its pointers; and (2) the runtime must maintain all metadata itself (*e.g.*, LRU), which used to be maintained by the kernel. Here we focus our discussion on AIFM [57]. AIFM proposes two abstractions for developers to manage remote memory: *remoteable pointer* and *dereference scope*.

Remoteable pointer. AIFM extends the *smart pointer* abstraction of C++ to implement remoteable pointers (`RemPtr`) for remote data management. There are two types of `RemPtr`: 64-bit unique remoteable pointers (similar to `std::unique_ptr`) and 128-bit shared remoteable pointers (similar to `std::shared_ptr`). Developers need to explicitly declare data as remote type and manage them via the `RemPtr`. For example, each unique `RemPtr` has 64 bits—the lower 47 bits are used as the virtual address of the data, and the upper 17 bits are used to record metadata, such as dirty (D), present (P), hot (H), evacuated (E), *etc.* When accessing data via a `RemPtr`, AIFM checks the metadata of the `RemPtr` to detect its status, *e.g.*, checking the P bit to see if the object is in local memory. Next, AIFM masks the `RemPtr` to obtain the actual virtual address.

Dereference scope. Each smart pointer dereference and subsequent raw pointer accesses must be enclosed by a dereference scope, which works as an *evacuation fence* to guarantee correctness. AIFM performs periodical *concurrent object evacuation* that swaps out cold objects to remote memory and compacts local memory to improve data locality. It is challenging to move objects when they are being used by other threads since moving objects requires updating all their pointers. Smart pointers solve this problem because these pointers can be recorded in object headers and updated after moves are conducted. However, an application may read raw pointers from smart pointers and store them in registers or on the stack, which cannot be updated by the runtime.

To guarantee correctness for pointer updating, AIFM requires developers to explicitly declare dereference scopes for each object, which define where raw pointers of the object may exist. Evacuation of the object never happens concurrently with the execution of any of its dereference scopes that started before the evacuation decision. A dereference scope serves as a synchronization mechanism between an event that moves the object and another that uses it.

3 Motivation

We now motivate the necessity of a hybrid data plane. We first demonstrate the diverse memory access patterns of real-world cloud applications and explain the underlying reasons. Next, we compare fetching performance between using a runtime and the kernel's paging system. For the runtime approach, we re-implemented applications with AIFM [57]. For paging, we used Fastswap [9]. Finally, we discuss the opportunities provided by *dynamic* path switching.

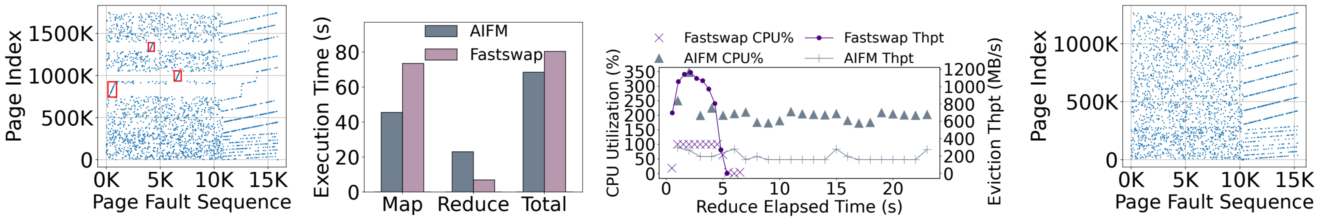
Diverse memory accesses. Real-world applications exhibit complicated memory access patterns, which are a combination of multiple primitive patterns such as sequential, strided, skewed, and random. Access patterns depend on at least two factors: (1) the computation model and (2) the data model. Next we elaborate on these factors:

On one hand, many applications are phase-changing and each phase follows a distinct computation model. On the other hand, the same phase may exhibit varied access patterns when processing different data structures.

An example is data-processing applications [76, 78] that implement MapReduce. We experiment with Metis [44], a MapReduce framework optimized for multicore architectures, with a Page View Count (PVC) program [29, 56] and report its page fault sequence in Figure 1(a). Since PVC is executed with 8 cores, we launch 8 threads for each (Map or Reduce) phase to exploit data parallelism. During the Map phase, each thread loads chunks of input data from the disk and initializes loaded website URLs and users as memory data. Next, PVC shuffles URLs into different buckets of a hash table based on their hash values. The Reduce phase scans each entry to count each URL's users.

The left/right part of Figure 1(a) illustrates the page fault sequence of the Map/Reduce phase. The Map phase (left) inserts URLs into the hash table, and accesses there are mostly random. However, given that the dataset used to run this program is *skewed*, there are several ranges of sequential accesses in the Map phase, as highlighted in the boxes (*i.e.*, certain hash buckets are much larger than others and hence traversing these buckets exhibits sequential patterns). During the Reduce phase (right), each task that aggregates users of URLs scans entries in a bucket sequentially, resulting in a clear sequential access pattern, as shown in the second (right) half of Figure 1(a).

Granularity-performance tradeoff. Object fetching minimizes I/O amplification by fetching fine-grained objects [14, 57]. However, compared to paging, object fetching does not always show clear benefits—for workloads with good locality, data on the same pages are accessed close in time and the kernel can already effectively and accurately prefetch data. When benefits are insignificant, the overhead for object-level memory management stands out. To compare fetching efficiency between the runtime and the kernel, we run the Metis



(a) Page Fault Trace 1 (b) Throughput (c) Memory Eviction (d) Page Fault Trace 2

Figure 1: Statistics of Metis PageViewCount (MPVC): (a) access patterns, (b) performance comparisons between AIFM and Fastswap, (c) comparisons of eviction throughput (dotted lines) and CPU usage (crosses and triangles) between AIFM and Fastswap, and (d) access patterns when input is changed to Wikipedia Italian [6]. For these experiments, 25% of the working set resides in the compute server's local memory. Sequential accesses (due to skewness) in the Map phase are highlighted in red boxes in (a), while in (d) such patterns do not exist.

PVC benchmark on AIFM and Fastswap, respectively. Figure 1(b) reports their performance comparisons.

Since a MapReduce program has clear phases, we broke down the execution time into Map and Reduce. AIFM outperforms Fastswap by 1.6× in the Map phase due to object fetching—most remote accesses in Map are random as words are inserted into different buckets of the hash map. On the contrary, AIFM underperforms Fastswap by 3.3× in the Reduce phase, which exhibits clear sequential patterns.

Object eviction cost. The main reason why object fetching underperforms paging for programs with good locality is the high cost associated with profiling objects and maintaining object-based LRU for eviction. For example, eviction must be done quickly as it blocks further memory allocations [55]. As a result, AIFM constantly maintains dozens of profiling/eviction threads to track the hotness of (billions of) objects and evict cold objects. However, if these threads cannot obtain enough CPU resources from the application, they end up scanning only a small percentage of objects before time runs out and then evict objects with limited hotness information, resulting in data thrashing (*i.e.*, hot objects get swapped out and quickly swapped back in).

Figure 1(c) compares the eviction throughput and CPU utilization for eviction of AIFM and Fastswap during the Reduce phase. AIFM continuously performs object-level hotness tracking and eviction with around 200% (up to 350%) CPU usage in the entire Reduce phase. On the contrary, Fastswap finishes most of the page eviction task within the first five seconds and consumes no more than 100% CPU resources during the eviction. Overall, Fastswap consumes *an order of magnitude* less compute (cycles) than AIFM for eviction over the Reduce phase. Even with significantly fewer CPU resources, Fastswap's eviction throughput is still ∼**5**× higher than that of AIFM, due to the low memory management cost associated with paging.

Necessity of online profiling and path switching. Offline profiling techniques [26, 37, 41, 54, 70] were proposed to analyze program semantics and data accesses. However, these techniques are ineffective in identifying the optimal solution for a real-world application for two major reasons.

On the one hand, even if the application's computation phases may be analyzed by an offline profiling technique, its access patterns can change dramatically in response to *inputs*. As Figure 1(d) demonstrates, when fed with a different dataset (which does not exhibit skewness), the program's access patterns change significantly—*e.g.*, due to the lack of skewness, the Map phase no longer exhibits sequential patterns. In fact, for any interactive applications including Memcached [5], DataFrame [46], or streaming data systems [17, 34, 64], their behaviors and access patterns vary significantly with different user requests and workloads.

On the other hand, as discussed earlier, object fetching consumes extensive CPU resources. This may be acceptable when CPU resources are not fully saturated but becomes problematic as soon as all CPU cores are occupied (*e.g.*, another tenant starts using the server). Clearly, offline profiling is not able to predict such environmental changes.

These issues necessitate a dynamic technique that can continuously profile program executions and perform runtime data path switching as new behaviors and/or environmental changes are detected. Our main objective is to use object fetching to minimize I/O amplification and enhance locality, paving the way for subsequent accesses to operate on data with established locality and thus benefit from paging that is considerably more resource efficient.

4 Atlas Design and Implementation

This section presents Atlas's design. Like AIFM, Atlas requires programs to use smart pointers (*i.e.*, to implement barriers) and declare dereference scopes for objects (inspired by C++ weak pointers [4] and Folly RCU guards [1]). Objects are managed by Atlas's hybrid data plane. Atlas can also take the same user-defined programming/offloading hints and object-level prefetching logic as required by AIFM. Atlas uses such hints in the object fetching path.

4.1 Overview

Inspired by the design of the Java heap [51], Atlas divides a page into *cards* to enable fine-grained profiling for accesses. For each page, Atlas builds a card access table (CAT), which is a bitmap where each set bit represents a card that has been accessed since the page was allocated or last swapped in.

CATs for contiguous pages are allocated contiguously in a separate memory space. This design enables not only fine-grained access profiling, but also simple mapping from a virtual address to its CAT entry—this can be done with efficient bit-wise operations on the address. Each card represents 16 consecutive bytes, which provides a fine enough granularity as most objects are at least 16 bytes in our workloads.

Atlas maintains a 1-bit *path selector flag* (PSF) for each page, which works as an indicator of the data path for data access on the page. A `runtime` value indicates that data should be retrieved by the runtime at the object granularity (*i.e.*, runtime path). A `paging` value indicates that data should be paged in by the kernel (*i.e.*, paging path). Atlas updates the PSF of each page to `runtime or paging` at the moment the page is swapped out if its CAR (*i.e.*, the percentage of the set bits among all bits in a CAT) goes below or above a threshold (*i.e.*, 80% used in our evaluation, see §5.4).

Ingress. Atlas uses a *read barrier* that executes at each *smart pointer dereference*. The barrier first checks whether the accessed data is remote. In AIFM, this is done by using a bit in each pointer to encode the location of the referenced object—these pointers are updated once the objects they point to are swapped in or out. Atlas, however, cannot adopt this approach due to the use of the hybrid data plane—when data is *paged* out, Atlas cannot update any pointers. To solve the problem without incurring the cost of checking with the kernel at every read, Atlas leverages *hardware transaction memory* and, in particular, Intel's TSX [31], to run a quick check—Atlas accesses the address in a hardware transaction, which aborts if the address is not on a mapped page.

Upon an abort, the barrier reads the PSF for the page to be accessed and determines which path (runtime *vs.* paging) the access should take. If the runtime path is taken, the object is moved (*i.e.*, address changed) to a local page on the compute server and its pointers are updated; otherwise, the page containing the object is swapped in as a whole and the address of the object remains the same (without requiring pointer updating).

Egress. Given that the majority of the object-fetching overhead comes from the need to find and evict cold objects, Atlas utilizes a single path, *i.e.*, paging, to swap out data. This approach achieves a sweet spot in balancing overhead and benefits—on one hand, it significantly reduces the compute resource usage for object fetching because of the elimination of maintaining an object-level LRU; on the other hand, given that object fetching gradually improves locality (by moving together objects accessed closely in time), the amount of useless data in each swap-out (and thus the I/O amplification) is reduced progressively during execution.

Another reason to not evict objects individually is that it can potentially *hurt locality*—after objects are fetched in, those that were scattered in remote memory but accessed together were moved into contiguous local space; however, these objects may not be evicted at the same time; evicting them individually would make them go to unrelated locations in remote memory, disrupting established locality.

Synchronization. Allowing the two paths to co-exist in harmony requires overcoming the following three synchronization challenges: (1) *ingress synchronization* between object-in and page-in, (2) *egress synchronization* between object-in and page-out, and (3) *move synchronization* between object-in and evacuation. AIFM already solves the third problem with the declaration of dereference scopes, while the other two are unique challenges that we target in Atlas.

4.2 Synchronization of the Two Paths

Atlas builds its object fetching path upon the same two abstractions used by AIFM: the smart pointer (which is an extension of C++ smart pointer) and the dereference scope. This section elaborates on the synchronization mechanism between the object fetching path and the paging path.

```
class AtlasUniquePtr<T>{
  struct AtlasMetadata{
    unsigned long is_moving : 1;
    unsigned long access : 1;
    unsigned long reserve : 2;
    unsigned long offload : 1;
    unsigned long size : 12;
    unsigned long addr : 47;
  } metadata; // 64 bits
  AtlasUniquePtr(T* obj);
  T* get_raw();
}
```

Figure 2: Atlas unique pointer metadata.

Pointer Metadata. Before discussing our barrier logic, we first present the format of Atlas pointers, which are built on C++ smart pointers. Atlas uses two types of smart pointers: unique pointers (similar to `std::unique_ptr`) and shared pointers (similar to `std::shared_ptr`). Figure 2 shows the layout of an Atlas unique pointer. These fields are added for the purpose of synchronization and pointer updating.

Each such pointer has 64-bit metadata, in which 47 bits (`addr`) store the object's raw pointer, 12 bits (`size`) record its size, 1 bit (`access`) represents whether the object has been accessed since the last evacuation (which will be used by the evacuator to group recently accessed objects, see §4.3), 1 bit (`offload`) indicates whether a function is being invoked on the object on the remote side, and 1 bit (`is_moving`) indicates whether the object is being moved (*e.g.*, due to evacuation); this bit will be used for synchronization between two threads trying to move the same object. The remaining 2 bits (`reserve`) are reserved for future use. Note that 12 bits can represent a size up to 4KB. Objects larger than that are placed in the huge-object space of the heap for which paging is the only option. `get_raw` retrieves the raw pointer from a smart pointer.

A shared pointer allows aliasing. Atlas treats the first shared pointer of an object as the main pointer. A shared pointer's layout is similar to a unique pointer, except that it has an additional 8 bytes to chain all pointers—when the main pointer is being released, Atlas follows the chain to select a new main pointer. If an object is referenced by shared pointers, Atlas needs to update all of them (by following the chain).

Developers need to explicitly declare data types with smart pointers. Developers can access data with raw (regular C++) pointers by first retrieving such raw pointers from smart pointers. However, this can only be done within an explicitly declared dereference scope. Figure 3 illustrates an example of retrieving and manipulating data from Atlas smart pointers, confined by a dereference scope. As discussed in §2, dereference scopes synchronize with object migration tasks—once raw pointers are retrieved and actively used, their objects are not allowed to move, and vice versa. Atlas executes a `pre_scope_barrier` and a `post_scope_barrier` at the beginning and the end of the dereference scope, respectively.

```
deref_scope (smart_ptr) {
  pre_scope_barier(smart_ptr); // Algorithm 1
  Data * object = smart_ptr.get_raw();
  /* Operations using the object */
  ...
  post_scope_barrier(smart_ptr); // Algorithm 2
}
```

Figure 3: Dereferencing an Atlas unique pointer in a deref scope.

Synchronization invariants. We present a set of high-level invariants that Atlas maintains to solve the three synchronization problems: (1) preventing an object from being fetched from the two paths simultaneously (object-in *vs.* page-in), (2) preventing pages containing objects that were just runtime-fetched from being immediately swapped out (object-in *vs.* page-out), and (3) preventing an object from being simultaneously runtime-fetched and moved by the evacuator (object-in *vs.* evacuation).

Invariant #1: Object-in vs. page-in. At any moment, all data on the same page must go through the same access path as guided by the page's PSF. In other words, Atlas prohibits scenarios where certain requests are served by paging while others are served by the runtime for the same page. Given that Atlas changes PSF only at page-out (as opposed to setting it while the page is in local memory), such scenarios can never occur and this invariant is guaranteed by design.

Note that there is no issue if two threads fetch the same page from the paging path—the kernel's swap system guarantees only one page can be mapped. Fetching the same object from two threads with the runtime path is not a concern either: it is a solved problem in the literature of moving garbage collectors [43] where pointer updating is used as a synchronization point and only one object is retained.

Invariant #2: Object-in vs. page-out. Since swap-out events can occur at any time with the runtime path uninformed, Atlas enforces that pages containing objects whose dereference scopes are actively executed cannot be swapped out. This is because if such pages are swapped out before their dereference scopes finish, these objects may be fetched back in immediately from the runtime path, requiring pointer updating. Pointer updating cannot be done when the raw pointers of these objects are active on the stack. As a result, these pages cannot be swapped out until none of their objects are executing their dereference scopes.

Algorithm 1: Atlas Pre-Scope Barrier (Simplified).

```
/* derefcnt > 0 precludes the page's swap-out     */
atom_inc(find_page_meta(addr).derefcnt)
if not tsx_check_local(addr) then     /* Remote object */
    if take_runtime_path(addr) then   /* Runtime path */
        new_addr ← find_addr(addr, this.size)
        /* Inc/dec the new/old page's derefcnt     */
        atom_inc(find_page_meta(new_addr).derefcnt)
        atom_dec(find_page_meta(addr).derefcnt)
        alloc_copy_update(addr, new_addr, this.size)
        this.metadata.addr ← new_addr
        addr ← new_addr
    end
    else                                 /* Paging path */
        * (char*) addr
    end
end
```

Algorithm 2: Atlas Post-Scope Barrier.

```
atom_dec(find_page_meta(this.addr).derefcnt)
```

Atlas achieves this by maintaining a per-page *deref count*, which is incremented when any object on the page enters a dereference scope and decremented when the scope finishes. Any page with a non-zero deref count is skipped when the kernel looks for swap-out victims. Note that this does not create much impact on performance because the pages whose objects are actively used are usually hot pages and unlikely to be selected as swap-out victims anyway.

One issue that may arise from this protection is a potential live lock on the object-fetching path: either an ill-defined large dereference scope or many active dereference scopes in a parallel application may potentially lead to too much data getting pinned in local memory, which may result in out-of-memory errors. To tackle this issue, Atlas monitors the pinned data and forces the flipping of their containing pages' PSFs (to use paging) upon memory pressure. Once these pages are swapped out, they will be paged in—this solves the problem as page-in does not need pointer updating.

Invariant #3: Dereference scope vs. evacuation. Evacuation threads may move an object while another thread is executing the object's dereference scope. This must not occur because evacuation requires pointer updating, which cannot be done when a dereference scope is being executed (and raw pointers are used). To this end, Atlas uses the page's deref count to synchronize between evacuation threads and dereference scopes. A non-zero dereference count prevents the page from being evacuated.

Compared to AIFM, Atlas employs a slightly different definition of dereference scope. AIFM chose to decouple dereference scopes from the barrier—it allows one dereference scope to cover multiple smart pointer dereferences, serving as a coarse-grained fence between application threads and the evacuator. On the contrary, Atlas employs *fine-grained* dereference scopes, each of which is associated with one single smart pointer dereference. This choice was made based on our observation of frequent evacuations; using coarse-grained dereference scopes would require constant synchronizations between application and evacuation threads, leading to performance and latency impact. Fine-grained dereference scopes not only reduce the degree of blocking but also help alleviate potential live locks. Although a finer granularity increases barrier overhead, this overhead is often amortized by a large number of raw pointer accesses and computation within each scope. A detailed overhead analysis can be found in §5.2 and §5.4.

With the invariants discussed above, we proceed to presenting our barrier logic, which is shown in Algorithm 1 and Algorithm 2. As illustrated in Figure 3, Atlas executes Algorithm 1 and Algorithm 2 at the beginning and the end of a dereference scope, respectively.

Pre-scope barrier. Atlas first atomically increments the deref count for the page containing the object (Line 1). This indicates that the page has an object whose dereference scope is being executed, preventing the paging system from swapping out the page (*i.e.*, Invariant #2). This step must be done before the barrier starts to guarantee that (1) if the page is local, it cannot be swapped out from this point on, or (2) if the object is remote, once it is fetched in, its containing page cannot be swapped out.

Atlas uses Intel's TSX [32] to efficiently check if the address `addr` is local. Atlas starts an RTM transaction, which contains nothing but a dereference of the object. If the object's containing page is unmapped, the RTM transaction will abort with a special status captured by Atlas, which verifies the status by checking with the kernel. This hardware-based check is ∼14× faster than a purely software-based approach that relies on a system call that walks the page table and checks whether the page is local based on its PTE. A `true` value (*i.e.*, the object is local) returned by TSX directs the execution to exit the barrier immediately. Otherwise, Atlas checks the PSF corresponding to the address (Line 3) to decide whether this access should take the runtime (Lines 4-9) or the paging path (Line 12).

Using TSX to check object location may introduce false positives—a transaction may abort even if data is local. Since such cases are rare (*e.g.*, less than 1/10000 in our experiments), Atlas takes an optimistic approach to handle them. Upon a TSX abort, Atlas sends an RDMA read to access the remote object and simultaneously issues a page table walk to verify the object's location. If the verification fails (indicating the object is local), the fetched object is discarded. This approach introduces only a negligible overhead (*i.e.*, a small number of unnecessary RDMA reads).

Runtime path. `take_runtime_path` in Algorithm 1 checks the PSF of the page corresponding to `addr` and returns `true` if the PSF is `runtime`, indicating that object fetching should be performed. For ease of presentation, Algorithm 1 is significantly simplified to *not* show details of how to synchronize between threads to guarantee the absence of race condition when multiple threads fetching the same object. Atlas first finds a new address to which the object will be moved (Line 4). Since this address is on a new page, before moving the object, the deref count of the new page must be incremented (Line 5) to ensure that from this point on, the new page cannot be swapped out until the dereference scope finishes (*i.e.*, Invariant #2). The barrier also needs to decrement the deref count of the old page (Line 6) that was incremented earlier in Line 1.

Next, Atlas fetches the object by allocating a new object of the same size (using our log-structured allocator discussed in §4.3), copying the object's data into the new object, and updates its pointers (Line 7). Atlas subsequently changes the `addr` field of the pointer to the new address (Line 8). Pointer updating is done by retrieving the object's pointer from its header and updating their addresses, in a way similar to how it is done in AIFM. If it is a shared pointer, all other pointers will be retrieved from the main one and updated accordingly. The object's `is_moving` field is used to synchronize between pointer updating events performed by multiple threads. The synchronization details are omitted for simplicity. After the object is moved to a local page, future accesses to the object will follow the PSF of the new page.

Paging path. The paging path simply touches the object (Line 12) to ensure that the page fault handling is *completed* after the execution passes this line.

Post-scope barrier. The post-scope barrier has much simpler logic, as shown in Algorithm 2. All it needs to do is to atomically decrement the page's deref count, indicating the finishing of the dereference scope. When its deref count becomes zero, this page is subject to swap-out again (*i.e.*, Invariant #2).

4.3 Memory Management

Atlas's heap is composed of a *normal-object* space, a *huge-object* space, a *metadata* space, and an *offload* space. Atlas manages the normal-object space via a log-structured allocator [57, 58] and maintains a background evacuator to reduce fragmentation by compacting live objects. Atlas does not handle huge objects that cannot fit into a page, placing them into the huge-object space and delegating their management to the kernel directly since they are too large to benefit from object-level management. Metadata such as CATs are accessed by both the runtime and paging system, and hence, it is shared between the user and kernel space. The offload space stores objects whose functions can be offloaded to the remote side. We will discuss it shortly.

Object allocation. The log-structured allocator maintains thread-local allocation buffers (TLAB) to reduce the global lock contention during parallel object allocation. The TLAB is managed at the granularity of log segment which is aligned with a page to guaranteed that no object can go cross the page boundary. Atlas allocates objects contiguously on the TLAB as prior research [65, 70] shows that objects allocated close in time exhibit similar usage patterns. In doing so, objects with temporal proximity are naturally grouped into the same log segment (page), enhancing locality.

Metadata allocation. Metadata such as dereference counters and card tables is allocated in a dedicated metadata space. Atlas maintains a card table for each page to record the object access information. Each card table is a bitmap where each bit represents a consecutive range of 16 bytes. Our experiments show that the sizes of most objects are larger than 8 bytes, making 16 bytes a natural choice for the card size. Each card table is allocated and initialized during the allocation of a log segment. It is freed along with the log segment. The space needed by the card tables is 1/128 of the total memory. In summary, the space overhead is less than 2%.

Object evacuation. The log-structure allocator [58] supports defragmentation via a copying-based evacuator, a technique widely used in modern garbage collectors [20]. In Atlas, we extend the evacuator to improve the temporal locality of pages by grouping hot objects into contiguous log segments (pages) during the evacuation. The evacuator runs concurrently with the application to reduce fragmentation.

The evacuator periodically scans log segments and evacuates a log segment with a high garbage ratio by copying its live objects to a newly allocated target segment. As a result, the target segment is free of fragmentation, and the source log segment can be freed right away. When moving an object, the evacuator maintains its corresponding card table values, *i.e.*, if the object was recently accessed on the source page, the evacuator marks its card bit on the target page during evacuation. Furthermore, Atlas improves evacuation efficiency by prioritizing log segments in local memory and delaying the processing of remote log segments until they are accessed or the free space runs out [67].

The Atlas runtime tracks whether an object has been accessed since the last evacuation via the `access` bit in the smart pointer (see Figure 2). This bit is set by the read barrier when the object is dereferenced and cleared by the evacuator at the end of each evacuation. The evacuator segregates objects that have been accessed since the last evacuation into a set of contiguously allocated log segments. We found this approach to be particularly effective in improving temporal locality for real-world workloads with *skewness* (*e.g.*, 90% of accesses hit 10% objects). The `access` bit allows Atlas to distinguish hot and cold objects in such workloads, leading to a substantial performance boost. Note that this operation is significantly more efficient than maintaining an object-level LRU for eviction. As opposed to ranking objects based on hotness, Atlas's `access` bit simply serves as an evacuation location indicator. Its functionality is similar to CAT but used differently; CAT is read and cleared by the kernel at page eviction while the `access` bit is read and cleared by the runtime at evacuation.

Computation offloading. As shown in many existing far-memory systems, such as Semeru [66], Mako [43], AIFM [57], and Mira [26], offloading memory-intensive operations to the remote side can effectively reduce the data movement overhead. A unique challenge for Atlas is how to enable offloading when paging is used. Under paging, remote memory is managed as a swap partition of a set of swap slots. These slots are agnostic about the remote server's memory addresses. Pointer addresses contained in a page are with respect to the compute server while the page can reside at a completely different address on the remote server. This address mismatch precludes the correct execution of a function on an object directly on the remote server.

To solve the problem, Atlas uses an approach that is similar to Semeru [66]—we reserve a dedicated offload space in the heap. Developers need to explicitly define remoteable data structures and functions (which are similar to those in AIFM). Objects registered as *remotable* are all allocated into this space. Pages in this space have guaranteed virtual address alignment between the compute and remote servers—we modify the paging system to ensure that a page at a virtual address A on the compute server is guaranteed to be still at address A on the remote server when evicted. Atlas requires users to guarantee a remotable data structure cannot reference a non-remotable object. This property ensures address consistency when a function is called remotely.

The offload space is an *object-in, page-out* space, which allows objects to be fetched only through the runtime. This is due to the need to synchronize between the servers for safe remote execution. When a remote function is being invoked on an object, the `offload` field in its smart pointer is used for synchronization—the runtime can not fetch the object until the remote function is finished (and the `offload` bit is cleared). Remotable objects can only be fetched into the offload space to ensure the above-stated properties.

5 Evaluation

5.1 Setup and Methodology

We wrote 7,675 lines of C/C++ code to implement Atlas's runtime library, and added support in the Linux kernel (version 5.14-rc5) for page management (*e.g.*, path synchronization). We ran experiments with one compute server and one memory server connected by a 200 Gbps Infiniband switch. Each server has 2 Intel Xeon Gold 6342 CPUs (24 physical cores each), 256 GB of memory, and a 100 Gbps Mellanox ConnectX-5 InfiniBand adapter. All evaluated systems ran on Ubuntu 18.04. We configured the servers following common practice for low latency [52], disabling Turbo Boost, CPU frequency scaling, and transparent huge pages.

Baselines. Atlas was implemented based on Fastswap and AIFM. For the paging path, Atlas uses unmodified Fastswap with added tasks of profiling and synchronization. For the runtime path, Atlas uses AIFM's ingress algorithm and paging at egress. For evaluation, we used AIFM [57] and Fastswap [9] as our baselines for object fetching and paging, respectively. For Fastswap, we ran the original applications to avoid unnecessary runtime overhead. For AIFM, we used the performance-tuned versions of applications, where all optimizations were enabled including per-thread access pattern tracking, object hotness tracking, and non-temporal programming hints [57]. We turned off offloading when evaluating throughput and latency, leaving its evaluation to §5.4.

Workloads. As shown in Table 1, we evaluated six real-world applications and two synthetic applications, including Metis [44]—an optimized MapReduce framework for multicore architectures, Aspen [17]—a purely functional tree-based graph processing framework, GraphOne [34]—a data store for real-time analytics on evolving graphs, as well as Memcached [5]—an in-memory key-value store. We ran Memcached with two different workloads: a real-world workload (MCD-CL) that comes from Meta's cache system CacheLib [12] and a synthetic workload (MCD-U) generated by YCSB [15] that follows a uniform distribution. We also employed two synthetic applications developed by AIFM's authors to compare Atlas and AIFM. These applications include one batch application, DataFrame [46], and one latency-critical application, WebService.

Covering a wide spectrum of domains and memory access patterns (*i.e.*, sequential, random, skewed, and mixed patterns), these applications can be divided into four categories:

First, both Memcached workloads exhibit random access patterns, leading to significant I/O amplification under paging. The real-world workload MCD-CL has a high level of skewness with *churn* behaviors. *Churn* refers to the phenomenon that hot data in the working set changes rapidly over time. On the contrary, the synthetic workload MCD-U demonstrates completely random behaviors, with no skewness and hot data. As a result, MCD-CL is more amenable to Atlas's dynamic locality improvement than MCD-U.

Second, GraphOne and and Aspen are evolving graph systems, which are representatives of applications that perform analytics over frequently updated datasets. GraphOne uses adjacency lists and edge lists to store an input graph while Aspen utilizes compressed purely-functional trees to store a graph, which supports a higher update rate. The working sets of these applications change continuously. Their accesses are very complex: the first stage builds the graph in memory, exhibiting a random pattern. The second stage runs iterative algorithms where the first iteration does not have locality and thus performs random accesses; the subsequent iterations would enjoy better locality if it runs on Atlas, which dynamically improves the locality during the first iteration. However, updates to the input graph disrupt the locality and hence there can also be many random accesses in the middle of the iterations. We used these two graph frameworks to evaluate how well Atlas can dynamically adjust the data layout and improve locality.

Third, Metis (MapReduce) and DataFrame represent bulk data processing systems with clear phase-changing behaviors (discussed in §3). These workloads are used to evaluate whether Atlas can accurately recognize access patterns and switch to the proper data path. DataFrame is additionally used to evaluate compute offloading due to its memory-intensive operations (§5.4).

Finally, WebService is an interactive web application exhibiting mixed access patterns, from random, pointer-chasing, to sequential accesses.

For Atlas to run these applications, we modified 263 lines of code for Metis, 278 lines for Aspen, 219 lines for GraphOne, and 391 lines for Memcached; the additional code was used to declare smart pointers and dereference scopes. It took one developer a few hours to port each program.

Memory setup. Each application was run with five local memory configurations: 13%, 25%, 50%, 75% and 100%, each representing a specific percentage of an application's working set that can fit into local memory. These configurations were enforced using `cgroup`. The first four configurations were employed to evaluate the performance of the three systems when using different amounts of remote memory, while the 100% (all local memory) configuration was used to assess the runtime overhead of Atlas and AIFM, introduced by the barriers (for smart pointer dereferencing), dereference trace recording (for object-level prefetching), and evacuation (for defragmentation), as well as other bookkeeping overheads; see Table 2 for more details.

5.2 Throughput

We first measured the throughput of the applications with varying local memory ratios. Overall, Atlas outperforms Fastswap and AIFM, respectively, by 3.2× and 1.5×, over the eight real-world applications using remote memory (from 13% to 75% local memory). When running locally (100% local memory), Atlas and AIFM incur an overall overhead of 19.1% and 14.0%, respectively, of which 10.2% and 2.3% are from the barriers. This section reports the overall performance and runtime overhead. We show a detailed overhead breakdown in §5.4.

MCD-CL and MCD-U. Both workloads were configured with the same operation ratios, *i.e.*, 87.4% get and 12.6% set. As shown in Figure 4(a), for a highly-skewed workload like MCD-CL, both Atlas and AIFM outperform Fastswap (by 6.4× and 3.2×, respectively). The performance difference comes primarily from the reduced I/O amplification—Fastswap fetches 26× and 30× more data than Atlas and AIFM, respectively, resulting in wasted memory (for storing unused data) and significantly more swaps. Under 100% local memory, Atlas and AIFM introduce an over-

Application	Dataset	Size	Characteristics
Memcached CacheLib [5] (**MCD-CL**)	Meta CacheLib [12]	50M records	Skewness with churn
Memcached Uniform (**MCD-U**)	Synthetic, uniform distribution [15]	50M records	Random access
GraphOne PageRank [34] (**GPR**)	Twitter 2010 [35]	1.5B Edges, 41.7M Vertices	Evolving graph
Aspen TriangleCount [17] (**ATC**)	Friendster [73]	1.8B Edges, 65.6M Vertices	Evolving graph
Metis Word Count [44] (**MWC**)	The News Crawl Corpus [72]	5.1GB	Phase-changing
Metis PageViewCount (**MPVC**)	Wikipedia English [6]	15GB	Phase-changing with mixed patterns
DataFrame [46] (**DF**)	NYC Taxi [3]	16 GB	Phase-changing with offloading
Web Service [57] (**WS**)	Synthetic [57]	10GB hashmap, 16GB array	Mixed patterns with offloading

Table 1: Applications used for our evaluation.

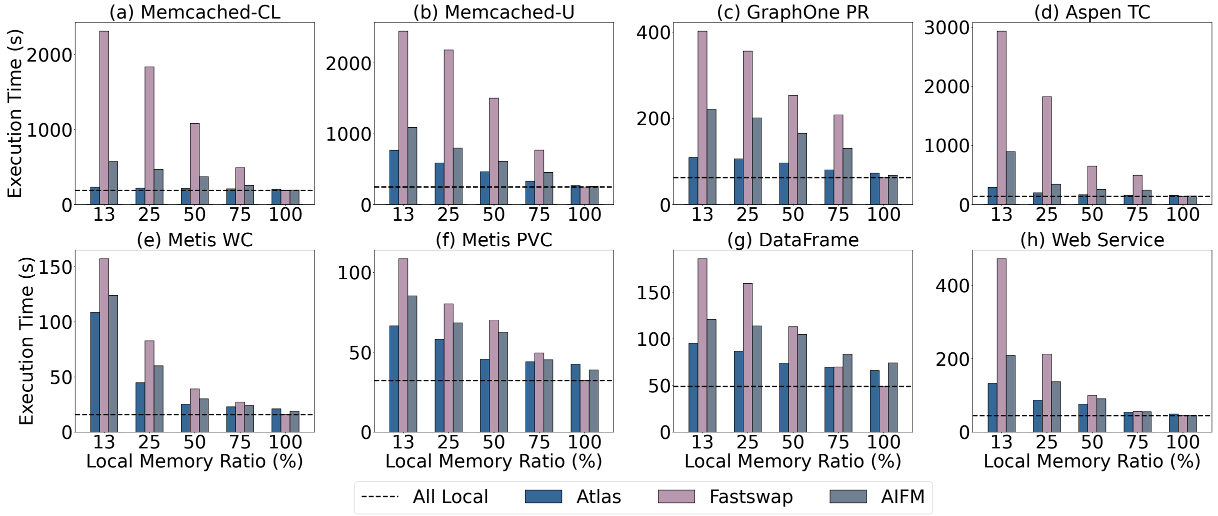


Figure 4: Throughput comparison between Atlas, Fastswap and AIFM with varying local memory ratios. "All Local" lines represent the performance of unmodified applications under 100% local memory.

all overhead of 9.0% and 3.2%, respectively, compared to Fastswap. The primary source of the overhead is the barriers, taking 6.2% and 1.5% of the execution time, respectively. Given that Memcached spends a substantial portion of its execution on communication, the barrier overhead, which is associated with the in-memory processing, is insignificant.

Compared to AIFM, Atlas further improves the performance by 1.2×, 1.8×, 2.2×, 2.5×, under the four different memory configurations (75%, 50%, 25%, and 13%). This improvement stems from a much higher eviction throughput (on average 4.6× higher) in Atlas due to the elimination of object eviction. In addition, Atlas's concurrent evacuator (§4.3) improves the temporal locality by segregating hot objects into contiguous pages, leading to an overall of 18% more accesses that go through the paging path (§5.4). This result was achieved when AIFM used 20 eviction threads while Atlas only used one single swap-out thread in the paging path. MCD-U performs random accesses with no hot data, hindering opportunities for Atlas to improve locality. Hence, the usefulness of the hybrid data plane is limited. However, Atlas still outperforms AIFM by up to 1.4× due to more efficient eviction, as shown in Figure 4(b).

GPR and ATC. To execute an evolving graph engine, we divided the input datasets [35] into three batches, which are incrementally fed to the graph engine. For each batch, the graph engine conducts the following three steps: load the updates, update the graph, and execute the analytics.

As Figure 4(c) shows, in the presence of remote memory, Atlas outperforms AIFM and Fastswap by an average of 1.8× and 3.1×, respectively, on GPR. As stated earlier, graph updating and the first iteration of analytics exhibit random access patterns. As such, GPR's throughput under AIFM is 1.7× higher than under Fastswap. For Atlas, when the analytics starts, objects are accessed and reordered by the object fetching in the first few iterations; in the subsequent iterations, pages storing edge objects are switched to using the paging path due to the gradually established locality. As a result, up to 82% of pages have their PSFs changed during the execution (from object fetching to paging), as demonstrated in Figure 7(b). This improves the analytics throughput.

ATC's computation stages and access patterns are both similar to those of GPR. For ATC, the trees storing the graph data are dynamically reorganized by Atlas's runtime path, leading to ∼38% of pages changing their PSFs (from object fetching to paging). In addition, evacuation improves locality by segregating hot objects from these trees into a few pages, reducing remote memory accesses by 24%. As demonstrated in Figure 4(d), ATC's overall throughput is 2.0× higher under Atlas than under AIFM.

When running on 100% local memory, Atlas's barrier overheads for both GPR and ATC are modest, 8.2% and 4.3%, due to the high ratio between raw pointer accesses and smart pointer dereferences. Oftentimes, one object dereference (*e.g.*, obtaining a vertex that contains a series of edges) is followed by dozens of raw pointer accesses (*e.g.*, to individual edges). Each dereference scope contains an average of *21* raw pointer accesses. In addition, for ATC, the barrier overhead is further diluted due to its higher computation and memory access costs (from poor spatial locality).

MWC and MPVC. Figure 4(e) and (f) respectively show the performance of MWC and MPVC. As discussed in §3, MPVC exhibits a two-phase behavior that can benefit from adaptive path switching, leading to a 1.2× and 1.4× improvement, compared with AIFM and Fastswap, respectively. MWC has a similar two-phase behavior with MPVC but exhibits more random accesses in its map phase, resulting in almost no page that can be flipped to `paging`. Compared to AIFM and Fastswap, MWC has 1.2× and 1.5× performance improvement, respectively.

For these two applications, the runtime overhead is relatively high—32.0% (Atlas) and 19.2% (AIFM), under 100% local memory. These two Metis workloads are both memory-intensive—they keep scanning data with high parallelism, leading to both high barrier overhead and profiling overhead (*e.g.*, for card profiling and access trace recording, see §5.4). Atlas's barrier overhead reaches up to 16.1% and 17.4% for MPVC and MWC, respectively, which are about 4× higher than that of AIFM.

DF. DF is a table-structured in-memory data structure with hundreds of columns and millions of rows, popularized in Pandas [48]. Users can slice data in different ways and run various statistics. As Figure 4(g) shows, Atlas outperforms AIFM by 1.2∼1.4× in the four remote-memory settings. We ran a client, developed by the AIFM authors, to conduct a series of *Copy* and *Shuffle* operations on *DF*. Similarly to Metis, *DF* demonstrates clear phase-changing behaviors when processing different operations—a *Copy* operation copies data from a column, exhibiting excellent spatial locality and a clear sequential pattern, while a *Shuffle* operation reorders rows for each column, exhibiting random patterns. Atlas achieves superior performance to AIFM and Fastswap, due to its adaptive access path selection.

AIFM suffers a higher runtime overhead (51.4%) compared to Atlas (34.7%) despite having a lighter barrier. The reason is that AIFM maintains a remote vector on the memory server for every DataFrame vector to support the eviction of individual objects with varied sizes. During the execution, DataFrame vectors keep getting allocated and resized. As a result, the remote data structure also needs to be frequently resized to maintain a valid mapping from local objects to their remote memory locations. Resizing is a heavy operation as it requires allocating memory and moving all existing objects. Therefore, it becomes a major source of overhead, which can take two-thirds of the runtime overhead under 100% local memory. On the other hand, under Atlas, eviction is handled by the Linux kernel at a fixed page size and there is no need to maintain any remote data structures. Note that frequent resizing of data structures was not observed in other applications. For example, for WS, the hash table array is allocated at the start of the application and its size remains fixed throughout the execution.

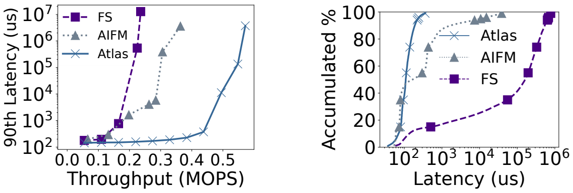
WS. WS is implemented by AIFM's authors to simulate a distributed workload. Each client (thread) sends 32 requests to look up keys in an in-memory hash table and fetches a single 8KB element from an array. This element is then encrypted with Crypto++ [7] and compressed using Snappy [23] before being sent back to the client. We use a 26GB dataset for the evaluation, which is consistent with the dataset used in AIFM [57]. Client requests are generated by following a Zipfian distribution.

As Figure 4(h) shows, compared to AIFM, Atlas improves WS' performance by an average of 1.3× with remote memory. This is due to an extremely large number of objects on the LRU list that must be analyzed by AIFM. AIFM's performance degradation is primarily due to the compute resource contention between application and evacuation threads (discussed in §3), making it hard for evacuation threads to quickly identify and evict cold objects. Consequently, AIFM ends up evicting arbitrary objects to reclaim memory, resulting in data thrashing. By using paging for eviction, Atlas improves the eviction throughput by 5.8×, lifting data eviction efficiency to 5.9 cycles/byte, which is 7.4× higher than that of AIFM (43.7 cycles/byte).

Atlas and AIFM have relatively low overhead for WS due to the coarse-grained data fetching (8KB element) and the subsequent compute-intensive encryption. As a result, Atlas and AIFM introduce a 10.1% and 1.9% runtime overhead under 100% local memory, respectively.

5.3 Latency

This section evaluates the latency distribution using the two latency-critical applications: WS and MCD-CL. The 25% local memory ratio was used in these experiments.



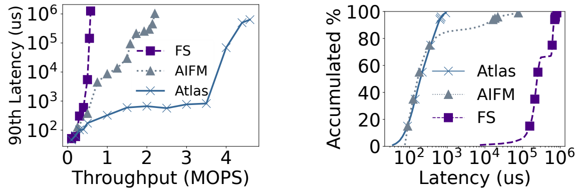
(a) 90th latency-throughput curve.

(b) Latency CDF.

Figure 5: (a) 90th latency as a function of throughput; (b) Latency CDF under 0.23 MOPS offered throughput. FS stands for Fastswap.

Web Service (WS). Figure 5(a) compares the tail latency among the three systems. Fastswap's tail latency rapidly grows due to page thrashing caused by severe access amplification. AIFM reduces amplification so that requests are less blocked by eviction. Despite the reduced amplification, AIFM still has to rank and evict individual key-value pairs, and hence the system saturates at 0.36 MOPS.

Atlas fetches individual key-value pairs initially via the runtime path and places those pairs which belong to the same request together on the same page (because these KV pairs are accessed close in time). As the execution progresses, Atlas switches to paging that can load multiple key-values pairs at the same time. Meanwhile, page-level eviction continuously offers a much higher eviction throughput so that it never blocks swap-ins. As a result, Atlas's tail latency stays low until 0.45 MOPS and can finally reach a peak throughput of 0.57 MOPS. As shown in Figure 5(b), the latencies of AIFM and Atlas are comparable until the 50th percentile, where the application starts accessing many remote objects leading to increased object management overhead. On the contrary, due to the optimized data layout which enables the efficient use of paging, Atlas experiences fewer remote accesses.

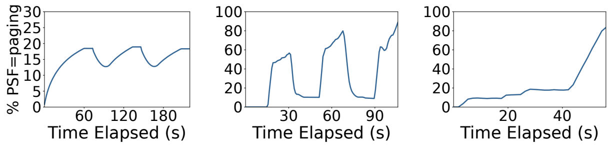


(a) 90^{th} latency-throughput curve. (b) Latency CDF.

Figure 6: (a) 90^{th} latency as a function of throughput; (b) Latency CDF under 1 MOPS offered throughput. FS stands for Fastswap.

MCD-CL. Memcached CacheLib is similar to Web Service as they both access key-value pairs from a hash table. The difference is that every request key in MDC-CL follows a Zipfian distribution, as opposed to accessing key-value pairs always in groups of 32. Figure 6 compares the tail latency among the three systems. It is clear that Atlas outperforms the other two systems. In addition to the same reasons explained above, MCD-CL is a skewed workload and hence a substantial portion (40%) of the improvement comes from the evacuation that groups hot objects in contiguous pages, making these pages amenable to paging.

5.4 Performance Drill Down



(a) MCD-CL (b) GraphOne PR (c) MPVC

Figure 7: The percentage of pages with PSF=`paging` in the memory footprint changes with the elapsed execution time.

Adaptive path switching. To understand the effectiveness of Atlas's adaptive path switching, we measured the percentage of the pages whose PSF is `paging` during the execution. Figure 7 demonstrates how this percentage changes during the execution for three applications: Memcached CacheLib (MCD-CL), GraphOne Pagerank (GPR) and Metis PageViewCount (MPVC). As Figure 7(a) shows, the number of pages that go through the paging path rises and falls over the time due to the *churn* behavior in MCD-CL discussed in §5.1. Since the workload is highly skewed, most accesses fall on a small number of hot objects, which stay in local memory and are moved into contiguous pages (with a high CAR) until the hot spot shifts.

As discussed in §5.1, the execution of GPR has experienced three batches of updates to the input graph, each of which contains two steps: graph building and analytics. During graph building, applying edge-level updates exhibits random access patterns, which can disrupt locality and leave many pages with a low CAR; these pages would have to go through the object fetching path. However, the subsequent analytics (like PageRank) runs multiple iterations; Atlas can quickly improve locality in the first few iterations, making pages turn their PSF to `paging` in subsequent iterations. This pattern can be clearly seen in Figure 7(b).

MPVC has a clear two-phase behavior (see Figure 1(a)) which can be accurately recognized by Atlas —the number of pages that go through the paging path increases dramatically as the phase change is detected by Atlas (shown in Figure 7(c)). To understand the individual contributions of object fetching and evacuation to the locality, we disabled the `access` bit tracking and let the evacuator move live objects without guidance. This reduces the overall percentage of pages that go through paging by 4% on average.

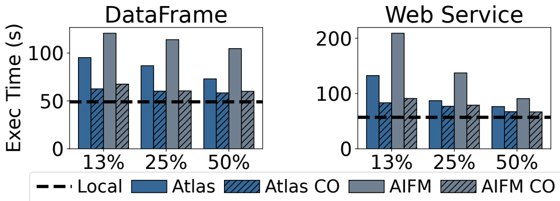


Figure 8: Throughput comparisons of DataFrame (DF) and Web Service (WS) when Atlas and AIFM enable compute offloading. CO stands for variants with compute offloading.

Computation offloading. We compared the offloading performance between Atlas and AIFM using DF and WS. Figure 8 shows the results of Atlas and AIFM with and without offloading. 18 cores were reserved on the remote side for both Atlas and AIFM, which is consistent with the offloading settings used by AIFM [57]. For DF, we offloaded the memory-intensive operations, *i.e.*, `Copy` and `Shuffle`, to the remote side. For WS, we offloaded the heavyweight array processing (on the 16GB data array). Compared to the setting where offloading is disabled (Figure 4 (g) and (h)), the throughputs of Atlas and AIFM are both dramatically improved (by up to 1.5× and 1.9× for DF, and 1.6× and 2.3× for WS, respectively), due to reduced remote accesses and data movement. On the other hand, Atlas and AIFM achieve comparable performance. This is because Atlas focuses on fetching efficiency; offloading reduces the need for fetching, making Atlas's benefit less significant.

Runtime overhead analysis. To understand the performance penalty introduced by the runtime of Atlas and AIFM, we break down and compare the runtime overhead by sources. When running with all local memory, the runtime overhead of Atlas and AIFM can be divided into five major components, listed in Table 2. Note that the overhead reported here represents the **worst-case scenario** for Atlas when compared against AIFM. When there is remote memory, part of Atlas's runtime overhead can be eliminated by switching to the paging path—dereference trace profiling is not used for paging as its goal is to analyze dereference traces for prefetching objects. Meanwhile, AIFM incurs more profiling overheads that do not exist under the all local memory setting, such as maintaining the object-level LRU for eviction.

Sources of overhead	Functionality	Affected systems
Barrier (Dereferencing)	Correctness guarantee, such as location check & synchronization	Atlas and AIFM
Card Profiling	Offering data path switching hints.	Atlas
Dereference Trace Profiling	Offering object-level prefetching hints	Atlas and AIFM
Evacuation	Defragmentation	Atlas and AIFM
Remote Data Structure Management	Managing object-level eviction	AIFM

Table 2: Major types of runtime overheads, operations involved in each type, and their affected systems.

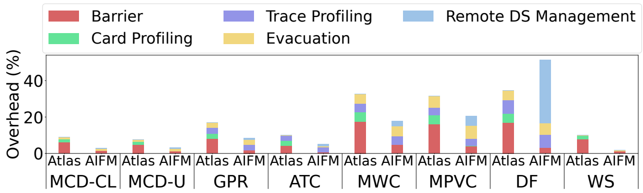

Figure 9: Runtime overhead breakdown: overhead is calculated as the ratio between the extra execution time introduced and the execution time under 100% local memory.

As shown in Figure 9, compared to Fastswap, the extra tasks in Atlas incur a runtime overhead of 7.7-34.7%, while AIFM's overhead is 1.9-51.4%. The overall overheads of the two systems are 19.1% and 14%, respectively. The primary source of overhead for both systems is the barrier (except for DF with AIFM, for which the reasons are explained in §5.2). Specifically, the Atlas barrier accounts for half of the total overhead (∼10%), and its cost is 4.4× of that of AIFM. Note that this overhead correlates with an application's memory access behavior: the most memory-intensive applications suffer the heaviest barrier overhead (MWC, MPVC, DF).

Although Atlas uses a heavier barrier, it underperforms AIFM by *only 4% under 100% local memory*. The reason is three-fold: (1) the barrier overhead is effectively amortized across the computation and raw pointer accesses (§5.2); (2) AIFM's use of coarse-grained dereference scopes leads to higher synchronization costs than Atlas; and (3) there are other operations that also contribute to the runtime overhead. Since the first item has been discussed earlier in this section, here we elaborate on the second and third items.

The barrier conducts two basic tasks, object location checking and synchronization. For location checking, Atlas has a much higher overhead than AIFM due to the use of TSX to detect an object's location whereas AIFM checks a bit on each reference. However, for synchronization, AIFM's coarse-grained dereference scopes incur a higher cost, which effectively reduces the performance gap between the barriers of the two systems. After selecting the victim segments, AIFM's evacuator must wait until all application threads exit their dereference scopes to avoid compacting objects being accessed through raw pointers. This design does not work well for big data applications with high object allocation rates, such as MWC, MPVC and Memcached. On the contrary, Atlas's fine-grained dereference scope design enables evacuation threads to skip the segments (each aligned to a page in Atlas) whose *deref count* is non-zero (indicating they are being used in active dereference scopes) instead of blocking the whole evacuation, leading to significantly reduced synchronization efforts. In fact, Atlas's CPU yield rate caused by synchronization is *an order of magnitude lower* than that of AIFM due to our non-blocking design.

Another major source of overhead is the dereference tracing (to provide prefetching hints), accounting for 14% and 19% of the total overhead for Atlas and AIFM, respectively. Among our applications, DF, MWC, MPVC and GPR use array data structures which are amenable to prefetching. As a result, there is a relatively high tracking overhead (accounting for 34% overhead on average) for both Atlas and AIFM. Other applications such as WS and Memcached use hash maps and small objects as their data structures, which are not as amenable to prefetching as arrays. Hence, for most of their memory accesses, the locations are not tracked and their tracing overhead is much lower. Note that with remote memory, the dereference tracing overhead is significantly lower under Atlas than under AIFM because a large amount of data (*e.g.*, up to 82% for GPR) goes through the paging path, which utilizes the lightweight page-level prefetcher.

CAR threshold. Figure 10 shows the influence of CAR threshold on the throughput of three applications. Picking the right CAR threshold is a tradeoff between fetching efficiency and resource waste. We used 80% as the CAR threshold for flipping PSF in our evaluation. A higher CAR is often too conservative. For example, in the case of MCD-CL, when the threshold is set to 100%, we observed that few pages can be flipped to `paging`. Therefore, most remote objects still have to be fetched individually instead of fetched in batches with page faults, leading to a 25% decrease in throughput. On the contrary, a lower CAR may result in

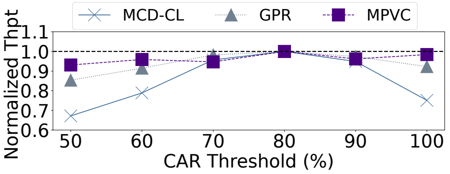

Figure 10: Sensitivity of the CAR threshold.

premature use of paging, leading to I/O amplification. As shown, the best performance is achieved when the threshold is between 80% and 90%. As such, we used the lower bound 80% based on the observation that the bandwidth of a modern network such as InfiniBand [49] is already high and will only become higher in the future, making it possible to transfer (slightly) more data with little overhead.

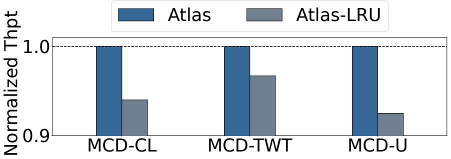

Figure 11: Normalized throughput of Memcached workloads running on Atlas and Atlas-LRU under 25% local memory.

Hotness tracking. Atlas uses an `access` bit on each smart pointer to segregate hot and cold objects during evacuation, offering benefits to workloads that exhibit skewness. We evaluated the effectiveness of Atlas's `access` bit with three skewed workloads, *i.e.*, highly-skewed (Meta, MCD-CL) [2], moderately-skewed (Twitter, MCD-TWT) [74] and uniformed without skewnewss (MCD-U) [15]. We compared Atlas with a baseline (Atlas-LRU) equipped with an LRU-like policy from CacheLib [12], which represents a more accurate approach to identifying hotness.

As shown in Figure 11, Atlas's single-bit design outperforms the LRU-like design by 7.5%, 3.3% and 6.0%, respectively. The LRU-like policy trades compute resources for accuracy by maintaining the logical ordering of objects via a linked list. Each dereference triggers a promotion that moves the object to the head of the LRU list. In order to reduce the overhead, we adopted *flat combining* [30] (to reduce thread lock contention) and ignored the dereferences of an object within 10s (to reduce promotion frequency for extremely hot objects) [12]. However, although an LRU-like policy can reduce the frequency of remote access, it incurs a maintenance overhead of up to 9% due to a huge number of objects.

Of course, the more bits used, the higher accuracy they bring. Atlas allows developers to customize the hotness tracking policy with the two reserved bits in each smart pointer (Figure 2). For our applications, we did not observe significant performance variations between using one and two access bits—likely the ability of distinguishing hot and cold objects is not increased much with two access bits.

6 Related Work

Disaggregation. Resource disaggregation has become a trending architecture for datacenters to improve resource utilization. Its key idea is to break the server hardware boundary and unstrand idle resources of remote servers by leveraging advanced network hardware [22, 28]. Existing systems have demonstrated the viability of disaggregated storage [33, 38], accelerators [50, 63, 75], network [60], and memory [25, 59]. For a memory-disaggregated system, memory spans across multiple servers. The efficient data path of Atlas can speed up the data transfer between servers.

Paging-based far memory. A practical way to deliver far memory is to leverage the paging system to access far memory. Google and Meta have reported their successful deployment of such systems in their datacenters [36, 71]. Many optimizations to the kernel data path have been proposed for improved efficiency, including but not limited to bypassing the block layer [9, 55], prefetching more accurately [45], and reducing interference [68]. The design of Atlas is orthogonal to the underlying paging systems and can directly benefit from optimizations within these systems.

Object-based far memory. Many runtime libraries offer new primitives for object-granularity far memory management, making them a more efficient alternative for scattered data on far memory. For example, AIFM [57] proposed remoteable data structures, FaRM [18] offered key-value interfaces, and Grappa [47] builds a software distributed memory. Atlas focuses on the cooperative use of its two data paths and benefits directly from existing optimizations.

Emerging hardware. Emerging hardware technologies unlock new opportunities for efficient far memory. Clio [27], StRoM [61], and RMC [10] offload functionalities to their customized hardware to reduce network traffic. Finally, CXL [16, 24, 39, 40, 77] and Project PBerry [13, 14] enable far memory access at the cache-line granularity. Atlas directly benefits from the throughput and latency advancements of new hardware technologies. Besides, for hardware solutions with a fixed access granularity, Atlas can improve data locality to improve data transfer efficiency.

7 Conclusion

We present Atlas, a hybrid dataplane that enables efficient far memory for bulk data and scattered objects simultaneously. Atlas outperforms both the state-of-the-art object-based and paging-based far memory systems.

A Artifact Appendix

A.1 Overview

Atlas is a kernel-runtime co-designed system to enable a hybrid remote memory data plane. The artifact includes the custom Linux kernel and the runtime library to enable Atlas-managed applications. To run the artifact, two servers with Intel CPUs connected by InfiniBand are required. The server running the application is the CPU server, while the other server providing remote memory is the memory server. Detailed instructions can be found in Atlas code repository.

A.2 Checklist

- **Hardware:** Two servers with Intel CPUs with TSX, connected by InfiniBand
- **Software Environment:** Ubuntu 18.04, 20.04 or 22.04, with the specified version of MLNX_OFED driver and provided Linux kernel described below
- **Public Link to Repository:** https://github.com/wangchenxi7/Atlas
- **Code License:** MIT License

A.3 Building the Linux Kernel

```
## all operations are performed on both
servers unless specified
cd linux-5.14-rc5
cp config .config
sudo apt install -y build-essential
bc python2 bison flex libelf-dev
libssl-dev libncurses-dev libncurses5-dev
libncursesw5-dev
./build_kernel.sh build
./build_kernel.sh install
./build_kernel.sh headers-install
## edit GRUB_DEFAULT="Advanced
options for Ubuntu>Ubuntu, with Linux
5.14.0-rc5+", or whatever the new kernel
version code is
## edit GRUB_CMDLINE_LINUX="nokaslr
transparent_hugepage=never
processor.max_cstate=0
intel_idle.max_cstate=0 tsx=on
tsx_async_abort=off mitigations=off"
sudo vim /etc/default/grub
sudo update-grub
sudo reboot
```

A.4 Setting up InfiniBand Connection

```
## use Ubuntu 18.04 as an example below
wget https://content.mellanox.com/ofed/
MLNX_OFED-5.5-1.0.3.2/MLNX_OFED_LINUX-5.5-
1.0.3.2-ubuntu18.04-x86_64.tgz
tar xzf MLNX_OFED_LINUX-5.5-1.0.3.2-
ubuntu18.04-x86_64.tgz
cd MLNX_OFED_LINUX-5.5-1.0.3.2-
ubuntu18.04-x86_64
sudo apt install -y bzip2
sudo ./mlnxofedinstall
-add-kernel-support
sudo /etc/init.d/openibd restart
sudo update-rc.d opensmd remove -f
sudo sed "s/# Default-Start:
null/# Default-Start:  2 3 4 5/g"
/etc/init.d/opensmd -i
sudo systemctl enable opensmd
sudo service opensmd start
## assign IPs to InfiniBand interfaces on
both servers
sudo nmtui
```

A.5 Building Atlas Runtime

```
## use gcc-9
cd atlas-runtime/third_party
git clone -depth 1 -b
54eaed1d8b56b1aa528be3bdd1877e59c56fa90c
https://github.com/jemalloc/jemalloc.git
cd ../bks_module/remoteswap
## on memory server
cd server && make
## on CPU server
cd client && make
cd ../../bks_drv && make
cd ../..  && mkdir build && cd build
cmake ..  && make -j
```

A.6 Running Atlas Applications

```
cd atlas-runtime/bks_module/remoteswap
## on memory server
cd server
##./rswap-server <memory server IB ip>
<memory server IB port> <memory pool size
in GBs> <CPU server core count> e.g.,
./rswap-server 172.16.16.1 9999 48 96
## on CPU server
cd client
## edit `mem_server_ip`,
`mem_server_port` and
`SWAP_PARTITION_SIZE_GB` to be consistent
with memory server parameters
vim manage_rswap_client.sh
bash manage_rswap_client.sh install
## run a test
cd atlas-runtime/build/tests/
runtime/unique_ptr
bash test.sh ./unique_ptr_test
```

Abstract

Despite being a powerful concept, distributed shared memory (DSM) has not been made practical due to the extensive synchronization needed between servers to implement memory coherence. This paper shows a practical DSM implementation based on the insight that the ownership model embedded in programming languages such as Rust automatically constrains the order of read and write, providing opportunities for significantly simplifying the coherence implementation if the ownership semantics can be exposed to and leveraged by the runtime. This paper discusses the design and implementation of DRust, a Rust-based DSM system that outperforms the two state-of-the-art DSM systems GAM and Grappa by up to **2.64**× and **29.16**× in throughput, and scales much better with the number of servers.

1 Introduction

The concept of distributed shared memory (DSM) received significant attention during the early years of distributed computing systems. This era witnessed a plethora of pioneering efforts, as exemplified by seminal works such as [10, 16–18, 31, 36, 49, 50, 56, 61–63, 80]. DSM offers the power of parallel computing using multiple processors and machines and, more crucially, streamlines the development of distributed applications with a unified, contiguous memory view.

The initial enthusiasm for DSM was tempered by significant performance bottlenecks, primarily due to the low network speeds prevalent during its nascent stages. Recent advances in hardware and networking technologies [3, 7, 12, 19, 23, 29, 33, 38, 40, 42, 46, 51, 54, 64, 66, 74, 78] have revitalized the DSM explorations. Several new DSM systems [14, 45, 60, 77, 81, 88] were proposed in recent years to take advantage of these enhanced networks. However, these systems are still far from achieving satisfactory performance, exhibiting poor scalability and substantial slowdown compared to their single-machine counterparts. This is mainly due to the intensive synchronization operations needed to ensure memory coherence across servers.

State of the art. The majority of existing DSM systems [6, 14, 45, 88] adopt an approach to achieve data consistency by adhering to the following invariant: for each data block to be accessed, the block is either located on a single node with potential read and write access, or it is replicated across multiple nodes with each having read access only. Prior to a server attempting to access a block, a DSM system checks the state of the block, invalidates copies of that block on all other servers, and then transmits the block to the requesting server. This synchronization process necessitates multiple network round trips. Even with RDMA, the incurred latency is still orders of magnitude higher compared to a single local access, significantly degrading overall performance. Effectively reducing the number of synchronizations is, therefore, crucial for minimizing DSM overhead and rendering it feasible for real-world deployment.

A practical strategy to minimize synchronization overhead involves implementing high-level protocols to guarantee exclusive access for each server. For instance, Apache Spark [91] utilizes an immutable data structure known as a resilient distributed dataset (RDD) for distributed access. However, RDD only facilitates coarse-grained distributed access, limiting each server to accessing a distinct partition of an RDD. While increasing access granularity enhances performance, it comes at the expense of reduced generality—Spark is tailored for bulk processing of batch data and is incapable of supporting distributed applications requiring object-level accesses, such as social networks where objects of various types and sizes (*e.g.*, images, connections, *etc.*) are created and manipulated upon each user request.

Insights. Our main observation is that synchronization overheads in existing DSM systems are introduced primarily due to the use of a generic approach that overlooks semantic information from programs. For example, many real-world concurrent programs are engineered with a single-writer-multiple-reader (SWMR) discipline to ensure correctness during concurrent operations. Leveraging such information

[⋆] Part of the work was done when Haoran Ma and Shi Liu interned at Alibaba Group.

can potentially eliminate the need to check the state of remote data blocks before accessing them, leading to dramatically improved performance. A major challenge is, however, how to expose such semantics in a sensible way so that the DSM system can see and act upon it.

One approach to convey such semantics, as demonstrated by AIFM [73] and Midas [68], involves exposing APIs that developers can invoke to specify program regions accessible only by a single writer. However, this process is cumbersome and error-prone, demanding a profound understanding of potential executions and involving substantial program writing. Our key insight in this endeavor is that the SWMR programming paradigm aligns seamlessly with *ownership types*, which have already been integrated into programming languages like Rust [75]. Rust is widely employed in the system community for dependable and secure implementation of low-level systems code.

Rust's ownership type inherently upholds SWMR properties in any compiled Rust program. The fundamental concept behind the ownership type is that each value is ensured to have a single unique variable as its owner throughout the execution. While multiple references to a value are allowed, only the owner and mutable references can modify the value. Moreover, only one of these references is permitted to be used for modifying the value at any given point.

When developing a DSM system on top of an ownership-based language like Rust, SWMR semantics are inherently embedded in any Rust program *by design*. Effortlessly extracting such information becomes possible with basic compiler support, sparing developers from the need for code rewriting. Utilizing the SWMR semantics from the program leads to a considerably simplified process for accessing data in DSM. In the case of a write access, the ownership type ensures exclusive access to the data. Consequently, DRust can move the data to the requesting machine, performing the write there without explicitly invalidating its copies on other machines. In the case of a read access, data can be efficiently replicated to (and cached in) each requesting machine, benefiting from the compiler-provided assurance of freedom from concurrent writes.

This paper presents DRust, an efficient Rust-based DSM implementation that enables object-level concurrent accesses by leveraging the SWMR semantics made explicit by Rust's ownership type. DRust automatically turns a single-machine Rust program into a DSM-based distributed version *without requiring code rewriting*. While extracting the ownership semantics appears straightforward, leveraging it to implement a distributed coherence protocol correctly and efficiently presents two main challenges.

The first challenge is *how to manage memory correctly and efficiently*. Rust's ownership type system is inherently designed for a single-machine environment, where the memory address of an object remains constant post-creation. This assumption is disrupted in a distributed environment, where objects may be migrated or duplicated on different machines. Such actions can lead to the risk of dangling pointers, potentially breaking memory coherence.

To tackle these issues, DRust builds a global heap spanning multiple servers based on the idea of partitioned global address space [21]. Each object in the heap has a unique global address in the address space, which can be used for accessing the object from any server. DRust re-implements Rust's memory management constructs to allocate objects in the global heap. Given that a server can have cached objects (to accelerate reads), DRust carefully crafts an ownership-based cache coherence protocol upon the global heap abstraction to achieve both memory coherence and efficiency (§4.1.1).

In a nutshell, our coherence protocol leverages the ownership semantics to eliminate the need for explicit cache invalidation. It allows multiple readers to fetch a copy of the object from its host server and cache it, but disallows any change to the global address and the value of the object. When a write access occurs, it must first borrow the ownership, at which point DRust moves the object in the global heap to a new address on the server issuing the write. The address change of the object automatically invalidates cache copies that use the stale address and triggers the subsequent readers to update the cache by fetching the object from its latest address.

The second challenge is *how to support transparency in programming*. Rust's standard libraries and programs were originally built for running on a single machine, and they cannot deal with distributed resources in a cluster. For example, a Rust program running on server A cannot spawn a thread on another server B, let alone synchronize threads between A and B. To enable a Rust program to run *as is* under DRust, we provide distributed threading utilities by restructuring critical elements of the Rust standard library, including threading, communication channels, and shared-state locks (§4.1.2). Our adapted libraries offer the same interfaces, making them compatible with single-machine Rust programs, but internally invoke our distributed scheduler, which determines where to run the thread and facilitates cross-server synchronization. We built them atop the ownership-based memory model, enabling the DRust runtime to safely pass references of objects between threads and automatically fetch the value from the global heap upon dereferencing.

With our programming abstractions, a Rust application can start on a single server and gradually spawn its threads to other servers. Under the hood, DRust employs a runtime to manage distributed physical compute and memory resources for the application. The runtime runs as a process on each node in the cluster, and they work cooperatively for cross-server memory allocation and thread scheduling. The runtime prioritizes the current server for object allocation and thread creation, but it will schedule the resource allocation request to another server under memory pressure (§4.2.1). To make cluster-wise decisions such as deciding the target server for global memory allocation and thread creation, DRust has a global controller that is launched together with the application. The global controller communicates with DRust runtime on each node to collect resource usage information and applies adaptive policies to achieve load balance (§4.2.2).

Results. We evaluated our system on four real-world applications in an eight-node cluster. Our evaluation demonstrated an average of 2.02× and 9.48× (up to 2.64× and 29.16×) speedup compared with two state-of-the-art DSM systems GAM and Grappa, respectively. Furthermore, DRust incurred a mere 2.42% slowdown compared to the original Rust program on a single machine with sufficient resources. DRust is available at `https://github.com/uclasystem/DRust`.

2 Background in Ownership

Over the past decades, numerous programming languages have been designed to provide safe memory management and data sharing. At the core of such a design is often a tradeoff between memory abstraction level and management efficiency. The ownership concept, and the Rust programming language built upon, are considered promising solutions that achieve a sweet spot between abstraction and efficiency. This section provides an overview of these techniques and explains how ownership can benefit DSM implementations.

Ownership Type. The ownership model has a long history in pursuit of memory-safe language designs and type systems [8, 9, 27, 43, 58, 83]. It has also inspired many systems for safe and efficient resource management [13, 41, 59, 89]. At a high level, ownership enhances a language's type system in a way that guarantees the memory and thread safety of a program with type checking done at compile time. The ownership model encompasses a range of concepts, among which the most important are *lifetimes* and *borrowing*.

An ownership-based type system uses lifetimes to control the allocation/deallocation of objects. It enforces that each object must have one and only one owner at a time. This allows the compiler to statically track an object's lifetime via its owner, and immediately deallocate the object once its owner goes out of scope, preventing memory leaks without using garbage collection that can introduce disruptive pauses to program execution.

To access an object, a program can create a reference from its owner, but the reference must "borrow" the permission from the owner, and "return" it to the owner after the access. Specifically, the type system allows the creation of multiple *immutable references* to an object from its owner for concurrent reads but prohibits any write with these references. It allows only one mutable reference to the object only when no other (mutable or immutable) references exist. Through borrowing, the ownership type disallows simultaneous writers and hence prevents data races. In addition, references must return the borrowed permission when they go out of scope. For any program that demonstrates type soundness, the type checker guarantees that references to an object can only reside within the object's lifetime; the object can be safely and automatically deallocated when its owner goes out of scope, by which time it has already lost all its references.

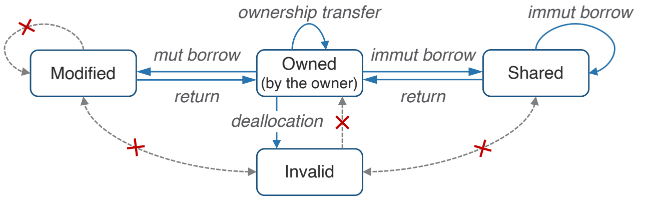

Figure 1: State machine for Rust's ownership-based memory model.

Finally, ownership can be transferred from one owner to another—*e.g.*, at a function call, the creation of a thread, or message passing (*i.e.*, via `channel`). However, the type system enforces that ownership transfer must occur in the absence of "borrowing". In other words, no other references can exist in scope when transferring the ownership, preventing data races during ownership transfers.

The guarantees provided by the ownership model with respect to object lifetime and data sharing can be summarized with the following four invariants:

1. **Singular Owner**: each value has one single owner at any time (which must also belong to one single thread).
2. **Safe Borrowing**: All references are created from the owner; permission borrowing and returning guarantees that references that can be used to access the object must be valid.
3. **Single Writer**: Each object allows one mutable reference at most, and it cannot coexist with any other references in the same scope.
4. **Multiple Reader**: Multiple references are permitted only when all of them are immutable.

The last two invariants are commonly called the single-writer-multiple-reader (SWMR) property in the DSM literature [57].

Rust Language. Rust offers a practical implementation of ownership and is designed with a range of zero-cost abstractions for efficient fine-grained resource management. Figure 1 depicts the state machine for Rust's ownership-based memory model. At a high level, this model restricts that the owner is always in the O (owned) state, and transitions between M (modified), S (shared), and I (invalid) must go through the O state[1]. Clearly, a distributed implementation of this approach avoids broadcasts or snooping, and only requires peer-to-peer message passing.

Listing 1 exemplifies a simple accumulator implemented in Rust (Lines 1–7). The `Accumulator` struct keeps an integer `val` and exposes an interface `add` to increment the value. Rust uses a smart pointer type `Box<T>` to store values on the heap; this pointer serves as the initial owner of the referenced value, as shown in Line 10 and 11. Line 13 instantiates `Accumulator` `a`, where the ownership is implicitly transferred from `val` to `a.val` during its initialization. Rust allows the creation of mutable and immutable references to access the value. For

[1] A transition from M to S is also possible as an optimization in Rust.

```
1  pub struct Accumulator { pub val: Box<i32>, }
2  impl Accumulator {
3    pub fn add(&mut self, delta: &i32)->i32 {
4      *self.val += *delta;
5      *self.val
6    }
7  }
8  fn main() {
9    // Allocates two integers in the heap.
10   let val: Box<i32> = Box::new(5); // val is an owner.
11   let mut b: Box<i32> = Box::new(0); // b is an owner.
12   // Ownership is transferred from val to a.val
13   let mut a = Accumulator{val};
14   { // Only one mutable reference is allowed.
15     let mutr: &mut i32 = &mut *b;
16     // No other reference is allowed now.
17     /* let another_r = &*b; */ // COMPILE ERROR!
18     *mutr = 10; // b == 10
19   }
20   { // Multiple immutable references are allowed.
21     let (b_r1, b_r2): (&i32, &i32) = (&*b, &*b);
22     // Mutable reference is prohibited now.
23     /* let b_mutr = &mut *b; */ // COMPILE ERROR!
24     // Passing by references won't transfer ownership.
25     let sync_add = a.add(b_r1); // a.val == 15
26     let sync_add = a.add(b_r2); // a.val == 25
27   }
28   {// Ownership of a and b is moved to the new thread.
29     // No reference should or can borrow a or b now.
30     let async_add = thread::spawn(move ||
31       a.add(&*b) // a.val == 35
32     ).join(); // lifetime of a and b ends
33     // Current thread cannot access a and b anymore.
34     /* println!("{}", a.val); */ // COMPILE ERROR!
35   }
36 }
```

Listing 1: A simple accumulator implementation in Rust.

example, Lines 14–19 create a singular mutable reference (`&mut`) to `b` and set its value to 10. Similarly, Lines 20–27 create two immutable references (`&`) to `b` and add them to `a` via two function calls. Note that passing references as arguments in function calls does not transfer their ownership.

Finally, Rust allows spawning new threads for concurrent programming, as shown in Lines 28–35. A new thread is created via `thread::spawn`, where the use of `move` captures `a` and `b` in the current scope and transfers their ownership to the newly spawned thread. Rust performs shallow copying for inter-thread communication, where only the pointers stored in `a` and `b` are transferred to the child thread while the actual values on the heap are not moved. Rust guarantees memory safety of `a` and `b` by tracking their ownership. At Line 32, when the child thread finishes its closure (*i.e.*, not necessarily after `join`), and `a` and `b` exit the scope (to which their ownership belongs), their lifetimes terminate and Rust deallocates them from the heap.

3 Motivation

DSM was proposed to eliminate the barrier of distributed programming by offering the same memory consistency model as single-machine shared memory. The core of its design is a software-based cache coherence protocol, which mimics a hardware-based approach on multi-core CPUs and synchronizes memory states on different servers by sending control messages between them. However, it is notoriously hard to implement cache coherence efficiently at the software level due to the high communication latency between physically disjointed servers.

Figure 2: Design overview of DRust.

High Synchronization Overheads for Coherence. To gain a high-level understanding of how much improvement can be achieved by improving the cache coherence protocol, we performed an analysis by running a real-world application DataFrame [67] with a state-of-the-art DSM system GAM [14] with a fast network. We first ran Dataframe on a single server with 16 CPU cores and 64GB memory. We then ran it with GAM on eight servers connected by a 40Gbps Infiniband network by evenly distributing the same amount of resources to eight servers (*i.e.*, each server uses 2 CPU cores and 8GB memory). Our experiments show a **2.4**× slowdown when Dataframe runs on eight servers.

A detailed examination reveals that such a slowdown stems primarily from its complicated coherence protocol. GAM runs a directory-based protocol, which assigns each DSM cache block a home node. Upon each object read/write, the home node tracks the state of its cache block and updates all cache copies for the state change, incurring extensive computation and network overhead. We broke down the average time spent on each component when accessing one object in the DSM. Reading a 512-byte (*i.e.*, GAM's default cache block size) uncached object in GAM takes 16μs, while the actual time to read the object over the network is only 3.6μs. In other words, maintaining cache coherence takes **77%** of the total time. This large memory access overhead significantly increases operation latency, hindering the practical deployment of distributed shared memory. With the single writer invariant inherent in the ownership model, we expect that most of this overhead can be eliminated, leading to significant ($>2\times$) speedups for each access.

4 Design

DRust is an efficient DSM framework atop the Rust programming language. As shown in Figure 2, it consists of

```
1  // Unmodified Rust code.
2  pub struct Accumulator { pub val: Box<i32>, }
3  impl Accumulator {
4    pub fn add(&mut self, delta: &i32)->i32 {
5      *self.val += *delta;
6      *self.val
7    }
8  }
9  fn main() {
10   // Allocates two integers in the distributed heap.
11   let val: Box<i32> = Box::new(5);
12   let b: Box<i32> = Box::new(10);
13   let mut a = Accumulator{val};
14   // a.val and b will be fetched to local.
15   let local_add = a.add(&*b); // a.val == 15
16   // Only refs to a and b are shipped to remote.
17   let remote_add = thread::spawn(move ||
18     a.add(&*b)).join(); // a.val == 25
19 }
```

Listing 2: DRust seamlessly transforms an unmodified accumulator implemented in Rust into a distributed version.

Rust-based programming abstractions for DSM (§4.1) and a runtime (§4.2) that manages distributed physical resources.

DRust is compatible with standard Rust. Listing 2 illustrates how the accumulator (shown in Listing 1) runs on DRust distributively without requiring code rewriting. The program starts running on a single machine A and the DRust runtime gradually allocates its memory and spawns new threads on different machines. Specifically, Lines 10–13 create `Accumulator` `a` and `b` where `a.val` and `b` are in the global heap. We use a global allocator to allocate objects in the global address space and hence these objects may be allocated on a different server. Line 15 synchronously adds `b` to `a` by fetching both values `a.val` and `b` to A's local memory (if they are allocated somewhere else). Line 17 spawns a new thread and ships the function closure to perform `add` asynchronously. This thread will be scheduled on a different server B if A's compute power has been saturated. In this case, DRust performs shallow copying and only ships the pointers stored in `a` and `b` to B without actually moving objects in the global heap. The newly-created thread relies on the DRust runtime to detect data locations and fetch objects upon dereferencing.

4.1 DRust Programming Abstraction

DRust provides each thread with a local stack and abstracts distributed memory as a shared global heap. Each server allocates thread stacks and backs one partition of the global heap with its physical memory. DRust re-implemented core memory management constructs including `Box`, `&`, and `&mut` for transparent heap access. This approach hides the complex details of memory allocation/deallocation, moving objects, and coherence maintenance (§4.1.1). DRust supports distributed threading and synchronization by adapting Rust's standard libraries atop the core language constructs (§4.1.2). Furthermore, DRust offers affinity annotations that allow developers to build more efficient applications by expressing data affinity semantics (§4.1.3).

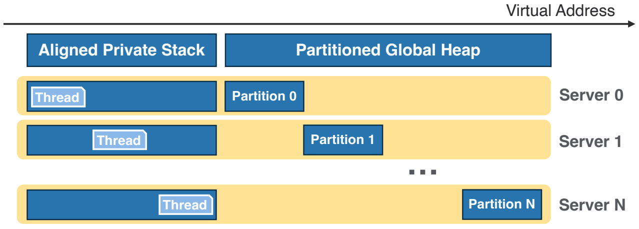

Figure 3: The address space layout of DRust. The stack is private to each thread but they share an aligned address space to ease migration, while the heap is globally shared and partitioned across servers.

4.1.1 Memory Management

Next, we discuss how DRust (re)implements the memory-related language constructs in Rust to achieve memory safety and memory coherence.

Address Space. As shown in Figure 3, DRust maintains an identical address space layout on all servers. It exposes distributed memory as a coherent shared heap to applications. Embracing the idea of partitioned global address space (PGAS) [21], it partitions the heap space and assigns each server a unique address range. The stack, in contrast, is private to each thread. However, DRust aligns the stack space on each server and pads stacks to avoid overlapping. This streamlines thread migration between servers as it allows a thread to keep its private stack address unchanged when being moved.

Coherence Protocol in a Nutshell. For efficiency, DRust employs a *call-by-reference* model for newly created threads. Upon creation of a thread, the DRust runtime only passes references or `Box` pointers to objects to the newly created thread. Upon dereferencing, objects are fetched to the server where the thread is executed.

When a *read access* of an object is issued on a server, our runtime simply fetches a copy of the object from its hosting server and places it in its *local cache*. As a result, multiple copies of the same object may exist on different servers. This allows multiple servers to read the object at the same time from their respective cached copies. Fetching a copy of the object for read does not change the object's address in the global space. When a *write access* occurs on an object, the server issuing the write must first obtain the object's write access permission through a *mutable borrow*. Our reimplementation of mutable borrow (discussed shortly) *moves*[2] *the object in the global heap to a new address* that belongs to that server. In doing so, the object's cached copies on other servers are automatically invalidated without sending explicit invalidation messages—subsequent reads on these servers must obtain an immutable reference to the object through an immutable borrow from its owner pointer, which has been updated to the new address immediately after

[2] The term "copy" is used to describe the process of adding an object into the cache without changing its global address. The term "move" means relocating the object into a server's heap partition, which requires changing its global address.

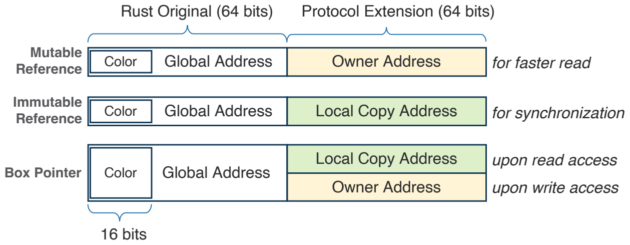

Figure 4: DRust repurposes Rust pointers and references to contain a global heap address and an extension field for its coherence protocol.

the mutable borrow returns. Upon identifying the owner's address change, each immutable borrow would direct a server to fetch a fresh version of the object from the new address as opposed to relying on a stale copy residing in its cache.

Note that this is a general protocol that covers the case that the object is on the same server that issues the write—as long as the server moves the object into a different location in the global heap, no other servers can read the stale copies of the object. However, this is not efficient as each local write requires moving the object to a new address. To address this inefficiency, DRust employs a pointer-coloring technique, inspired by the designs of many concurrent garbage collectors [1, 52]. Discussed at the end of this subsection, this technique offers a more efficient solution for handling local writes.

Pointer Layout. In order to support this protocol, each pointer must remember not only the object's global address, but also the address of the cached copy in a server's local cache (to avoid redundant remote fetches). As such, we modify Rust's pointer structure, as illustrated in Figure 4. DRust internally extends each Rust `Box` pointer and reference with an additional 64-bit field, which is used differently for read and write access. At a high level, the field records the address of the cached copy for faster read accesses; for write accesses, this field records the address of the object's owner for post-write synchronization. Additionally, DRust reserves the highest 16 bits in the global address field as "color" bits. These bits record the version number of the pointer and play a crucial role in DRust's efficient handling of local writes.

Next, we discuss how DRust reimplements Rust's ownership operations to realize the distributed coherence protocol. For ease of presentation, this subsection focuses on a simplified version of the protocol. A complete coherence protocol and its proof of memory coherence are available in [53].

Mutable Borrow. Mutable borrow creates a mutable reference that holds exclusive access to the referenced object for writing. Algorithm 1 outlines the procedures for both dereferencing and dropping a mutable reference. When performing dereferencing, DRust first checks the object's location (Line 2) and performs direct access if the object's address belongs to the heap partition of the machine A that executes the access. Otherwise, DRust *moves* it to A's heap partition (as opposed to caching it) (Line 3). The move, conducted in the following three steps, changes the object's global address. DRust (1) copies the object into A's heap at an address p, (2) updates the mutable reference with the address p, and (3) asynchronously requests the remote server that previously stored the object to deallocate the original object.

Algorithm 1: Access logic for mutable references.

```
Input: A mutable reference $m$ containing a global address
       $m.g$ and the owner address $m.o$.
Output: A local memory address to be written to.
1 Function DEREFMUT ($m$):
2     if $\neg$ISLOCAL ($m.g$) then
3         $m.g \leftarrow$ MOVE (CLEARCOLOR ($m.g$))
4     return CLEARCOLOR ($m.g$)
5 Function DROPMUTREF ($m$):
6     $c' \leftarrow$ GETCOLOR ($m.g$) $+1$
7     WRITE ($m.o$, APPENDCOLOR ($m.g$, $c'$))
```

A challenge arises with its original owner `Box`, which now becomes a dangling pointer, pointing to an invalid memory location. Fortunately, the integrity of the system is maintained by the single-writer invariant (referenced as Invariant 3). This invariant ensures that while the mutable reference remains alive, no other entity, including the original owner, can access the data. To ensure correctness, when this new reference is dropped, DRust synchronously updates the original owner `Box`, redirecting it to the new address p (Line 7). As a result, the original owner always possesses the latest view of the object. Additionally, all modifications made through this mutable reference are visible in all subsequent accesses, as they necessitate borrowing permission from the updated owner `Box`. The single-writer invariant also eliminates the possibility of simultaneous updates to the owner, ensuring that updating the owner is free from concurrency issues.

Immutable Borrow. Immutable borrowing allows concurrent reads to the same object from immutable references on the same or different servers. As detailed in Algorithm 2, DRust handles the dereferencing of immutable references by first checking the object's location (Line 2). For remote objects, DRust creates a local copy in the *per-node read-only "cache"* and records its local address in the reference's extension field (see Figure 4). This preserves the original global address of the object, ensuring that any new immutable reference—whether it is derived from the owner `Box` or from another immutable reference—can always access the original object from the global heap.

As opposed to being a separate memory space, our "cache" provides a "virtual" aggregation of all local copies maintained on each server. These copies reside in the regular heap, managed by a per-node hashmap H. This hashmap maps each global address to a pair of its local address and the number of local immutable references to the local copy. To prevent redundant copies of an object on the same server, DRust checks the hashmap H before creating a new local copy

Algorithm 2: Access logic for immutable reference.

```
Input: A shared immutable reference $r$ containing a global
       address $r.g$ and a local copy address $r.l$, and a local
       cache hashmap $H$.
Output: A local memory address for reading.
1  Function Deref ($r$,$H$):
2      if IsLocal ($r.g$) then
3          return ClearColor ($r.g$)
4      else
5          if $r.l = Null$ then
6              Atomic {
7              if $r.g \in H$ then
8                  $\langle l',cnt\rangle \leftarrow$ GetEntry ($H, r.g$)
9                  $r.l \leftarrow l'$
10                 UpdateEntry ($H, r.g, \langle l', cnt+1\rangle$)
11             else
12                 $r.l \leftarrow$ Copy (ClearColor ($r.g$))
13                 InsertEntry ($H, r.g, \langle r.l,1\rangle$)
14             }
15         return $r.l$
16 Function DropRef ($r$,$H$):
17     if $r.l \neq Null$ then
18         Atomic {
19         $\langle l', cnt\rangle \leftarrow$ GetEntry ($H, r.g$)
20         UpdateEntry ($H, r.g, \langle l', cnt-1\rangle$)
21         }
```

(Line 7). If a local copy is already present, DRust increments its reference count in H and updates the extension field in the immutable reference to point to this copy (Lines 8–10). If no existing copy is found, a new one is created (Lines 12–13). Since the hashmap uses objects' global addresses as keys, if an object has been modified by another server since its last read, its global address must have changed, making cache lookup fail even if a (stale) local copy exists.

DRust actively updates the reference count of each local copy when an immutable reference is either dereferenced or dropped, as outlined in Lines 10 and 20. Utilizing these counts, the DRust runtime periodically scans the "cache" and lazily reclaims unreferenced copies (*i.e.*, those with a zero reference count) under memory pressure (§4.2.1). This mechanism, in conjunction with the safe borrowing invariant (2), prevents the local cache from memory leaks or illegal accesses.

Owner Access without Borrow. DRust treats a direct memory access via the owner `Box` as a pair of mutable/immutable borrow and return. Depending on the reference type, DRust uses the extension field of `Box` accordingly and executes the read/write dereferencing logic. A special case arises when a mutable owner is immutably borrowed and becomes immutable until all borrowed references return. In this case, the owner can only cache the object during the borrow and delay the move until the borrow finishes. This would not create any correctness issues because the owner cannot be used for write access during this period.

Algorithm 3: Utility functions for pointer coloring.

```
Function GetColor ($g$):
    return $g \gg 48$
Function ClearColor ($g$):
    return $g$ & $((1 \ll 48) - 1)$
Function AppendColor ($g$, $c$):
    return ClearColor ($g$) | $(c \ll 48)$
```

Ownership Transfer. Similar to Rust, DRust does not move the actual value during the transfer and only copies the `Box` pointer. DRust additionally checks and resets the pointer's extension field and frees the cached copy in the executing machine's cache to avoid cache leakage.

Memory Deallocation. Like Rust, DRust tracks the lifetime of an object via its owner. Given that ownership transfer is implemented by only evicting the cached copy of the object (without changing its global presence), the memory safety of DRust's global heap is preserved by the singular owner invariant (1). In other words, DRust still guarantees that when an object's owner goes out of scope, the object must be unreachable (and dead) and can be safely deallocated.

Consistency Model. Our protocol, together with Rust's ownership model, offers *sequential consistency* for cross-server memory accesses in safe Rust programs (*i.e.*, following the original Rust, no guarantees can be provided when Rust `Unsafe` is used), which is a strong consistency order. Therefore, it allows any safe Rust program to preserve its memory consistency on DSM. Sequential consistency necessitates a coherent memory system, requiring not only the SWMR invariant but also the *data-value* invariant [57]. In simple terms, the data-value invariant requires that the latest write to a value is immediately visible to subsequent readers. As discussed earlier, DRust's protocol moves an object upon a write and updates the owner immediately. Therefore, the latest value is globally visible after each mutable borrow finishes. Subsequent read accesses, either in the Owned state or the Shared state, are hence guaranteed to see the moved object and read its latest value.

Optimizing for Local Writes. A special case is that a server issues a write to an object that resides in its own heap partition. While the coherence protocol still guarantees safety, requiring moving an object in its local heap each time it is written clearly brings inefficiencies. To optimize for local writes, DRust adopts a pointer-coloring method, inspired by the design of concurrent garbage collectors in a managed runtime system such as JVM [1, 52]. Several utility pointer coloring functions are shown in Algorithm 3 which are used when dereferencing and dropping a reference. We reserve the first 16 bits of a global address as a "color". The color value stored in the object's owner gets incremented upon the expiration of a mutable reference, as detailed in Lines 6–7 in Algorithm 1. Any subsequent immutable borrow would look up the cache with the object's global address. Even if the actual address remains the same, its color changes if a write has occurred. As such, the lookup would not return any stale copy from the local cache.

The 16-bit `color` field may overflow when the pointer keeps being borrowed for local writes on the same server. DRust implements a *move-on-overflow* strategy that moves the object to a new address and resets its color to zero once the maximum color value is reached (2^{16}), thereby preventing overflow and maintaining system integrity and performance.

Writing Unsafe Code in DRust. Rust allows developers to bypass compiler safety checks and write *unsafe* code for low-level operations such as accessing raw pointers and mutating shared variables at their own risk [44, 70]. Since DRust relies on SWMR semantics enforced by Rust's ownership types, DRust ensures consistency and memory safety only in the "safe" Rust code. DRust does not cache objects in unsafe code but allows developers to implement their own cache. Developers must ensure that they do not violate consistency in unsafe code blocks where type safety is not enforced. This caution mirrors practices in other managed languages, like native code in Java and unsafe code in C#. To assist developers, DRust offers primitives such as `dalloc`, `dread`, and `dwrite` for managing data on the global DSM heap.

4.1.2 Adapting Rust Standard Libraries

To further reduce the barrier for programs to run distributively, we reimplement several standard Rust libraries atop DRust's core memory constructs covering four categories: threading for distributed computation (`std::thread`), inter-thread channel for communication (`std::sync::mpsc`), reference-counted pointers for ownership sharing (`std::sync::Rc` and `std::sync::Arc`), and shared-state locks for concurrency control (`std::sync::Mutex` and `std::sync::atomic`).

Threading. DRust's threading library enables Rust threads to run distributively with two major adaptations. First, it enables distributed thread launching by re-implementing the `spawn` interface. Internally, it captures the thread body as a closure during compile time and forwards it to the runtime. During execution, the runtime launches the thread according to each server's load (details in §4.2.1). Second, DRust performs implicit ownership transfers between the parent and the child threads at the start or the end of the child thread execution. Thanks to the distributed ownership transfer support provided by DRust's memory model, the implementation in the threading library is hidden from developers and preserves type soundness and memory safety. Additionally, DRust is compatible with advanced thread utilities such as `thread::scope`, which allows for the spawning of scoped threads that can borrow non-static data. These utilities ensure that all threads are joined at the end of their scope and can internally utilize DRust's functions for spawning and joining threads, thus extending their applicability to the distributed setting.

Inter-Thread Channel. DRust extends Rust's channel to connect two distributed threads for message passing. DRust internally builds a network-based message queue for cross-server messages. Benefiting from the shared global heap, `Box` pointers and references can be safely copied and remain valid across servers. Therefore, the sender can push an object into the channel *as is* without serialization, even if it may contain `Box` pointers. DRust forwards the object binary bytes to the receiver over the network, and the receiver can recover the object from the binary by direct type conversion without deserialization.

Ownership Sharing. Rust allows multiple owners to share an object via reference-counted smart pointers, which count the number of live owners. In this case, smart pointers only have read access, and the object lifetime terminates when all owners die and the reference count hits zero. DRust does not require special treatment for `Rc` as it only allows ownership sharing inside a single thread. For `Arc` which shares ownership among multiple threads, DRust handles it in a similar way to immutable references with on-demand local caching and lazy eviction.

Shared-State Concurrency. Rust supports shared-state concurrency, primarily through its atomics and mutexes, where threads commonly share an atomic-typed value or one mutex via ownership sharing (*i.e.*, `Arc`). Unfortunately, the ownership model cannot type check concurrent read/write to shared states. Hence, Rust relies on an *unsafe* implementation in its standard library. §4.1.1 already provides a general discussion on writing unsafe code in DRust, and here we focus on DRust's implementation for distributed shared states.

Shared states create a unique challenge for DRust, as they may be replicated on multiple servers and those states must be synchronized among these servers. For example, an `Arc<AtomicBool>` may be replicated across different servers and used independently, causing multi-version issues if not synchronized properly. DRust addresses this inconsistency by allocating the actual value on the global heap and storing only the `Box` pointer in `atomic` types. This design allows atomics to be freely moved or replicated across servers while keeping a single version of the actual value. To synchronize concurrent operations on atomics, DRust adapts methods of atomic types to forward the operation as a message to the server storing the actual value, which serializes all operations with unsafe logic similar to the original Rust to guarantee atomicity and memory consistency. Similarly, DRust implements `Mutex` by allocating its metadata and owned object on the global heap and leaving only `Box` pointers in the mutex struct. Concurrent operations on mutexes are serialized on the server storing the mutex.

```
1  pub struct Node { val: i32, next: Option<TBox<Node>>, }
2  pub struct List { pub head: Option<Box<Node>>, }
3  impl List {
4    pub fn sum(&self) -> i32 {
5      let mut total: i32 = 0;
6      if let Some(r) = &self.head {
7        let mut node = &**r; // Fetch whole list to local.
8        loop { // Iterate every list node.
9          // Accessing node is guaranteed local.
10         total += (*node).val;
11         if let Some(next) = &node.next {
12           node = &**next;
13         } else { break; }
14       }
15     }
16     total
17   }
18 }
```

Listing 3: A linked list implementation with TBox in DRust. The use of TBox ties list nodes one by one. Iterating a list will fetch all nodes together (if they are on another server), and henceforth accessing any node is guaranteed local.

4.1.3 Affinity Annotations

To further improve performance, DRust allows developers to provide optional data affinity semantics via annotations. These annotations are useful for many datacenter applications that make extensive use of object-oriented data structures that require *pointer-chasing* to access. For instance, Memcached [55] uses a chained hash table where each hash bucket stores its KV pairs with a linked list. To find one KV pair from a bucket, Memcached has to iterate the linked list following the node pointers. However, frequent pointer chasing is unfavorable in a distributed setting, where each pointer dereference incurs additional runtime checks and potential cross-server traffic. It would be beneficial for the runtime to colocate them on the same server and schedule the computation there.

Data-Affinity Pointer. To expose data affinity for clustered placement, DRust includes a new pointer type TBox for developers to “tie” a heap object to its owner. TBox shares the same interfaces as the ordinary Box and can be used as a drop-in replacement for Box. However, TBox enforces that the pointed-to object must reside on the same server as its owner. In other words, when its owner object is copied or moved, the object referenced by TBox will be copied or moved as well. TBox can be used in a nested manner to allow a large union of objects to be co-located. The DRust runtime fetches (*i.e.*, copies or moves) them together in a single batch, leading to fewer network round-trips and higher throughput. TBox can also be assigned to and owned by a stack variable, in which case the referenced object is pinned onto the heap partition of the server that hosts the stack and cannot be moved. Dereferencing a TBox is thus guaranteed to be a local access—DRust optimizes it by skipping the runtime check.

Listing 3 presents a linked list implementation using TBox. Our linked list uses TBox (Line 1) to specify the data affinity between consecutive nodes. As a result, all list nodes are chained with TBox, forming an affinity group. Line 4–17 define a sum function that calculates the total sum of all node values. Assuming the list is non-empty, Line 7 dereferences the pointer to the head node, and the DRust runtime checks the location of the head node and fetches the entire list of nodes together if they are not local. Next, accessing each node inside the loop body (Line 8–14) is guaranteed local and hence skips runtime checks. Compared to using Box directly, TBox makes both data fetching and accessing more efficient.

```
1 fn main() {
2   let val: Box<i32> = Box::new(5);
3   let mut a = Accumulator{val};
4   let remote_add = spawn_to(a.val, move ||
5     a.add(10)).join(); // a.val == 15
6 }
```

Listing 4: A distributed accumulator can leverage spawn_to to offload a thread to the server where a.val locates.

Data-Affinity Thread. To expose the affinity between data and computation for thread scheduling, DRust extends its threading library with a spawn_to interface. spawn_to mirrors the ordinary spawn interface to spawn a new thread but takes an additional Box pointer argument, which indicates where the thread should be created. The runtime checks where the Box points to and creates the new thread on that same server. A common practice to use spawn_to is to pass the mostly-accessed object as the location indicator. Listing 4 presents how the distributed accumulator (shown in Listing 2) can use spawn_to to offload a thread to the same server as a.val resides. Line 5 hence performs local dereference to a.val inside a.add().

4.2 DRust Runtime System

DRust’s runtime system is the core component that manages memory and compute resources. It includes a runtime library (§4.2.1) that is linked to each application and launched on each server and a cluster-wise global controller (§4.2.2).

4.2.1 Application-Integrated Runtime

The runtime library consists of a communication layer to support inter-server coordination and data transfer, a heap allocator to manage the heap partition and the read-only cache, and a thread scheduler to launch and schedule application threads.

Communication Layer. The DRust runtime uses its communication layer to support the cache coherence protocol and cross-server memory accesses. The communication layer consists of a control plane and a data plane, both built with RDMA. The control plane leverages *two-sided verbs* to send and receive small control messages, and the receiver can perform the coherence logic upon receiving the message to minimize the end-to-end latency. The data plane, in contrast, is specialized for bulky data transfer with one-sided verbs. It fetches an object as a whole with a single RDMA message upon pointer dereferencing without interrupting the target server, minimizing both latency and CPU usage.

Heap Allocator. The DRust runtime provides standard memory allocation interfaces and always returns global addresses to the upper-level language abstractions. It prioritizes local memory allocation as long as the local heap partition has sufficient space. This strategy improves data locality by colocating an object with its creating thread.

When the local heap partition is depleted, DRust queries the global controller and allocates memory on the most vacant server. For remote memory allocation, it forwards the request to the target server by sending a message through the communication layer and returns the allocated address to the user. Memory deallocation follows a similar logic but it bypasses the controller and finds the server directly via the object's global address. The allocator does not reserve separate space for the local cache. Instead, it manages the cache as part of the local heap partition and always allocates cached entries in the local heap partition. Under memory pressure, the allocator will scan the local cache and evict entries that are no longer used (*i.e.*, reference count hits zero).

Thread Scheduler. The DRust thread scheduler runs in the user space and schedules threads locally to maximize CPU utilization. It also provides thread migration functionalities, facilitating the global controller to balance load between busy and vacant servers.

The scheduler represents a newly created user thread as a closure, which includes a function pointer and a set of initial arguments (*i.e.*, references). It collaborates with the global controller to allocate a unique stack space for a thread (see Figure 3), and starts the thread by executing the closure.

The scheduler adopts the method of cooperative multitasking and context switches between threads *non-preemptively*. A running thread yields its control flow proactively when developers call `await` or reactively upon long-latency operations. Similarly to other systems [60, 65, 82], our scheduler handles context switches as function calls, which allow DRust to save only a few registers per thread.

The scheduler supports creating/migrating a thread to another server as well. To migrate a thread, DRust sends its function pointer, the saved register state, and its stack to the target server. Because each thread reserves its stack address range globally, DRust can copy the stack across servers without changing its address. Therefore, the thread can be easily resumed by directly calling the function pointer with the saved register state on the target server. DRust generates code for state transmission during the compile time for the scheduler to call upon thread migration.

4.2.2 Global Controller

The controller runs as a daemon process on the machine where the program is launched. It manages cluster resources and coordinates memory allocation and thread migration. It periodically pings each server to probe and record its resource usage (CPU and memory). It controls resource allocation in cooperation with the DRust runtime on each server. When allocating memory or creating a thread, the runtime will first query the controller, which chooses a target server following adaptive policies (discussed later), and then coordinate with the runtime on the target server to perform the actual operation. The controller also maintains a global table to track the location of each thread; the table is queried and updated by the scheduler when migrating a thread.

During program execution, servers may run into imbalanced loads when objects get relocated or new threads are created. DRust balances the load of each server by *migrating* threads from the busy server to less occupied ones, following an adaptive policy to minimize cross-server memory accesses. If a server is about to run out of memory (>90% memory usage), the controller keeps migrating the thread that consumes the most local heap memory until the pressure is resolved. If the server is under compute congestion (>90% CPU usage), the controller migrates threads that frequently access remote objects. The thread is then moved to the server it accesses the most unless the target server is also overloaded, in which case it moves to a vacant server instead.

4.2.3 Fault Tolerance

In DRust, the global heap can be replicated to tolerate failures. Replication creates copies for each heap partition at the same virtual address on backup servers. Threads, in contrast, are not replicated for efficiency and are only executed with the primary global heap. To maintain a synchronized view between the primary heap partition and its backup copy, a thread must additionally write back to the backup partition after each mutable borrow. However, our insight is that the thread can batch modifications to an object and delay the write-back until the object ownership is transferred to another server, which is the time point that the object becomes visible to threads on other servers. When a server with a primary heap partition fails, the controller will automatically promote its backup server to the primary and add a new backup server.

5 Implementation

The majority of DRust was implemented in Rust except for its communication library which is in C. We implemented DRust's core language constructs as three Rust types (*i.e.*, `struct`): `Ref<T>`, `MutRef<T>`, and `DBox<T>`. They serve as the counterpart for the original Rust `&T`, `&mut T`, and `Box<T>`, respectively. We implemented the coherence protocol with traits on these types, including `Copy`, `Clone`, and `Drop`, which are automatically embedded into the program source code and executed when references/pointers are created or destroyed. To support unmodified Rust programs, we changed the Rust compiler and added additional compilation passes to transform Rust references and `Box` pointers into corresponding types in DRust.

Our communication layer links `libibverbs` directly for fast and kernel-bypassing RDMA networking. We implemented a low-level C library that covers basic connection establishment and exposes high-level Rust interfaces for various RDMA verbs, including `RDMA_READ`, `RDMA_WRITE`, `RDMA_SEND`, `RDMA_RECV`, `ATOMIC_FETCH_AND_ADD`, and `ATOMIC_CMP_AND_SWP`.

We primarily utilize one-sided `READ` and `WRITE` verbs for data transfers between servers, as they outperform the two-sided `SEND`/`RECV` counterparts—one-sided operations bypass the CPU and OS at the receiver side, whereas two-sided operations require the receiver to pre-post `RECV` verbs and await notification upon message arrival. For instance, when a remote object is accessed via mutable references, DRust copies the object to local memory using the `READ` verb. Upon dropping the reference, DRust updates the original owner `Box` to reflect the new address, a process executed using the `WRITE` verb. Conversely, two-sided `SEND`/`RECV` verbs are utilized for control message exchanges, such as establishing connections across servers. Atomic verbs `ATOMIC_FETCH_AND_ADD`, and `ATOMIC_CMP_AND_SWP` are primarily utilized for implementing shared states (e.g., atomic types and mutexes). DRust uses the RC (reliable connection) transport type to ensure reliable transmission and strict message ordering.

Our heap allocator implementation piggybacks Rust's original allocator and aligns its virtual address range with the heap partition range. Our thread scheduler was built upon Tokio [82] for its efficient user thread and cooperative scheduling integration. The global controller is responsible for managing all threads in the cluster and padding their stacks to avoid address overlapping.

6 Limitations

DRust's design has three limitations. First, although DRust permits the use of unsafe code, its consistency guarantees are only applicable to safe Rust code. In unsafe code blocks, developers are responsible for ensuring consistency themselves. Second, DRust's superior performance relies on SWMR semantics exposed by applications. In cases where data is mostly under shared states (such as `Mutex`), DRust degenerates into a traditional DSM system; all concurrent accesses to the same data have to be centralized and serialized by the server responsible for the shared states. However, such scenarios contradict Rust's recommended programming practices. Finally, the current implementation of DRust does not support address space layout randomization (ASLR) yet, and we have temporarily disabled it. However, DRust's design is compatible with ASLR as long as DRust threads share the same randomized address space layout on each server. This can be achieved by delegating the randomization of stack and heap address allocation in DRust to its global controller, a feature that will be supported in future versions of DRust.

7 Evaluation

Setup. We evaluated our system on an 8-node cluster, where each node was equipped with dual Intel Xeon E5-2640 v3 processors (16 cores), 128GB of RAM, and a 40 Gbps Mellanox ConnectX-3 InfiniBand network adapter, connected by a Mellanox 100 Gbps InfiniBand switch. All servers ran Ubuntu 18.04 with kernel 5.14. We disabled hyperthreading, CPU frequency scaling, OS security mitigations in accordance with common practices [69, 72].

Application	**Dataset**	**Memory (GB)**	**Comp. Intensity (cycles/byte)**
DataFrame [67]	h2oai [37]	64	110.13
SocialNet [32]	Socfb-Penn94 [71]	64	86.09
GEMM [11]	LAPACK [2]	96	300.63
KV Store [14]	YCSB [22]	48	48.15

Table 1: Applications used in the evaluation.

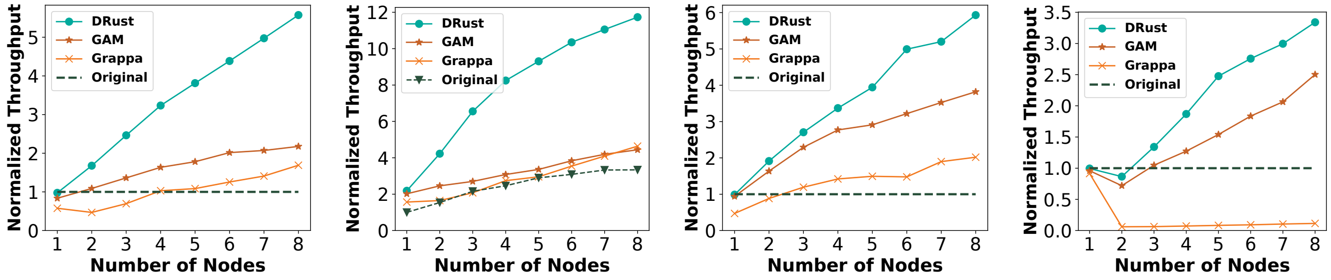
Methodology. We compared DRust with two state-of-the-art DSM systems, GAM [14] and Grappa [60]. For a fair comparison, we ported the evaluated applications to each baseline system and invested extensive effort in tuning parameters to achieve their best possible performance. GAM offers ordinary object read/write interfaces, and we exported it as a library to Rust and hooked pointer dereferencing to use GAM's API without program modification. Grappa, in contrast, offers a drastically different programming abstraction that requires rewriting the program to access shared memory via *delegation*. Therefore, we re-implemented applications in C++ and re-structured them using Grappa's abstractions.

7.1 Applications

We evaluated four representative datacenter applications covering a wide range of use cases and resource demands, including data analytics, microservices, scientific computation, and key-value storage, as shown in Table 1.

DataFrame is an in-memory data analytics framework similar to Spark [91] and Pandas [90]. We built our library atop Polars [67], a native DataFrame engine in Rust offering OLAP query APIs such as `filter`, `groupby`, and `join`. DataFrame organizes the dataset as columnar format tables in shared memory, and user queries will manipulate table columns by reading/writing rows and transforming them into new tables. DataFrame exploits data-level parallelism by internally partitioning columns by row into an array of small chunks where each chunk can be processed independently. We additionally applied `TBox` to annotate chunks from the same table column for co-location and used `spawn_to` to offload columnar operations to the data side to improve data locality and performance. Note that such annotations were not necessary for the application to run; they were added for additional performance optimizations.

SocialNet is a twitter-like web service from the DeathStarBench suite [32]. It is composed of 12 microservices with complicated call dependencies. Each microservice in SocialNet can scale independently with replicas, thereby offering higher throughput with more servers. SocialNet decouples the process of user texts, media resources, and storage into different microservices, and it employs RPCs to pass values (texts, media files, *etc.*) between them. DRust enables



(a) DataFrame (318 s) (b) SocialNet (120 ops/s) (c) GEMM (1039 s) (d) KV Store (2.7 Mops/s)

Figure 5: Application throughput when running with DRust, GAM, and Grappa, normalized to the throughput of their original implementation running on a single node. The number in the parenthesis is the original application's throughput on a single node.

SocialNet to pass only references in RPCs, eliminating the serialization/deserialization overhead and redundant data copies. Because SocialNet was implemented in C++ and deployed with Docker Swarm [28], we ported it into Rust for our evaluation. We followed its original microservice structure but changed the RPC call sites to pass references instead of values, and we followed the original orchestration configuration to spread and scale each microservice in the cluster. We did not use any affinity annotations for SocialNet.

GEMM (general purpose matrix multiplication) is a highly-optimized matrix multiplication routine from the BLAS library [11]. We ported the library using the same divide-and-conquer algorithm by recursively partitioning each matrix into small chunks for parallel processing and reducing the final results. Input and output matrices are stored in the shared memory, where each subroutine will read two input matrix chunks and write the partial results back to the output matrix. Our port strictly followed the original implementation without using additional affinity annotation.

KV Store is an in-memory key-value cache engine similar to Memcached [55]. It uses a hash table to store KV pairs in shared memory and mutexes to synchronize concurrent requests. We used YCSB benchmark [22] to generate zipf load with 90% GET and 10% SET using default skewness parameter 0.99.

7.2 Scaling Performance

In this experiment, we investigated whether DRust can speed up applications by distributing them in a cluster and how well they can scale with the number of servers used. For each application, we first ran it *as is* on a single server without using DSM and measured its throughput. Then, we ran the same application on DSM (subject to modifications when running Grappa) with the same configuration but on varying numbers of servers and measured the throughput normalized to its single-node throughput (*i.e.*, strong scaling). As GAM and Grappa cannot adaptively balance the workload across servers, we evenly distributed the application's working set and threads among all participating nodes. Ideally, an application should scale linearly and enjoy proportionally higher throughput with more nodes. However, this is usually unachievable because of the limited parallelism of real-world applications and the coherence overhead of DSM systems, and a good result for DRust will show that applications' throughput can get close to their ideal throughput.

Figure 5 shows the results for each application respectively. DRust outperforms both GAM and Grappa in all cases. On a single node, it is 1.04–2.10× faster than two baseline DSMs, while only adding a maximum overhead of 2.42% compared to the original program. When running with multiple nodes, DRust scales up applications significantly better than GAM and Grappa. On eight nodes, DRust achieves a throughput that is 1.33–2.64× higher than that of GAM, 2.53–29.16× higher than that of Grappa.

Compared to each program's single-machine performance, using DSM over DRust enables each program to easily leverage the available distributed resources and achieve a throughput that is 3.34–11.73× higher than their single-machine counterparts. Next, we discuss each application to explain the scalability difference between DRust and the baseline DSMs.

DataFrame. As shown in Figure 5a, compared with its original version, DataFrame running on eight nodes with DRust achieves 5.57× higher throughput, whereas with GAM and Grappa, the throughput improvements are 2.18× and 1.69×, respectively. In other words, DataFrame with DRust is 2.56× and 3.29× faster than GAM and Grappa on eight nodes, respectively.

A detailed examination reveals that the performance difference comes from the *shared index table* in each DataFrame operation and the *shared chunks* between dependent DataFrame operations. In each operation, DataFrame constructs an index hash table to track the mapping from each destination chunk in the output column to all its source chunks in the input column. This index table is shared by all index-builder threads and worker threads. During processing, index-builder threads will concurrently insert into the index table using the destination chunk ID as the key and an array of source chunk IDs as the value, and worker threads will look up the shared index table and retrieve source chunks for processing. As a result, the massive writes and reads to the shared table can incur heavy coherence overhead. Further, DataFrame passes chunks as references between dependent operations and relies on the DSM system for actual data movement. However, it only performs lightweight computation over the fetched data (*i.e.*, low compute intensity as shown in Table 1), making the coherence overhead stand out.

DRust outperforms GAM and scales much better because of its light coherence protocol, which incurs negligible object move overhead for writes and no coherence overhead for reads. The use of affinity annotations also helps DataFrame colocate worker threads with their frequently accessed data, bringing 20% additional boost (details in §7.3). GAM, in contrast, has to invalidate each cache block upon each write and read, thereby bottlenecked by the extensive coherence traffic. Grappa performs the worst in all three DSM systems due to its *always-delegation* programming model, which implements every global memory read/write via a delegated function call. The cost for delegation overwhelms the actual memory access latency in this case, ruining the performance of the shared hash table. Grappa's delegation overhead actually causes a 1.23× slowdown when scaling DataFrame from a single node to two nodes.

SocialNet. Since SocialNet is microservice-based and can be deployed distributively, we added another baseline by running the original (non-DSM) code but deploying it on varying numbers of nodes. Figure 5b demonstrates the performance of all systems. SocialNet runs consistently faster with all three DSM systems compared to the original version. DRust, GAM, and Grappa achieve a 2.18×, 2.02×, and 1.57× speedup on a single node and a 3.51×, 1.33×, and 1.39× speedup on eight nodes, respectively. In the conventional setup, SocialNet requires data—such as text and media files—to be serialized into byte streams for network transmission, and then deserialized back into usable formats at the receiving end. This serialization and deserialization process is computationally intensive, particularly for large or complex data objects. In contrast, DSM systems enable SocialNet to pass references instead of the entire data values required by remote procedure calls. This approach eliminates the need for serialization and deserialization, reduces redundant data copies, and significantly enhances performance. DRust scales much better than GAM and Grappa thanks to its lightweight coherence protocol, achieving up to 2.77× and 3.16× higher throughput than GAM and Grappa, respectively.

GEMM. GEMM differs from the previous two applications in its high compute intensity and relatively infrequent shared memory accesses. In this application, matrices are transformed and divided into smaller sub-matrices for parallel processing. Each computing thread, responsible for multiplying sub-matrices, is assigned to a server. These threads cache their respective sub-matrices in the server's local memory and access them repeatedly to compute product results. This process is highly compute-intensive. As depicted in Figure 5c, DRust and GAM scale well for GEMM and achieve 5.93×, 3.82× speedup with eight nodes. In contrast, Grappa only achieves a 2.02× speedup with eight nodes due to its inability to cache sub-matrices locally, necessitating frequent remote accesses. DRust's superior performance over GAM, with a 1.55× higher speedup on eight nodes, is primarily due to its more efficient handling of initial cross-server data accesses required when a sub-matrix is first accessed remotely. Unlike GAM, which incurs significant runtime overhead due to the maintenance of state and location of data copies, DRust directly copies data to local memory, without any complex cross-server synchronization operations, thus enhancing overall efficiency.

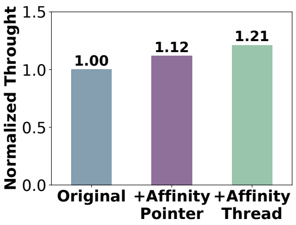


Figure 6: Effectiveness of DRust's affinity annotations.

Latency (cycles)	Average	Median	P90
`DRust`	395	356	536
`Rust`	364	332	496

Table 2: DRust's `Box` pointer only adds a small dereferencing cost compared to Rust's ordinary `Box`.

KV Store. KV Store is the most DSM-unfriendly application in our evaluation because it exposes poor memory locality and low compute intensity, which amplifies the overhead of cross-server memory accesses. In addition, it uses mutexes to synchronize between workers and the structure of the program does not lend itself to ownership-based read/write ordering.

Figure 5d shows the results. KV Store experiences a slowdown on all three DSM systems when scaling from a single node to two nodes (13% for DRust, 25% for GAM, and 93% for Grappa). However, the impact is mitigated when more servers are enlisted—DRust and GAM achieve 3.34× and 2.50× higher throughput on eight nodes compared to the original KV Store implementation, respectively. Due to the limited ownership semantics exposed by mutexes, DRust does not scale as well with KV Store as with other applications. DRust is 1.33× faster than GAM on eight nodes, benefiting from its adaptive load balancing and a more efficient implementation of mutexes utilizing one-sided RDMA atomic verbs, whereas GAM depends on less efficient two-sided RDMA messages for synchronization. Grappa, in contrast, incurs the highest distribution overhead and poorest scalability, primarily because each PUT/GET operation requires remote delegation, and nodes handling popular objects become bottlenecked due to skewed load.

7.3 Drill-Down Experiments

Affinity Annotations. In this experiment, we evaluated the individual contributions of affinity annotations by enabling each of them incrementally for DataFrame on eight nodes. Figure 6 reports the results. Using `TBox` helps DataFrame group chunks from the same column and eliminates the runtime dereference check overhead for single-column operations (*e.g.*, `filter`), bringing a 12% throughput improvement. Adding `spawn_to` further improves the throughput by 9% by

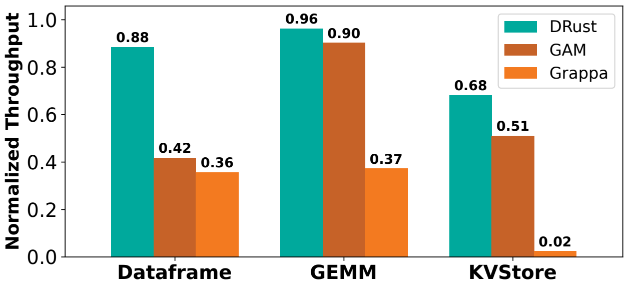

Figure 7: Comparison of cache coherence costs between DRust, GAM, and Grappa on eight nodes.

informing DRust runtime to colocate the worker thread to its input columns, which reduces cross-server memory accesses.

Runtime Dereference Checks. We measured the latency of dereferencing DRust's `Box` pointer and compared it with an ordinary Rust `Box` pointer. Both of them point to an 8-byte object in local memory and not in CPUs cache, which represents the common path for pointer dereferencing. Table 2 reports the results. DRust only adds a small overhead of ∼30 cycles. Note that this microbenchmark is extremely memory-intensive, whereas real-world applications usually employ larger object sizes and are more compute-intensive, further mitigating the runtime check overhead. For our evaluated applications, we observed a 1.02% overhead for DataFrame and a 1.14% overhead for BLAS, when they run with DRust on a single node, respectively.

Thread Migration Latency. To quantify how quickly DRust can resolve the workload imbalance, we measured the latency for the DRust runtime to migrate a thread by running GEMM on eight nodes and repeated the experiment for ten times. On average, DRust migrated 15 threads with an average of 218μs latency for each migration.

Cost of Cache Coherence. In this experiment, we ran each application again on a single node and eight nodes but fixed the total amount of CPU and memory resources. For the eight-node setting, we distributed the resources evenly to each node and measured application throughput. We expect to see a slowdown due to the cost of running the coherence protocol and cross-server memory accesses, but a good result for DRust should show that application performance remains close to its original single-node version. Figure 7 reports the results. SocialNet uses pass-by-value RPCs in its original version and is significantly slower than our DSM-based version, so it is omitted in the evaluation. DRust adds only moderate cache coherence cost with an overhead of 32% in the worst case (KV Store) and 4% in the best case (GEMM). GAM and Grappa, in contrast, incur much higher overheads ranging from 10% to 98% for different applications.

8 Related Work

Software DSM Systems. Distributed cache coherence protocols and their implementations for DSM have been extensively studied since 1980s [16–18, 31, 36, 49, 50, 56, 61–63, 80]. Among them, Munin [10] and TreadMarks [6] proposed relaxed consistency models and simpler protocols trying to alleviate the coherence overhead. Recent DSM systems leveraged today's advanced hardware such as RDMA [14, 45, 60, 77, 81, 92] to improve efficiency.

Disaggregated and Remote Memory. Memory disaggregation and remote memory techniques are another promising approach to scaling applications out of a single machine. Their key idea is to connect a host server with large memory pools [33, 40, 46] via fast datacenter network, which can be accessed by applications via OS kernel [4, 69, 76, 86] or software runtimes [34, 52, 73, 84, 85, 87]. However, they do not provide cache coherence.

Distributed Programming Abstractions. Researchers have studied and proposed new programming languages and abstractions. Munin [10] built a type system that defines types for local and global pointers and tracks whether the pointer is shared via type checking. X10 [20, 39] and UPC [30] introduce function offloading interfaces for distributed computing and additional type annotations to reduce the runtime overhead. Ray [89] and Nu [72] are two recent systems proposing new abstractions for distributed programming. Unlike DRust, they require effort to port applications to avoid fine-grained memory sharing.

Hardware-Accelerated DSM. Specialized datacenter network technologies and emerging hardware designs stand for another trend to accelerate DSM. Clio [35], StRoM [79], and RMC [5] reduce remote memory access latency by offloading tasks into customized hardware. Concordia [88], Kona [15], and CXL [23–26, 47, 48, 92] enable block-level or cache-line-level memory coherence with their hardware-implemented protocols. DRust can benefit from advances in hardware support and achieve better scalability.

9 Conclusion

This paper presents DRust, a practical DSM system based on the ownership model. It automatically turns a single-machine Rust program into its distributed version with a lightweight coherence protocol guided by language semantics. DRust significantly outperforms existing state-of-the-art DSM systems, demonstrating that a language-guided DSM can achieve strong memory consistency, transparency, and efficiency simultaneously.

A Artifact Appendix

A.1 Artifact Summary

DRust is an efficient, consistent, and user-friendly DSM system featuring a lightweight coherence protocol guided by language semantics. DRust allows for seamless scaling of single-machine applications to multi-server environments without sacrificing performance. Demonstrating significant improvements over existing DSM systems, DRust combines strong memory consistency, transparency, and efficiency effectively.

A.2 Artifact Check-list

- **Hardware:** Intel servers equipped with InfiniBand

- **Software Environment:** Rust 1.69.0, GCC 5.5, Linux Kernel 5.4, Ubuntu 18.04, MLNX-OFED 4.9

- **Public Link to Repository:** https://github.com/uclasystem/DRust

- **Code License:** GNU General Public License (GPL)

A.3 Description

A.3.1 DRust's Codebase

DRust comprises four main components:

- An RDMA communication library written in C
- The DRust library
- Applications integrated with DRust
- Necessary shell scripts and configuration files

A.3.2 Deploying DRust

The initial step in deploying DRust involves cloning the source code on all involved servers:

```
git clone git@github.com:uclasystem/DRust.git
```

Adjust several configurations according to your server setup and operational requirements:

1. Set the Number of Servers:

    - Define TOTAL_NUM_SERVERS in comm-lib/rdma-common.h based on the total number of available servers.

    - Similarly, adjust NUM_SERVERS in drust/src/conf.rs.

2. Configure the Distributed Heap Size by setting UNIT_HEAP_SIZE_GB in drust/src/conf.rs to the required heap size per server, e.g., 16 for 16GB.

3. Update the InfiniBand IP addresses and ports in comm-lib/rdma-server-lib.c:

    ```
    const char *ip_str[2] = {"10.0.0.1",
    "10.0.0.2"};
    const char *port_str[2] = {"9400", "9401"};
    ```

4. In drust.json, update each server's IP address and specify three available ports.

Following configuration, build DRust as follows:

```
# Compile the communication static library
cd comm-lib
make -j lib
# Copy the static library to the DRust directory
cp libmyrdma.a ../drust/
# Compile the Rust components
cd ../drust
cargo build --release
```

Deploy the compiled binary across all servers post-build, ensuring its correct distribution:

```
scp target/release/drust user@ip:DRust/drust.out
```

A.3.3 Running Applications

DRust is bundled with four example applications: Dataframe, GEMM, KVStore, and SocialNet. Follow these steps to execute them:

1. Launch the DRust executable on all servers, excluding the main server:

    ```
    # Start the DRust process with the specified
    server index and application name.
    # For example, ./../drust.out -s 7 -a gemm
    cd drust
    ./../drust.out -s server_id -a app_name
    ```

2. On the main server:

    ```
    # Start the main DRust process with the
    specified application.
    cd drust
    ./../drust.out -s 0 -a app_name
    ```

More details of DRust's installation and deployment can be found in DRust's code repository.

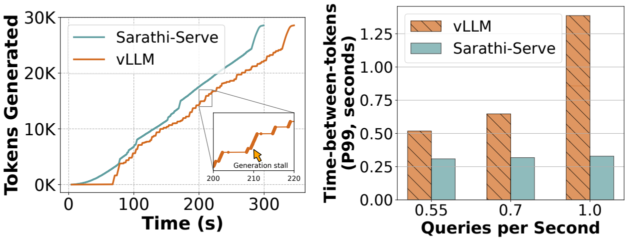
Abstract

Each LLM serving request goes through two phases. The first is *prefill* which processes the entire input prompt and produces the first output token and the second is *decode* which generates the rest of output tokens, one-at-a-time. Prefill iterations have high latency but saturate GPU compute due to parallel processing of the input prompt. In contrast, decode iterations have low latency but also low compute utilization because a decode iteration processes only a single token per request. This makes batching highly effective for decodes and consequently for overall throughput. However, batching multiple requests leads to an interleaving of prefill and decode iterations which makes it challenging to achieve both high throughput and low latency.

We introduce an efficient LLM inference scheduler, Sarathi-Serve, to address this throughput-latency tradeoff. Sarathi-Serve introduces *chunked-prefills* which splits a prefill request into near equal sized chunks and creates *stall-free* schedules that adds new requests in a batch without pausing ongoing decodes. Stall-free scheduling unlocks the opportunity to improve throughput with large batch sizes while minimizing the effect of batching on latency. Furthermore, uniform batches in Sarathi-Serve ameliorate the imbalance between iterations, resulting in minimal pipeline bubbles.

Our techniques yield significant improvements in inference performance across models and hardware under tail latency constraints. For Mistral-7B on single A100 GPUs, we achieve 2.6× higher serving capacity and up to 3.7× higher serving capacity for the Yi-34B model on two A100 GPUs as compared to vLLM. When used with pipeline parallelism on Falcon-180B, Sarathi-Serve provides up to 5.6× gain in the end-to-end serving capacity. The source code for Sarathi-Serve is available at https://github.com/microsoft/sarathi-serve.



(a) Generation stall.

(b) High tail latency.

Figure 1: Yi-34B running on two A100 GPUs serving 128 requests from *arxiv-summarisation* trace. 1a highlights one of the many generation stalls lasting over several seconds in vLLM [53]. 1b shows the impact of increasing load on tail latency. Sarathi-Serve improves throughput while eliminating generation stalls.

1 Introduction

Large language models (LLMs) [34,35,52,57,71] have shown impressive abilities in a wide variety of tasks spanning natural language processing, question answering, code generation, etc. This has led to tremendous increase in their usage across many applications such as chatbots [2, 5, 6, 57], search [4, 9, 11, 19, 25], code assistants [1, 8, 20], etc. The significant GPU compute required for running inference on large models, coupled with significant increase in their usage, has made LLM inference a dominant GPU workload today. Thus, optimizing LLM inference has been a key focus for many recent systems [29, 53, 58, 59, 63, 75, 77].

Optimizing throughput and latency are both important objectives in LLM inference since the former helps keep serving costs tractable while the latter is necessary to meet application requirements. In this paper, we show that current LLM serving systems have to face a tradeoff between throughput and latency. In particular, LLM inference throughput can be increased significantly with batching. However, the way existing systems batch multiple requests leads to a compromise on either throughput or latency. For example, Figure 1b shows

*Part of this work was done during an internship at MSR India.

that increasing load can significantly increase tail latency in a state-of-the-art LLM serving system vLLM [53].

Each LLM inference request goes through two phases – a *prefill* phase followed by a *decode* phase. The *prefill* phase corresponds to the processing of the input prompt and the *decode* phase corresponds to the autoregressive token generation. The prefill phase is compute-bound because it processes all tokens of an input prompt in parallel whereas the decode phase is memory-bound because it processes only one token per-request at a time. Therefore, decodes benefit significantly from batching because larger batches can use GPUs more efficiently whereas prefills do not benefit from batching.

Current LLM inference schedulers can be broadly classified into two categories[1], namely, *prefill-prioritizing* and *decode-prioritizing* depending on how they schedule the prefill and decode phases while batching requests. In this paper, we argue that both strategies have fundamental pitfalls that make them unsuitable for serving online inference (see Figure 2).

Traditional request-level batching systems such as FasterTransformer [7] employ *decode-prioritizing* scheduling. These systems submit a batch of requests to the execution engine that first computes the prefill phase of all requests and then schedules their decode phase. The batch completes only after all requests in it have finished their decode phase i.e., new prefills are not scheduled as long as one or more requests are doing decodes. This strategy optimizes inference for latency metric time-between-tokens or TBT – an important performance metric for LLMs. This is because new requests do not affect the execution of ongoing requests in their decode phase. However, *decode-prioritizing* schedulers severely compromise on throughput because even if some requests in a batch finish early, the execution continues with reduced batch size until the completion of the last request.

Orca [75] introduced iteration-level batching wherein requests can dynamically enter or exit a batch at the granularity of individual iterations. Iteration-level batching improves throughput by avoiding inefficiencies of request-level batching systems. Orca and several other recent systems like vLLM [23] combine iteration-level batching with *prefill-prioritizing* scheduling wherein they eagerly schedule the prefill phase of one or more requests first i.e., whenever GPU memory becomes available. This way, *prefill-prioritizing* schedulers have better throughput because computing prefills first allows subsequent decodes to operate at high batch sizes. However, prioritizing prefills leads to high latency because it interferes with ongoing decodes. Since prefills can take arbitrarily long time depending on the lengths of the given prompts, *prefill-prioritizing* schedulers lead to an undesirable phenomenon that we refer to as *generation stalls* in this paper. For example, Figure 1a shows that a generation stall in vLLM can last over several seconds.

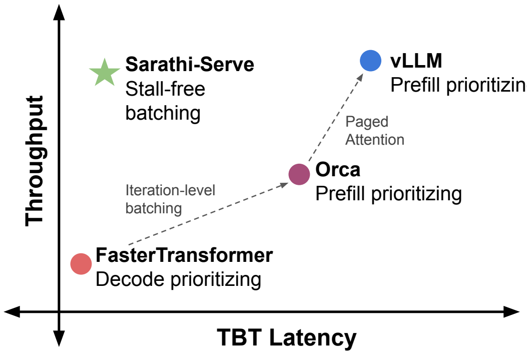


Figure 2: Current LLM serving systems involve a tradeoff between throughput and latency depending on their scheduling policy. Prioritizing prefills optimizes throughput but sacrifices TBT (time-between-tokens) tail latency whereas prioritizing decodes has the opposite effect. Sarathi-Serve serves high throughput with low TBT latency via stall-free batching. (The figure is illustrative and actual values will depend on the model and workload characteristics.)

Another challenge introduced by traditional iteration-level scheduling systems like Orca [75] is pipeline stalls or bubbles [49]. These appear in pipeline-parallelism (PP) deployments that are needed to scale LLM inference across several nodes. In servers with high bandwidth connectivity such as NVIDIA DGX A100 [16], tensor-parallelism (TP) [64] can enable deployment of an LLM on up to 8 GPUs, supporting large batch sizes with low latencies. However, TP can have prohibitively high latencies when hyper-clusters are unavailable [33]. Thus, as an alternative to TP, pipeline-parallelism (PP) [33, 55] is typically used across commodity networks. Existing systems rely on micro-batches to mitigate pipeline stalls or bubbles [49]. However, the standard micro-batch based scheduling can still lead to pipeline bubbles due to the unique characteristics of LLM inference. Specifically, LLM inference consists of a mixture of varying length prefills and decodes. The resulting schedule can thus have wildly varying runtimes across different micro-batches that waste GPU cycles and degrade the overall system throughput.

To address these challenges, we propose Sarathi-Serve, a scheduler to balance the throughput-latency tradeoff for scalable online LLM inference serving. Sarathi-Serve is based on two key ideas: *chunked-prefills* and *stall-free* scheduling. *Chunked-prefills* splits a prefill request into equal compute-sized chunks and computes a prompt's prefill phase over multiple iterations (each with a subset of the prompt tokens). *Stall-free* scheduling allows *new requests to join a running batch without pausing ongoing decodes*. This involves constructing a batch by coalescing all the on-going decodes with one (or more) prefill chunks from new requests such that each batch reaches the pre-configured chunk size. Sarathi-Serve builds upon iteration-level batching but with an important distinction: it throttles the number of prefill tokens in each it-

[1] We classify recent schedulers Splitwise [58] and DistServe [77] under a third category "disaggregated" and discuss them in §6.

eration while admitting new requests in a running batch. This not only bounds the latency of each iteration, but also makes it nearly independent of the total length of input prompts. This way, Sarathi-Serve minimizes the effect of computing new prefills on the TBT of ongoing decodes enabling both high throughput and low TBT latency.

In addition, hybrid batches (consisting of prefill and decode tokens) constructed by Sarathi-Serve have a near-uniform compute requirement. With pipeline-parallelism, this allows us to create balanced micro-batching based schedules that significantly reduce pipeline bubbles and improve GPU utilization, thus allowing efficient and scalable deployments.

We evaluate Sarathi-Serve across different models and hardware — Mistral-7B on a single A100, Yi-34B on 2 A100 GPUs with 2-way tensor parallelism, LLaMA2-70B on 8 A40 GPUs, and Falcon-180B with 2-way pipeline and 4-way tensor parallelism across 8 A100 GPUs connected over commodity ethernet. For Yi-34B, Sarathi-Serve improves system serving capacity by up to 3.7× under different SLO targets. Similarly for Mistral-7B, we achieve up to 2.6× higher serving capacity. Sarathi-Serve also reduces pipeline bubbles, resulting in up to 5.6× gains in end-to-end serving capacity for Falcon-180B deployed with pipeline parallelism.

The main contributions of our paper include:

1. We identify a number of pitfalls in the current LLM serving systems, particularly in the context of navigating the throughput-latency tradeoff.
2. We introduce two simple-yet-effective techniques, *chunked-prefills* and *stall-free batching*, to improve the performance of an LLM serving system.
3. We show generality through extensive evaluation over multiple models, hardware, and parallelism strategies demonstrating that Sarathi-Serve improves model serving capacity by up to an order of magnitude.

2 Background

In this section, we describe the typical LLM model architecture along with their auto-regressive inference process. We also provide an overview of the scheduling policies and important performance metrics.

2.1 The Transformer Architecture

Popular large language models, like, GPT-3 [18], LLaMA [66], Yi [24] etc. are decoder-only transformer models trained on next token prediction tasks. These models consist of a stack of layers identical in structure. Each layer contains two modules – self-attention and feed-forward network (FFN).

Self-attention module: The self-attention module is central to the transformer architecture [67], enabling each part of a sequence to consider all previous parts for generating a contextual representation. During the computation of self-attention, first the Query (Q), Key (K) and Value (V) vectors corresponding to each input token are obtained via a linear transformation. Next, the *attention* operator computes a semantic relationship among all tokens of a sequence. This involves computing a dot-product of each Q vector with K vectors of all preceding tokens of the sequence, followed by a softmax operation to obtain a weight vector, which is then used to compute a weighted average of the V vectors. This attention computation can be performed across multiple *heads*, whose outputs are combined using a linear transformation.

Feed-forward network (FFN): FFN typically consists of two linear transformations with a non-linear activation in between. The first linear layer transforms an input token embedding of dimension h to a higher dimension $h2$. This is followed by an activation function, typically ReLU or GELU [27,46]. Finally, the second linear layer, transforms the token embedding back to the original dimension h.

2.2 LLM Inference Process

Autoregressive decoding: LLM inference consists of two distinct phases – a *prefill* phase followed by a *decode* phase. The prefill phase processes the user's input prompt and produces the first output token. Subsequently, the decode phase generates output tokens one at a time wherein the token generated in the previous step is passed through the model to generate the next token until a special *end-of-sequence* token is generated. Note that the decode phase requires access to all the keys and values associated with all the previously processed tokens to perform the attention operation. To avoid repeated recomputation, contemporary LLM inference systems store activations in KV-cache [7,64,75].

A typical LLM prompt contains 100s-1000s of input tokens Table 2, [76]. During the prefill phase all these prompt tokens are processed in parallel in a single iteration. The parallel processing allows efficient utilization of GPU compute. On the contrary, the decode phase involves a full forward pass of the model over a single token generated in the previous iteration. This leads to low compute utilization making decodes memory-bound.

Batched LLM inference in multi-tenant environment: A production serving system must deal with concurrent requests from multiple users. Naively processing requests in a sequential manner leads to a severe under-utilization of GPU compute. In order to achieve higher GPU utilization, LLM serving systems leverage batching to process multiple requests concurrently. This is particularly effective for the decode phase processing which has lower computational intensity at low batch sizes. Higher batch sizes allows the cost of fetching model parameters to be amortized across multiple requests.

Recently, several complementary techniques have been proposed to optimize throughput by enabling support for larger batch sizes. Kwon et al. propose PagedAttention [53], which allows more requests to concurrently execute, eliminating fragmentation in *KV-cache*. The use of Multi Query Attention

Algorithm 1 Request-level batching. New requests are admitted only if there are no decodes left (line 3). This optimizes TBT but wastes GPU compute in many decode-only iterations (line 10) with potentially small batch sizes.

```
1:  Initialize current batch $B \leftarrow \emptyset$
2:  while True do
3:      if $B = \emptyset$ then
4:          $R_{new} \leftarrow$ get_next_request()
5:          while can_allocate_request($R_{new}$) do
6:              $B \leftarrow B + R_{new}$
7:              $R_{new} \leftarrow$ get_next_request()
8:          prefill($B$)
9:      else
10:         decode($B$)
11:         $B \leftarrow$ filter_finished_requests($B$)
```

Algorithm 2 Iteration-level batching (vLLM). Prefills are executed eagerly (lines 8-9), potentially introducing a generation stall for ongoing decodes (line 12).

```
1:  Initialize current batch $B \leftarrow \emptyset$
2:  while True do
3:      $B_{new} \leftarrow \emptyset$
4:      $R_{new} \leftarrow$ get_next_request()
5:      while can_allocate_request($R_{new}$) do
6:          $B_{new} \leftarrow B_{new} + R_{new}$
7:          $R_{new} \leftarrow$ get_next_request()
8:      if $B_{new} \neq \emptyset$ then
9:          prefill($B_{new}$)
10:         $B \leftarrow B + B_{new}$
11:     else
12:         decode($B$)
13:     $B \leftarrow$ filter_finished_requests($B$)
```

(MQA) [61], Group Query Attention (GQA) [30] in leading edge LLM models like LLaMA2 [66], Falcon [31] and Yi [24] has also significantly helped in alleviating memory bottleneck in LLM inference. For instance, LLaMA2-70B model has a 8× smaller KV-cache footprint compared to LLaMA-65B.

2.3 Multi-GPU LLM Inference

With ever-increasing growth in model sizes, it becomes necessary to scale LLMs to multi-GPU or even multi-node deployments [22, 59]. Furthermore, LLM inference throughput, specifically that of the decode phase is limited by the maximum batch size we can fit on a GPU. Inference efficiency can therefore benefit from model-parallelism which allows larger batch sizes by sharding model weights across multiple GPUs. Prior work has employed both tensor-parallelism (TP) [64] and pipeline-parallelism (PP) [7, 72, 75] for this purpose.

TP shards each layer across the participating GPUs by splitting the model weights and KV-cache equally across GPU workers. This way, TP can linearly scale per-GPU batch size. However, TP involves a high communication cost due to two all-reduce operations per layer – one in attention computation and the other in FFN [64]. Moreover, since these communication operations are in the critical path, TP is preferred only within a single node where GPUs are connected via high bandwidth interconnects like NVLink.

Compared to TP, PP splits a model layer-wise, where each GPU is responsible for a subset of layers. To keep all GPUs in the 'pipeline' busy, *micro-batching* is employed. These micro-batches move along the pipeline from one stage to the next at each iteration. PP has much better compute-communication ratio compared to TP, as it only needs to send activations once for multiple layers of compute. Furthermore, PP requires communication only via point-to-point communication operations, compared to the more expensive allreduces in TP. Thus, PP is more efficient than TP when high-bandwidth interconnects are unavailable *e.g.,* in cross-node deployments.

2.4 Performance Metrics

There are two primary latency metrics of interest for LLM serving: TTFT (time-to-first-token) and TBT (time-between-tokens). For a given request, TTFT measures the latency of generating the first output token from the moment a request arrives in the system. This metric reflects the initial responsiveness of the model. TBT on the other hand measures the interval between the generation of consecutive output tokens of a request, and affects the overall perceived fluidity of the response. When system is under load, low throughput can lead to large scheduling delays and consequently higher TTFT.

In addition, we use a throughput metric, *Capacity*, defined as the maximum request load (queries-per-second) a system can sustain while meeting certain latency targets. Higher capacity is desirable because it reduces the cost of serving.

2.5 Scheduling Policies for LLM Inference

The scheduler is responsible for admission control and batching policy. For the ease of exposition, we investigate existing LLM inference schedulers by broadly classifying them under two categories – *prefill-prioritizing* and *decode-prioritizing*.

Conventional inference engines like FasterTransformer [7], Triton Inference Server [17] use *decode-prioritizing* schedules with request-level batching *i.e.,* they pick a batch of requests and execute it until *all* requests in the batch complete (Algorithm 1). This approach reduces the operational complexity of the scheduling framework but at the expense of inefficient resource utilization. Different requests in a batch typically have a large variation in the number of input and output tokens. Request-level schedulers pad shorter requests with zeros to match their length with the longest request in the batch which results in wasteful compute and longer wait times for pending requests [75].

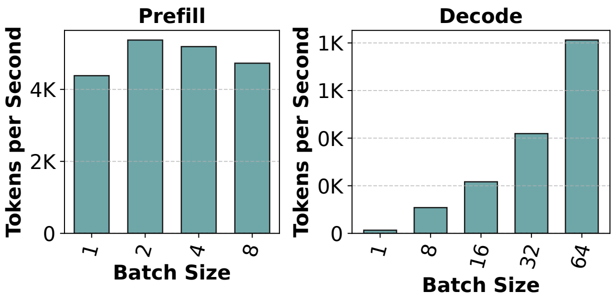

Figure 3: Throughput of the prefill and decode phases with different batch sizes for Mistral-7B running on a single A100 GPU. We use prompt length of 1024 for both prefill and decode experiments. Note that different y-axis, showing prefills are much more efficient than decode. Further, note that *batching boosts decode throughput almost linearly but has a marginal effect on prefill throughput.*

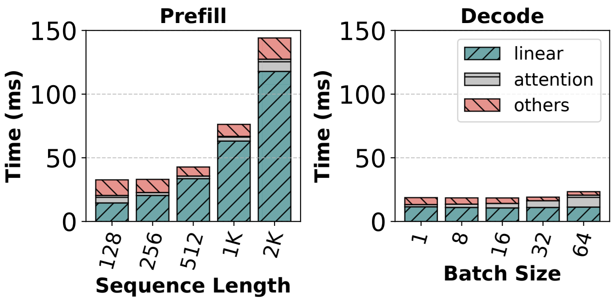

Figure 4: Prefill and decode time with different input sizes for Mistral-7B running on single A100 GPU. Linear layers contribute to the majority of runtime in both prefill and decode phases. Due to the low arithmetic intensity in decode batches, the cost of linear operation for 1 decode token is nearly same as 128 prefill tokens.

To avoid wasted compute of request-level batching, Orca [75] introduced a fine-grained iteration-level batching mechanism where requests can dynamically enter and exit a batch after each model iteration.(Algorithm 2). This approach can significantly increase system throughput and is being used in many LLM inference serving systems today *e.g.,* vLLM [23], TensorRT-LLM [21], and LightLLM [12].

Current iteration-level batching systems such as vLLM [23] and Orca [75] use *prefill-prioritizing* schedules that eagerly admit new requests in a running batch at the first available opportunity, e.g., whenever GPU memory becomes available. Prioritizing prefills can improve throughput because it increases the batch size of subsequent decode iterations.

3 Motivation

In this section, we first analyse the cost of prefill and decode operations. We then highlight the throughput-latency trade-off and pipeline bubbles that appear in serving LLMs.

3.1 Cost Analysis of Prefill and Decode

As discussed in §2.2, while the *prefill* phase processes all input tokens in parallel and effectively saturates GPU compute, the *decode* phase processes only a single token at a time and is very inefficient. Figure 3 illustrates throughput as a function of batch size, and we can observe that while for decode iterations throughput increases roughly linearly with batch size, prefill throughput almost saturates even with a single request.

Takeaway-1: *The two phases of LLM inference – prefill and decode – demonstrate contrasting behaviors wherein batching boosts decode phase throughput immensely but has little effect on prefill throughput.*

Figure 4 breaks down the prefill and decode compute times into linear, attention and others, and shows their individual contributions. From the figure, we see that linear operators contribute to the majority of the runtime cost. While attention cost grows quadratically with sequence length, linear operators still contribute more than 80% to the total time even at high sequence lengths. Therefore, optimizing linear operators is important for improving LLM inference.

Low Compute Utilization during Decodes: Low compute utilization during the decode phase is a waste of GPU's processing capacity. To understand this further, we analyze the arithmetic intensity of prefill and decode iterations. Since the majority of the time in LLM inference is spent in linear operators, we focus our analysis on them.

Matrix multiplication kernels overlap memory accesses along with computation of math operations. The total execution time of an operation can be approximated to $T = \max(T_{\text{math}}, T_{\text{mem}})$, where T_{math} and T_{mem} represent the time spent on math and memory fetch operations respectively. An operation is considered memory-bound if $T_{\text{math}} < T_{\text{mem}}$. Memory-bound operations have low Model FLOPs Utilization (MFU) [35]. On the other hand, compute-bound operations have low Model Bandwidth Utilization (MBU). When $T_{\text{math}} = T_{\text{mem}}$, both compute and memory bandwidth utilization are maximized. Arithmetic intensity quantifies the number of math operations performed per byte of data fetched from the memory. At the optimal point, the arithmetic intensity of operation matches the FLOPS-to-Bandwidth ratio of the device. Figure 5 shows arithmetic intensity as a function of the number of tokens in the batch for linear layers in LLaMA2-70B running on four A100 GPUs. Prefill batches amortize the cost of fetching weights of the linear operators from HBM memory to GPU cache over a large number of tokens, allowing it to have high arithmetic intensity. In contrast, decode batches have very low computation intensity. Figure 6 shows the total execution time of linear operators in

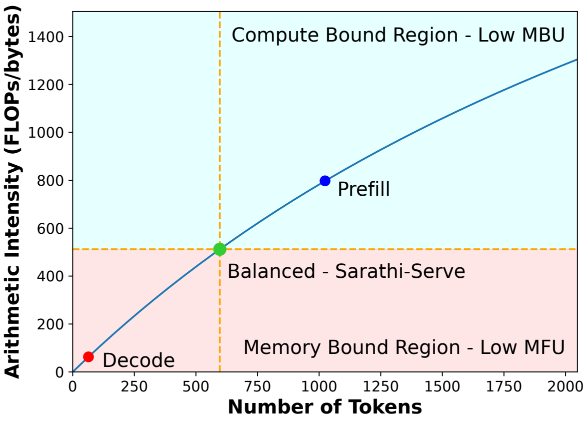

Figure 5: Arithmetic intensity trend for LLaMA2-70B linear operations with different number of token running on four A100s. Decode batches have low arithmetic intensity *i.e.,* they are bottlenecked by memory fetch time, leading to low compute utilization. Prefill batches are compute bound with sub-optimal bandwidth utilization. Sarathi-Serve forms balanced batches by combining decodes and prefill chunks to maximize both compute and bandwidth utilization.

an iteration for LLaMA2-70B as a function of the number of tokens. Note that execution time increases only marginally in the beginning *i.e.,* as long as the batch is in a memory-bound regime, but linearly afterwards *i.e.,* when the batch becomes compute-bound.[2]

Takeaway-2: *Decode batches operate in memory-bound regime leaving compute underutilized. This implies that more tokens can be processed along with a decode batch without significantly increasing its latency.*

3.2 Throughput-Latency Trade-off

Iteration-level batching improves system throughput but we show that it comes at the cost of high TBT latency due to a phenomenon we call *generation stalls*.

Figure 7 compares different scheduling policies. The example shows a timeline (left to right) of requests A, B, C and D. Requests A and B are in decode phase at the start of the interval and after one iteration, requests C and D enter the system. Orca and vLLM both use FCFS iteration-level batching with eager admission of prefill requests but differ in their batch composition policy. Orca supports hybrid batches composed of both prefill and decode requests whereas vLLM only supports batches that contain either all prefill or all decode requests. Irrespective of this difference, both Orca and vLLM can improve throughput by maximizing the batch size

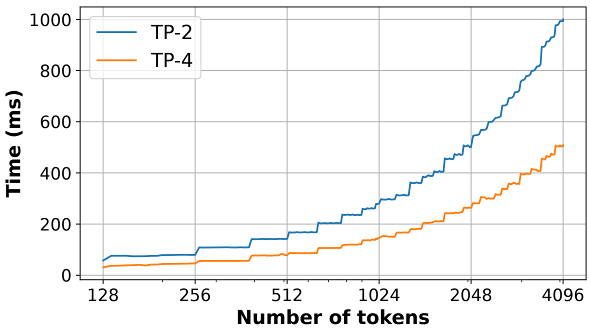

Figure 6: Linear layer execution time as function of number of tokens in a batch for LLaMA2-70B on A100(s) with different tensor parallel degrees. When the number of tokens is small, execution time is dictated by the cost of fetching weights from HBM memory. Hence, execution time is largely stagnant in the 128-512 tokens range, especially for higher tensor parallel degrees. Once the number of tokens in the batch cross a critical threshold, the operation become compute bound and the runtime increases linearly with number of tokens.

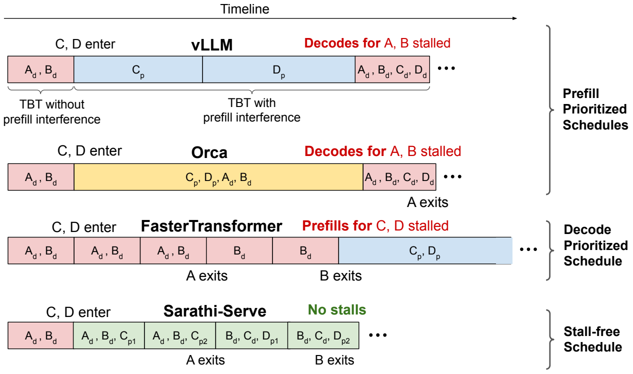

Figure 7: A generation stall occurs when one or more prefills are scheduled in between consecutive decode iterations of a request. A, B, C and D represent different requests. Subscript d represents a decode iteration, p represents a full prefill and $p0$, $p1$ represent two chunked prefills of a given prompt. vLLM induces generation stalls by scheduling as many prefills as possible before resuming ongoing decodes. Despite supporting hybrid batches, Orca cannot mitigate generation stalls because the execution time of batches containing long prompts remains high. FasterTransformer is free of generation stalls as it finishes all ongoing decodes before scheduling a new prefill but compromises on throughput due to low decode batch size. In contrast, Sarathi-Serve generates a schedule that eliminates generation stalls yet delivers high throughput.

in subsequent decode iterations. However, eagerly scheduling prefills of requests C and D delays the decodes of already running requests A and B because an iteration that computes one or more prefills can take several seconds depending on the

[2] Theoretically, we expect the operators to become compute-bound at ∼200 tokens on A100 GPUs, however, in practice we observe that it happens at ∼500-600 tokens for higher tensor parallel dimensions due to fixed overheads.

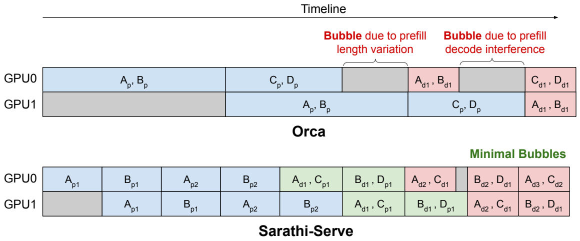

Figure 8: A 2-way pipeline parallel iteration-level schedule in Orca across 4 requests (A,B,C,D) shows the existence of pipeline bubbles due to non-uniform batch execution times. Sarathi-Serve is able to minimize these stalls by creating uniform-compute batches.

lengths of input prompts. Therefore, *prefill-prioritizing* schedulers can introduce *generation stalls* for ongoing decodes resulting in latency spikes caused by high TBT.

In contrast to iteration-level batching, request-level batching systems such as FasterTransformer [7] do not schedule new requests until *all* the already running requests complete their decode phase (line 3 in Algorithm 1). In Figure 7, the prefills for requests C and D get stalled until requests A and B both exit the system. Therefore, *decode-prioritizing* systems provide low TBT latency albeit at the cost of low system throughput. For example, Kwon et al. [53] show that iteration-level batching with PagedAttention can achieve an order of magnitude higher throughput compared to FasterTransformer.

One way to reduce latency spikes in iteration-level batching systems is to use smaller batch sizes as recommended in Orca [75]. However, lowering batch size adversely impacts throughput as shown in §2.2. Therefore, existing systems are forced to trade-off between throughput and latency depending on the desired SLOs.

Takeaway-3: *The interleaving of prefills and decodes involves a trade-off between throughput and latency for current LLM inference schedulers. State-of-the-art systems today use prefill-prioritizing schedules that trade TBT latency for high throughput.*

3.3 Pipeline Bubbles waste GPU Cycles

Pipeline-parallelism (PP) is a popular strategy for cross-node deployment of large models, owing to its lower communication overheads compared to Tensor Parallelism (TP). A challenge with PP, however, is that it introduces *pipeline bubbles* or periods of GPU inactivity as subsequent pipeline stages have to wait for the completion of the corresponding micro-batch in the prior stages. Pipeline bubbles is a known problem in training jobs, where they arise between the forward and backward passes due to prior stages needing to wait for the backward pass to arrive. Micro-batching is a common technique used in PP training jobs to mitigate pipeline bubbles [33, 49, 55].

Inference jobs only require forward computation and therefore one might expect that micro-batching can eliminate pipeline bubbles during inference. In fact, prior work on transformer inference, such as, FasterTransformer [7] and FastServe [72] use micro-batches but do not mention pipeline-bubbles. Recently proposed Orca [75] also suggests that iteration-level scheduling eliminates bubbles in pipeline scheduling (see Figure 8 in [75]). However, our experiments show that even with iteration-level scheduling, pipeline bubbles can waste significant GPU cycles with PP (§5.3).

Each micro-batch (or iteration) in LLM inference can require a different amount of compute (and consequently has varying execution time), depending on the composition of prefill and decode tokens in the micro-batch (see Figure 8). We identify three types of bubbles during inference: (1) bubbles like PB_1 that occur due to the varying number of prefill tokens in two consecutive micro-batches (2) bubbles like PB_2 that occur due to different compute times of prefill and decode stages when one is followed by the other, and (3) bubbles like PB_3 that occur due to difference in decode compute times between micro-batches since the attention cost depends on the accumulated context length (size of the KV-cache) and varies across requests. For Falcon-180B, a single prompt of 4k tokens takes $\approx$ 1150 ms to execute compared to a decode only iteration with batch size 32 which would take about $\approx$ 200 ms to execute. Interleaving of these iteration could result in a bubble of $\approx$ 950 ms. These pipeline bubbles are wasted GPU cycles and directly correspond to a loss in serving throughput and increased latency. This problem is aggravated with increase in prompt lengths and batch size, due to longer and more frequent prefill iterations respectively. If we can ensure that each micro-batch performs uniform computation, we can mitigate these pipeline bubbles.

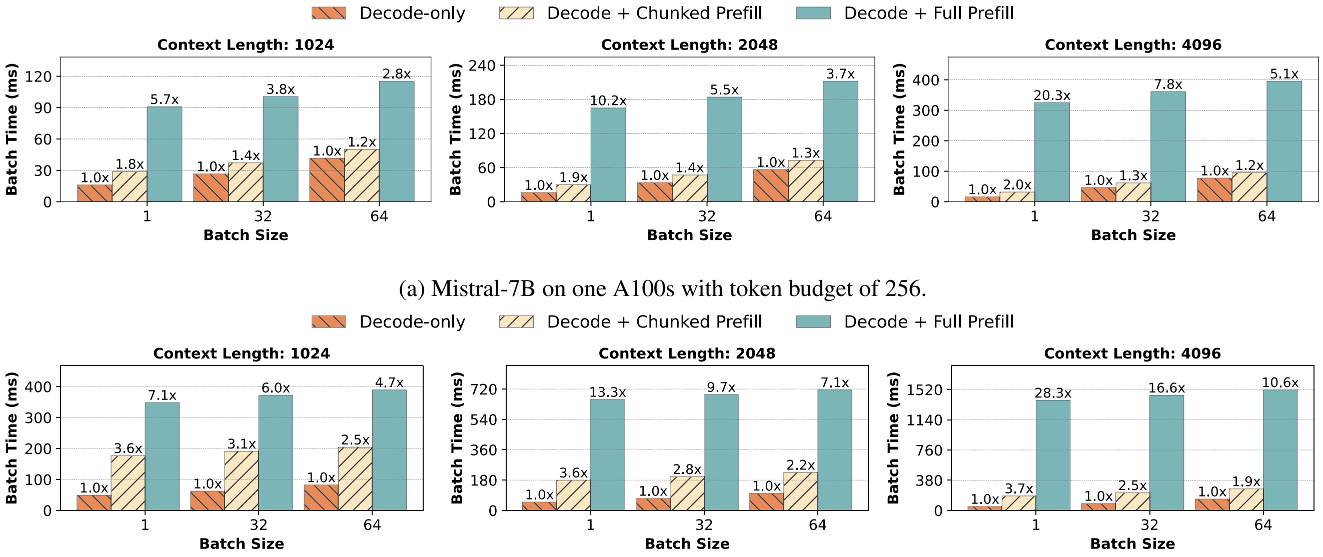
Takeaway-4: *There can be a large variance in compute time of LLM iterations depending on composition of prefill- and decode-tokens in the batch. This can lead to significant bubbles when using pipeline-parallelism.*

4 Sarathi-Serve: Design and Implementation

We now discuss the design and implementation of Sarathi-Serve — a system that provides high throughput with predictable tail latency via two key techniques – *chunked-prefills* and *stall-free batching*.

4.1 Chunked-prefills

As we show in §3.1, decode batches are heavily memory bound with low arithmetic intensity. This slack in arithmetic intensity presents an opportunity to piggyback additional computation in decode batches. Naively, this can be done by creating hybrid batches which combine the memory bound decodes along with compute bound prefills. However, in many practical scenarios, input prompts contain several thousand tokens



(a) Mistral-7B on one A100s with token budget of 256.

(b) LLaMA2-70B on four A100s with token budget of 512.

Figure 9: The incremental cost of coalescing prefills with decode batches. We consider two batching schemes – (i) Decode + Full Prefill represents the hybrid batching of Orca wherein the entire prefill is executed in a single iteration along with ongoing decodes. (ii) Decode + Chunked Prefill represents Sarathi-Serve wherein prefills are chunked before being coalesced with ongoing decodes with a fixed token budget. Sarathi-Serve processes prefill tokens with much lower impact on the latency of decodes. Further, the relative impact of Sarathi-Serve on latency reduces with higher decode batch size and context lengths.

on average *e.g.,* Table 2 shows that the median prompt size in *openchat_sharegpt4* and *arxiv_summarization* datasets is 1730 and 7059 respectively. Combining these long prefills with decode iterations would lead to high TBT latency.

To tackle this challenge, we present a technique called *chunked-prefills* which allows computing large prefills in small chunks across several iterations. *Chunked-prefills* is a prefill splitting mechanism hinged on two key insights. First, as discussed in §3.1, a prefill request with modest sequence length can effectively saturate GPU compute. For example, in Figure 4, prefill throughput starts saturating around sequence length of 512 tokens. Second, in many practical scenarios, input prompts contain several thousand tokens on average (Table 2). This provides an opportunity to break large prefill requests into smaller units of compute which are still large enough to saturate GPU compute. In Sarathi-Serve, we leverage this mechanism to form batches with appropriate number of tokens such that we can utilize the compute potential in decode batches without violating the TBT SLO.

4.2 *Stall-free batching*

The Sarathi-Serve scheduler is an iteration-level scheduler that leverages *chunked-prefills* and coalescing of prefills and decodes to improve throughput while minimizing latency.

Unlike Orca and vLLM which stall existing decodes to execute prefills, Sarathi-Serve leverages the arithmetic intensity slack in decode iterations to execute prefills without delaying the execution of decode requests in the system. We call this approach *stall-free batching* (Algorithm 3). Sarathi-Serve first calculates the budget of maximum number of tokens that can be executed in a batch based on user specified SLO. We describe the considerations involved in determining this token budget in depth in §4.3. In every scheduling iteration, we first pack all the running decodes in the next batch (lines 6-8 in Algorithm 3). After that, we include any partially completed prefill (lines 9-12). Only after all the running requests have been accommodated, we admit new requests (lines 13-20). When adding prefill requests to the batch, we compute the maximum chunk size that can be accommodated within the leftover token budget for that batch (lines 11, 15). By restricting the computational load in every iteration, *stall-free batching* ensures that decodes never experience a generation stall due to a co-running prefill chunk. We compare the latency for hybrid batches with and without chunked prefills in Figure 9. Naive hybrid batching leads to dramatic increase of up to 28.3× in the TBT latency compared to a decode-only batch. In contrast, Sarathi-Serve provides a much tighter bound on latency with chunking.

Figure 7 shows the scheduling policy of Sarathi-Serve in action, for the same example used in §3.2. The first iteration is decode-only as there are no prefills to be computed. However, after a new request C enters the system, Sarathi-Serve first splits the prefill of C into two chunks and schedules them in

Algorithm 3 *Stall-free batching* with Sarathi-Serve. First the batch is filled with with ongoing decode tokens (lines 6-8) and optionally one prefill chunk from ongoing (lines 10-12). Finally, new requests are added (lines 13-20) within the token budget so as to maximize throughput with minimal latency impact on the TBT of delaying the ongoing decodes.

```
 1: Input: $T_{max}$, Application TBT SLO.
 2: Initialize $token\_budget$, $\tau \leftarrow$ compute_token_buget($T_{max}$)
 3: Initialize $batch\_num\_tokens$, $n_t \leftarrow 0$
 4: Initialize current batch $B \leftarrow \emptyset$
 5: while True do
 6:     for $R$ in $B$ do
 7:         if is_prefill_complete($R$) then
 8:             $n_t \leftarrow n_t + 1$
 9:     for $R$ in $B$ do
10:         if not is_prefill_complete($R$) then
11:             $c \leftarrow$ get_next_chunk_size($R$, $\tau$, $n_t$)
12:             $n_t \leftarrow n_t + c$
13:     $R_{new} \leftarrow$ get_next_request()
14:     while can_allocate_request($R_{new}$) $\wedge$ $n_t < \tau$ do
15:         $c \leftarrow$ get_next_chunk_size($R_{new}$, $\tau$, $n_t$)
16:         if $c > 0$ then
17:             $n_t \leftarrow n_t + c$
18:             $B \leftarrow R_{new}$
19:         else
20:             break
21:
22:     process_hybrid_batch($B$)
23:     $B \leftarrow$ filter_finished_requests($B$)
24:     $n_t \leftarrow 0$
```

subsequent iterations. At the same time, with *stall-free batching*, it coalesces the chunked prefills with ongoing decodes of A and B. This way, Sarathi-Serve stalls neither decodes nor prefills unlike existing systems, allowing Sarathi-Serve to be largely free of latency spikes in TBT without compromising throughput. Furthermore, *stall-free batching* combined with *chunked-prefills* also ensures uniform compute hybrid batches in most cases, which helps reduce bubbles when using pipeline parallelism, thereby enabling efficient and scalable deployments.

4.3 Determining Token Budget

The token budget is determined based on two competing factors — TBT SLO requirement and *chunked-prefills* overhead. From a TBT minimization point of view, a smaller token budget is preferable because iterations with fewer prefill tokens have lower latency. However, smaller token budget can result in excessive chunking of prefills resulting in overheads due to 1) lower GPU utilization and 2) repeated KV-cache access in the attention operation which we discuss below.

During the computation of *chunked-prefills*, the attention operation for every chunk of a prompt needs to access the KV-cache of *all* prior chunks of the same prompt. This results in increased memory reads from the GPU HBM even though the computational cost is unchanged. For example, if a prefill sequence is split into N chunks, then the first chunk's KV-cache is loaded $N-1$ times, the second chunk's KV-cache is loaded $N-2$ times, and so on. However, we find that even at small chunk sizes attention prefill operation is compute bound operation. In practice, there can be small overhead associated with chunking due to fixed overheads of kernel launch, etc. We present a detailed study of the overheads of *chunked-prefills* in §5.4.

Thus, one needs to take into account the trade-offs between prefill overhead and decode latency while determining the token budget. This can be handled with a one-time profiling of batches with different number of tokens and setting the token budget to maximum number of tokens that can be packed in a batch without violating TBT SLO.

Another factor that influences the choice of token budget is the *tile-quantization* effect [13]. GPUs compute matmuls by partitioning the given matrices into tiles and assigning them to different thread blocks for parallel computation. Here, each thread block refers to a group of GPU threads and computes the same number of arithmetic operations. Therefore, matmuls achieve maximum GPU utilization when the matrix dimensions are divisible by the tile size. Otherwise, due to *tile-quantization*, some thread blocks perform extraneous computation [13]. We observe that tile-quantization can dramatically increase prefill computation time *e.g.,* in some cases, using chunk size of 257 can increase prefill time by 32% compared to that with chunk size 256.

Finally, when using pipeline parallelism the effect of token budget on pipeline bubbles should also be taken into account. Larger chunks lead to higher inter-batch runtime variations that result in pipeline bubbles which results in lower overall system throughput. On the other hand, picking a very small token budget can lead to higher overhead due to lower arithmetic intensity and other fixed overheads.

Therefore, selecting a suitable token budget is a complex decision which depends on the desired TBT SLO, parallelism configuration, and specific hardware properties. We leverage Vidur [28], a LLM inference profiler and simulator to determine the token budget that maximizes system capacity under specific deployment scenario.

4.4 Implementation

We implement Sarathi-Serve on top of the open-source implementation of vLLM [23, 53]. We added support for paged chunk prefill using FlashAttention v2 [38] and FlashInfer [74] kernels. We use FlashAttention backend for all the evaluations in this paper due to its support for wider set of models. We also extend the base vLLM codebase to support various

Model	Attention Mechanism	GPU Configuration	Memory Total (per-GPU)
Mistral-7B	GQA-SW	1 A100	80GB (80GB)
Yi-34B	GQA	2 A100s (TP2)	160GB (80GB)
LLaMA2-70B	GQA	8 A40s (TP4-PP2)	384GB (48GB)
Falcon-180B	GQA	4 A100s×2 nodes (TP4-PP2)	640GB (80GB)

Table 1: Models and GPU configurations (GQA: grouped-query attention, SW: sliding window).

Dataset	Prompt Tokens			Output Tokens		
	Median	P90	Std.	Median	P90	Std.
openchat_sharegpt4	1730	5696	2088	415	834	101
arxiv_summarization	7059	12985	3638	208	371	265

scheduling policies, chunked prefills, pipeline parallelism and an extensive telemetry system. We use NCCL [15] for both pipeline and tensor parallel communication. Source code for the project is available at https://github.com/microsoft/sarathi-serve.

5 Evaluation

We evaluate Sarathi-Serve on a variety of popular models and GPU configurations (see Table 1) and two datasets (see Table 2). We consider vLLM and Orca as baseline because they represent the state-of-the-art for LLM inference. Our evaluation seeks to answer the following questions:

1. What is the maximum load a model replica can serve under specific Service Level Objective (SLO) constraints with different inference serving systems (§5.1) and how does this load vary with varying SLO constraints (§5.2)?
2. How does Sarathi-Serve perform under various deployments such as TP and PP? (§5.3)
3. What is the overhead of *chunked-prefills*? (§5.4.1)
4. What is the effect of each of *chunked-prefills* and *stall-free batching* in isolation as opposed to using them in tandem? (§5.4.2)

Models and Environment: We evaluate Sarathi-Serve across four different models Mistral-7B [51], Yi-34B [24], LLaMA2-70B [66] and Falcon-180B [31] – these models are among the best in their model size categories. We use two different server configurations. For all models except LLaMA2-70B we use Azure NC96ads v4 VMs, each equipped with 4 NVIDIA 80GB A100 GPUs, connected with pairwise NVLINK. The machines are connected with a 100 Gbps ethernet connection. For LLaMA2-70B, we use a server with eight pairwise connected NVIDIA 48GB A40 GPUs. We run Yi-34B in a 2-way tensor parallel configuration (TP-2), and LLaMA2-70B and Falcon-180B in a hybrid parallel configuration with four tensor parallel workers and two pipeline stages for (TP4-PP2).

Model	*relaxed* SLO P99 TBT (s)	*strict* SLO P99 TBT (s)
Mistral-7B	0.5	0.1
Yi-34B	1	0.2
LLaMA2-70B	5	1
Falcon-180B	5	1

Table 3: SLOs for different model configurations.

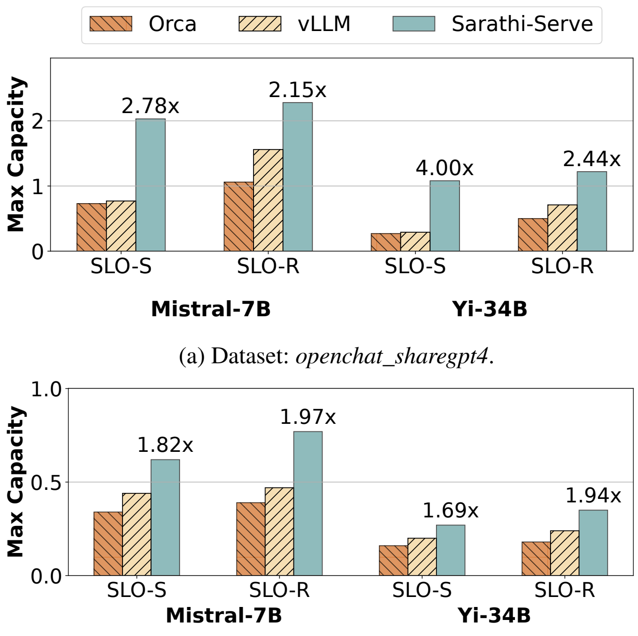
Workloads: In order to emulate the real-world serving scenarios, we generate traces by using the request length characteristics from the *openchat_sharegpt4* [68] and *arxiv_summarization* [36] datasets (Table 2). The *openchat_sharegpt4* trace contains user-shared conversations with ChatGPT-4 [6]. A conversation may contain multiple rounds of interactions between the user and chatbot. Each such interaction round is performed as a separate request to the system. This multi-round nature leads to high relative variance in the prompt lengths. In contrast, *arxiv_summarization* is a collection of scientific publications and their summaries (abstracts) on arXiv.org [3]. This dataset contains longer prompts and lower variance in the number of output tokens, and is representative of LLM workloads such as Microsoft M365 Copilot [14] and Google Duet AI [10] etc. The request arrival times are generated using Poisson distribution. We filter outliers of these datasets by removing requests with total length more than 8192 and 16384 tokens, respectively.

Metrics: We focus on the median value for the TTFT since this metric is obtained only once per user request and on the 99th percentile (P99) for TBT values since every decode token results in a TBT latency value.

5.1 Capacity Evaluation

We evaluate Sarathi-Serve, Orca and vLLM on all four models and both datasets under two different latency configurations: *relaxed* and *strict*. Similar to Patel et al. [58], to account for the intrinsic performance limitations of a model and hardware pair, we define the SLO on P99 TBT to be equal to 5× and 25× the execution time of a decode iteration for a request (with prefill length of 4k and 32 batch size) running without any prefill interference for the *strict* and *relaxed* settings, respectively. Table 3 shows a summary of the absolute SLO thresholds. Note that the *strict* SLO represents the latency target desired for interactive applications like chatbots. On the other hand, the *relaxed* configuration is exemplary of systems where the complete sequence of output tokens should be generated within a predictable time limit but the TBT constraints on individual tokens is not very strict. For all load experiments, we ensure that the maximum load is sustainable, i.e., the queuing delay does not blow up (we use a limit of 2 seconds on median scheduling delay).

Figure 10 and Figure 11 show the results of our capacity



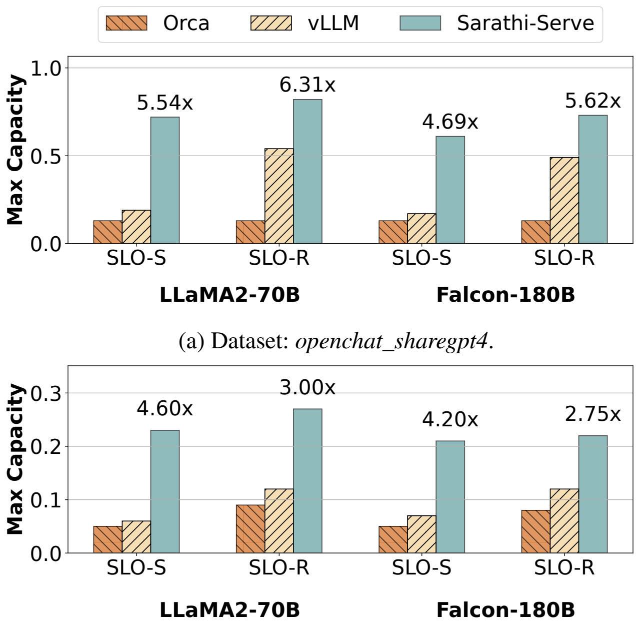
(a) Dataset: *openchat_sharegpt4*.

(b) Dataset: *arxiv_summarization*.

Figure 10: Capacity (in queries per second) of Mistral-7B and Yi-34B with different schedulers under strict (SLO-S) and relaxed (SLO-R) latency SLOs.

experiments. Sarathi-Serve consistently outperforms Orca and vLLM in all cases across models and workloads. Under *strict* SLO, Sarathi-Serve can sustain up to 4.0× higher load compared to Orca and 3.7× higher load than vLLM under *strict* SLO (Yi-34B, *openchat_sharegpt4*). For larger models using pipeline parallelism, Sarathi-Serve achieves gains of up to 6.3× and 4.3× compared to Orca and vLLM respectively (LLaMA2-70B, *openchat_sharegpt4*) due to few pipeline bubbles.

We observe that in most scenarios, Orca and vLLM violate the P99 TBT latency SLO before they can reach their maximum serviceable throughput. Thus, we observe relaxing the latency target leads to considerable increase in their model serving capacity. In Sarathi-Serve, one can adjust the chunk size based on the desired SLO. Therefore, we use a strict token budget and split prompts into smaller chunks when operating under *strict* latency SLO. This reduces system efficiency marginally but allows us to achieve lower tail latency. On the other hand, when the latency constraint is relaxed, we increase the token budget to allow more efficient prefills. We use token budget of 2048 and 512 for all models under the *relaxed* and *strict* settings, respectively, except for the LLaMA2-70B *relaxed* configuration where we use token budget of 1536 to reduce the impact of pipeline bubbles. The system performance can be further enhanced by dynamically varying the token budget based on workload characteristics. We leave this exploration for future work.



(a) Dataset: *openchat_sharegpt4*.

(b) Dataset: *arxiv_summarization*.

Figure 11: Capacity of LLaMA2-70B and Falcon-180B (models with pipeline parallelism) with different schedulers under strict (SLO-S) and relaxed (SLO-R) latency SLOs.

We further notice that vLLM significantly outperforms Orca under relaxed setting. The reason for this is two-fold. First, Orca batches prompts for multiple requests together (*max sequence length * batch size* compared to *max sequence length* in vLLM), which can lead to even higher tail latency in some cases. Second, vLLM supports a much larger batch size compared to Orca. The lower batch size in Orca is due to the lack of PagedAttention and the large activation memory footprint associated with processing batches with excessively large number of tokens.

Finally, note that the capacity of each system is higher for *openchat_sharegpt4* dataset compared to the *arxiv_summarization* dataset. This is expected because prompts in the *arxiv_summarization* datasets are much longer - 7059 vs 1730 median tokens as shown in Table 2. The larger prompts makes Orca and vLLM more susceptible to latency violations due to higher processing time of these longer prefills.

5.2 Throughput-Latency Tradeoff

To fully understand the throughput-latency tradeoff in LLM serving systems, we vary the P99 TBT latency SLO and observe the impact on system capacity for vLLM and Sarathi-Serve. Figure 12 shows the results for Mistral-7B and Yi-34B models with five different SLO values for the *openchat_sharegpt4* dataset.

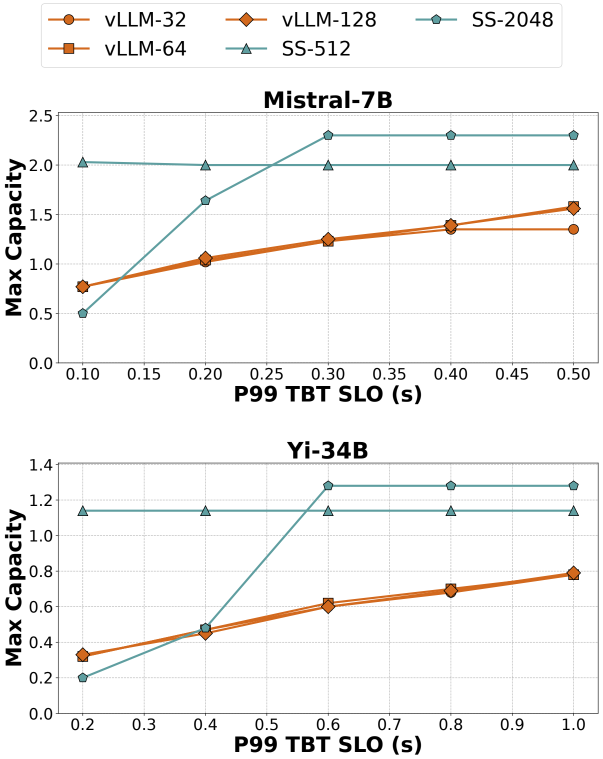


Figure 12: Latency – Throughput tradeoff in vLLM and Sarathi-Serve for Mistral-7B and Yi-34B models on *openchat_sharegpt4* dataset. We evaluate vLLM with three different max batch sizes of 32, 64 and 128. For Sarathi-Serve, we consider token budget of 512 and 2048 with max batch size of 128. Sarathi-Serve delivers 3.5× higher capacity under stringent SLOs for Yi-34B using *Stall-free batching*.

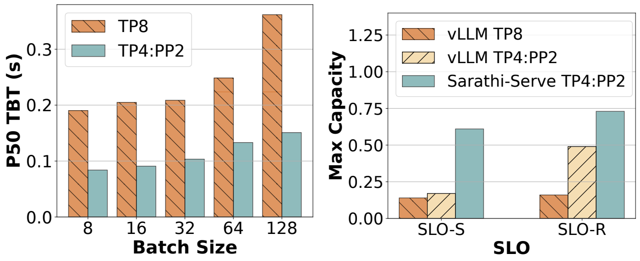
We evaluate vLLM with three different batch sizes in an attempt to navigate the latency-throughput trade-off as prescribed by Yu et al. [75]. The maximum capacity of vLLM gets capped due to generation stalls under stringent TBT SLOs. Notably, the capacity of vLLM remains largely identical for all the three batch size settings. This implies that even though PagedAttention enables large batch sizes with efficient memory management – in practical situations with latency constraints, vLLM cannot leverage the large batch size due to the steep latency-throughput tradeoff made by it's *prefill-prioritizing* scheduler.

On the other hand, the latency-throughput tradeoff in Sarathi-Serve can be precisely controlled by varying the token budget. Sarathi-Serve achieves 3.5× higher capacity compared to vLLM under strict SLO (100ms, Mistral-7B) using a small token budget of 512. For scenarios with more relaxed SLO constraints, picking a larger token budget of 2048 allows Sarathi-Serve to operate more efficiently resulting in 1.65× higher capacity compared to vLLM (1s, Yi-34B).



(a) TBT (Falcon-180B).

(b) Capacity (Falcon-180B).

Figure 13: TP scales poorly across nodes. (a) Median TBT for decode-only batches: cross node TP increases median TBT by more than 2× compared to a 4-way TP within node and PP across nodes. (b) Capacity under strict (SLO-S) and relaxed (SLO-R) latency SLOs: Sarathi-Serve increases Falcon-180B's serving capacity by 4.3× and 3.6× over vLLM's TP-only and hybrid-parallel configurations under strict SLOs.

5.3 Making Pipeline Parallel Viable

We now show that Sarathi-Serve makes it feasible to efficiently serve LLM inference across commodity networks with efficient pipeline parallelism. For these experiments, we run Falcon-180B over two nodes, each with four A100 GPUs, connected over 100 Gbps Ethernet. We evaluate model capacity under three configurations: vLLM with 8-way TP, vLLM with our pipeline-parallel implementation and Sarathi-Serve with pipeline-parallel. For PP configurations, we do 4-way TP within node and 2-way PP across nodes.

Figure 13a shows the latency for decode-only batches for Falcon-180B with purely tensor parallel TP-8 deployment compared to a TP-4 PP-2 hybrid parallel configuration. We observe that the median latency for tensor parallelism is ∼ 2× higher than pipeline parallelism. This is because TP incurs high communication overhead due to cross-node all-reduces.

Figure 13b shows the capacity for tensor and hybrid parallel configurations for Falcon-180B on *openchat_sharegpt4* dataset. Note that unlike the hybrid parallel configuration, TP achieves low capacity even under the *relaxed* SLO due to high latency. Even though vLLM can support a fairly high load with hybrid parallelism under *relaxed* SLO, it's performance drops sharply under the *strict* regime due to pipeline bubbles. Sarathi-Serve on the other hand, leverages *chunked-prefills* to reduce the variation in the execution time between microbatches to avoid pipeline bubbles, resulting in a 1.48× increase in capacity under *relaxed* SLOs and 3.6× increase in capacity under *strict* SLOs.

5.4 Ablation Study

In this subsection, we conduct an ablation study on different aspects on Sarathi-Serve. In particular, we are interested in answering the following two questions: 1) what is the effect of

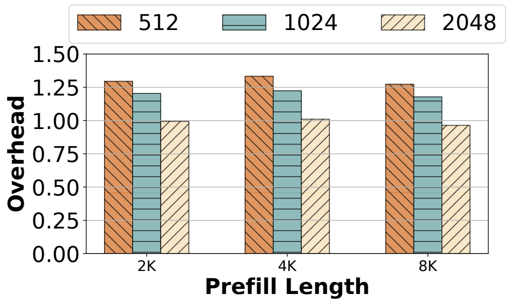


Figure 14: Overhead of *chunked-prefills* in prefill computation for Yi-34B (TP-2) normalized to the cost of no-chunking, shown for various prompt lengths using chunk lengths of 512, 1024 and 2048.

Scheduler	*openchat_sharegpt4*		*arxiv_summarization*	
	P50 TTFT	P99 TBT	P50 TTFT	P99 TBT
hybrid-batching-only	0.53	0.68	3.78	1.38
chunked-prefills-only	1.04	0.17	5.38	0.20
Sarathi-Serve (combined)	0.76	0.14	3.90	0.17

Table 4: TTFT and TBT latency measured in seconds for *hybrid-batching* and *chunked-prefills* used in isolation as well as when they are used in tandem, evaluated over 128 requests for Yi-34B running on two A100s with a token budget of 1024. By using both *hybrid-batching* and *chunked-prefills*, Sarathi-Serve is able to lower both TTFT and TBT.

chunking on prefill throughput, and 2) analyzing the impact of hybrid-batching and chunking on latency. While we provide results only for a few experiments in this section, all the trends discussed below are consistent across various model-hardware combinations.

5.4.1 Overhead of *chunked-prefills*

Figure 14 shows how much overhead chunking adds in Yi-34B – on overall prefill runtime. As expected, smaller chunks introduce higher overhead as shown by the gradually decreasing bar heights in Figure 14. However, even with the smallest chunk size of 512, we observe a moderate overhead of at most ∼25%. Whereas with the larger token budget of 2048, chunked prefills have almost negligible overhead.

5.4.2 Impact of individual techniques

Finally, Table 4 shows the TTFT and TBT latency with each component of Sarathi-Serve evaluated in isolation *i.e., chunked-prefills*-only, *hybrid-batching*-only (mixed batches with both prefill and decode requests) and when they are used in tandem. These results show that the two techniques work best together: *chunked-prefills*-only increases TTFT as prefill chunks are slightly inefficient whereas *hybrid-batching*-only increases TBT because long prefills can still create generation stalls. When used together, Sarathi-Serve improves performance along both dimensions.

6 Related Work

Model serving systems: Systems such as Clipper [37], TensorFlow-Serving [56], Clockwork [45] and BatchMaker [44] study various placement, caching and batching strategies for model serving. However, these systems fail to address the challenges of auto-regressive transformer inference. More recently, systems such as Orca [75], vLLM [53], FlexGen [63], FasterTransformers [7], LightSeq [70], and TurboTransformers [42] propose domain-specific optimizations for transformer inference. FlexGen [63] optimizes LLM inference for throughput in resource-constrained offline scenarios i.e., it is not suitable for online serving. FastServe [72] proposed a preemptive scheduling framework for LLM inference to minimize the job completion times. We present a detailed comparison with Orca and vLLM as they represent the state-of-the-art in LLM inference.

Another approach that has emerged recently is to disaggregate the prefill and decode phases on different replicas as proposed in SplitWise, DistServe and TetriInfer [47, 58, 77]. These solutions can entirely eliminate the interference between prefills and decodes. However, disaggregation requires migrating the KV cache of *each* request upon the completion of its prefill phase which could be challenging in the absence of high-bandwidth interconnects between different replicas. In addition, this approach also under-utilizes the GPU memory capacity of the prefill replicas i.e., only the decode replicas are responsible for storing the KV cache. On the positive side, disaggregated approaches can execute prefills with maximum efficiency (and therefore yield better TTFT) unlike chunked prefills that are somewhat slower than full prefills. We leave a quantitative comparison between Sarathi-Serve and disaggregation-based solutions for future work.

Recently, Sheng et al. [62] proposed modification to iteration-level batching algorithm to ensure fairness among clients in a multi-tenant environment. FastServe [72] uses a preemption based scheduling mechanism to mitigate head-of-the-line blocking. Such algorithmic optimizations are complimentary to our approach and can benefit from lower prefill-decode interference enabled by Sarathi-Serve. Another recent system, APIServe [26] adopted chunked prefills from Sarathi to utilize wasted compute in decode batches for ahead-of-time prefill recomputation for multi-turn API serving.

Improving GPU utilization for transformers: Recent works have proposed various optimizations to improve the hardware utilization for transformers. FasterTransformer uses model-specific GPU kernel implementations. CocoNet [50] and [69] aim to overlap compute with communication to improve GPU utilization: these techniques are specially useful while using a high degree of tensor-parallel for distributed models where communication time can dominate compute. Further, the cost of computing self-attention grows quadratically with sequence length and hence can become significant for long contexts. [38,39,60] have proposed various techniques to minimize the memory bottlenecks of self-attention with careful tiling and work partitioning. In addition, various parallelization strategies have been explore to optimize model placement. These techniques are orthogonal to Sarathi-Serve.

Model optimizations: A significant body of work around model innovations has attempted to address the shortcomings of transformer-based language models or to take the next leap forward in model architectures, beyond transformers. For example, multi-query attention [61] shares the same keys and values across all the attention heads to reduce the size of the KV-cache, allowing to fit a larger batch size on the GPUs. Several recent works have also shown that the model sizes can be compressed significantly using quantization [40, 41, 43, 73]. Mixture-of-expert models are aimed primarily at reducing the number of model parameters that get activated in an iteration [32, 48, 54]. More recently, retentive networks have been proposed as a successor to transformers [65]. In contrast, we focus on addressing the performance issues of popular transformer models from a GPU's perspective.

7 Conclusion

Optimizing LLM inference for high throughput and low latency is desirable but challenging. We presented a broad characterization of existing LLM inference schedulers by dividing them into two categories – *prefill-prioritizing* and *decode-prioritizing*. In general, we argue that the former category is better at optimizing throughput whereas the latter is better at optimizing TBT latency. However, none of them is ideal when optimizing throughput and latency are both important.

To address this tradeoff, we introduce Sarathi-Serve—a system that instantiates a novel approach comprised of *chunked-prefills* and *stall-free batching*. Sarathi-Serve chunks input prompts into smaller units of work to create stall-free schedules. This way, Sarathi-Serve can add new requests in a running batch without pausing ongoing decodes. Our evaluation shows that Sarathi-Serve improves the serving capacity of Mistral-7B by up to 2.6× on a single A100 GPU and up to 5.6× for Falcon-180B on 8 A100 GPUs.

A Artifact Appendix

Abstract

Our open source artifact is available on GitHub. This repository contains our implementation of Sarathi-Serve as well as the harnesses and scripts for running and plotting the experiments described in this paper.

This repository originally started as a fork of the vLLM project. Sarathi-Serve is a lightweight high-performance research prototype and doesn't have complete feature parity with open-source vLLM. We have only retained the most critical features and adopted the codebase for faster research iterations.

Scope

This artifact allows the readers to validate the claims made in the Sarathi-Serve paper (the figures) and provides a means to replicate the experiments described. The artifact can be used to set up the necessary environment, execute the main results, and perform microbenchmarks, thus providing a comprehensive understanding of the key claims in Sarathi-Serve.

Contents

The repository is structured as follows, the primary source code for the system is contained in directory */sarathi*. The implementations for custom CUDA kernels are within the */csrc* directory. All the scripts to reproduce the experiments are in */osdi-experiments* and finally, the trace files used for the experiments are stored in */data*.

Hosting

You can obtain our artifacts from GitHub: GitHub. The main branch of the Github repository is actively updated, but we will maintain clear and accessible instructions about our artifacts in an easily identifiable README file. All the detailed instructions and README files to reproduce the experiments in the OSDI paper are available in the branch *osdi-sarathi-serve*.

Requirements

Sarathi-Serve has been tested with CUDA 12.1 on A100 and A40 GPUs. The specific GPU SKUs on which the experiments were performed and the parallelism strategies used are clearly explained in the README corresponding to the figures in the artifact, for ease of reproducibility.

ServerlessLLM: Low-Latency Serverless Inference for Large Language Models

Yao Fu[1] Leyang Xue[1] Yeqi Huang[1] Andrei-Octavian Brabete[1] Dmitrii Ustiugov[2] Yuvraj Patel[1] Luo Mai[1]

[1]*University of Edinburgh* [2]*NTU Singapore*

Abstract

This paper presents ServerlessLLM, a distributed system designed to support low-latency serverless inference for Large Language Models (LLMs). By harnessing the substantial near-GPU storage and memory capacities of inference servers, ServerlessLLM achieves effective local checkpoint storage, minimizing the need for remote checkpoint downloads and ensuring efficient checkpoint loading. The design of ServerlessLLM features three core contributions: (i) *fast multi-tier checkpoint loading*, featuring a new loading-optimized checkpoint format and a multi-tier loading system, fully utilizing the bandwidth of complex storage hierarchies on GPU servers; (ii) *efficient live migration of LLM inference*, which enables newly initiated inferences to capitalize on local checkpoint storage while ensuring minimal user interruption; and (iii) *startup-time-optimized model scheduling*, which assesses the locality statuses of checkpoints on each server and schedules the model onto servers that minimize the time to start the inference. Comprehensive evaluations, including microbenchmarks and real-world scenarios, demonstrate that ServerlessLLM dramatically outperforms state-of-the-art serverless systems, reducing latency by 10 - 200X across various LLM inference workloads.

1 Introduction

Large Language Models (LLMs) have recently been integrated into various online applications, such as programming assistants [26], search engines [21], and conversational bots [54]. These applications process user inputs, such as questions, by breaking them down into tokens (e.g., words). LLMs generate responses in an autoregressive manner, predicting each subsequent token based on the combination of input tokens and those already generated, until a sentence-ending token (EoS) is reached. To optimize this process, LLMs utilize key-value caches to store intermediate results, thereby minimizing redundant computations.

Serving LLMs at scale presents significant challenges due to the extensive GPU resources required and the stringent low response time constraints demanded by interactive services. Additionally, LLM inference latency is unpredictable as it depends on the output length, which varies significantly due to iterative token generation [27, 42, 81].

To achieve low latency, processing an LLM request often requires multiple GPUs for durations ranging from seconds to minutes. In practice, service providers hosting LLMs need to cater to a diverse range of developers, leading to substantial GPU consumption [20] and impacting the sustainability of LLM services [23]. Consequently, LLM inference services are compelled to impose strict limits on the number of requests users can send (e.g., 40 messages per 3 hours for ChatGPT [54]), highlighting the providers' current challenges in meeting demand. Researchers predict that LLM inference costs could escalate by more than 50 times as it approaches the popularity of Google Search [23].

To reduce GPU consumption, LLM service operators are turning to serverless inference, as demonstrated in platforms such as Amazon SageMaker [63], Azure [50], KServe [16], and HuggingFace [35]. In this model, developers upload their LLM checkpoints, which include both model execution and parameter files, to a checkpoint storage system. When a request is received, a model loading scheduler selects available GPUs to initiate these checkpoints. A request router then directs the inference request to the selected GPUs. This serverless approach allows infrastructure providers to efficiently multiplex LLMs on GPUs, improving resource utilization. Additionally, it offers economic advantages to infrastructure users, who incur costs only for each request's duration, thereby avoiding expensive long-term GPU reservations.

While serverless inference offers cost savings for deploying LLMs, it also introduces significant latency overheads. These overheads are commonly attributed to inference cold starts, a frequent issue in serverless workloads, as demonstrated by public traces [64, 92]. Cold starts are especially prolonged for LLM checkpoints, whose sizes can range from gigabytes [11, 76, 91] to terabytes [29]. The vast size is due to the immense number of parameters in such models, leading to notable delays when downloading from remote storage.

Moreover, these checkpoints consist of numerous tensors, each with unique structures and sizes. The complex process of loading these tensors onto GPUs, which involves file deserialization, memory allocation, and tensor shape parsing, further compounds these delays.

We aim to explore system designs that support low-latency serverless inference for LLMs. We note that GPU-based inference servers typically feature a sophisticated yet underutilized storage hierarchy, equipped with extensive host memory and storage capacities. Current serverless inference systems, such as KServe [16] and Ray Serve [73], often only utilize a fraction of the available host memory and minimally employ SSDs for caching checkpoints from the model repository. This observation has led us to propose a novel system design: leveraging the multi-tier storage hierarchy for local checkpoint storage and harnessing their significant storage bandwidth for efficient checkpoint loading.

However, several open concerns arise when implementing local checkpoint storage: (i) Given the complex storage architecture of a GPU server, which includes multiple GPUs, DRAM, SSDs, and remote storage, all interconnected through various links such as PCIe, NVMe, and network connections, how can we optimize the loading of LLM checkpoints to fully exploit the available bandwidth? (ii) Assigning requests to servers with pre-loaded checkpoints can avoid the need for remote checkpoint downloads, but this strategy might lead to prolonged queuing delays or high preemption costs. This is particularly challenging as LLMs typically have long, unpredictable inference durations, which differ markedly from traditional deep neural network inference. (iii) In a distributed cluster where model requests are concurrently served and checkpoints are preloaded onto various layers of local storage, which servers should be strategically selected to minimize the time required to start a model inference?

To address the above, we have designed and implemented ServerlessLLM, which includes three core contributions:

(1) Fast multi-tier checkpoint loading. ServerlessLLM can maximize the storage bandwidth usage of GPU servers for LLM checkpoint loading. It introduces (i) a new *loading-optimized checkpoint* that supports sequential, chunk-based reading and efficient tensor in-memory addressing, and (ii) an *efficient multi-tier checkpoint storage system* that can harness the substantial capacity and bandwidth on a multi-tier storage hierarchy, through an in-memory data chunk pool, memory-copy efficient data path, and a multi-stage data loading pipeline.

(2) Efficient live migration of LLM inference. We motivate the need for live migration of LLM inference and are the first to implement LLM live migration in serverless inference systems to enhance the performance when supporting locality-driven inference. To achieve high efficiency when migrating LLM inference, we have implemented two strategic designs: (i) the source server migrates only the tokens, rather than the large kv-cache, which significantly reduces network traffic during the migration; and (ii) it triggers an efficient re-computation of the kv-cache at the destination server, ensuring migration can complete in a timely manner.

(3) Startup-time-optimized model scheduling. ServerlessLLM aids serverless inference systems by enabling latency-preserving, locality-aware model scheduling. It integrates cost models for accurately estimating the time of loading checkpoints from different tiers in the storage hierarchy and the time of migrating an LLM inference to another server. Based on the estimation results, Phantom can choose the best server to minimize model startup latency.

We have conducted comprehensive evaluation to compare ServerlessLLM against various baseline methods in a GPU cluster. Micro-benchmark results revealed that ServerlessLLM's LLM checkpoint loading significantly outperforms existing systems such as Safetensors [36], and PyTorch [58], achieving loading times that are 3.6 - 8.2X faster. This performance enhancement is particularly notable with large LLMs like OPT [91], LLaMA-2 [76], and Falcon [11]. ServerlessLLM also supports emerging LoRA adaptors [34], achieving 4.4X speed-ups in checkpoint loading.

Furthermore, we evaluated ServerlessLLM with real-world serverless workloads, modeled on the public Azure Trace [64], and benchmarked it against KServe, Ray Serve, and a Ray Serve variant with local checkpoint caching. In these scenarios, ServerlessLLM demonstrated a 10 to 200 times improvement in latency for running OPT model inferences across datasets (i.e., GSM8K [25] and ShareGPT [83]). These results underscore ServerlessLLM's effectiveness in combining fast checkpoint loading, efficient inference migration, and optimized scheduling for model loading. The source code for ServerlessLLM is released at https://github.com/ServerlessLLM/ServerlessLLM.

2 Background and Motivation

2.1 Why Serverless Inference for LLMs

Numerous companies, including Amazon, Azure, Google, HuggingFace, Together AI [6], Deepinfra [2], Replicate [5], Databricks [7], Fireworks-AI [3], and Cohere [4], have introduced serverless inference services (also known as serverless model entrypoints). These services enable users to deploy standard open-source LLMs either in their original form or by modifying them through fine-tuning or by running custom-built models.

Serverless inference can significantly reduce costs for LLM users by charging only for the duration of inference and the volume of processed data. These serverless platforms also offer functionalities such as auto-scaling and auto-failure-recovery to keep instances in an "always-on" state. For the providing companies, serverless inference allows effective

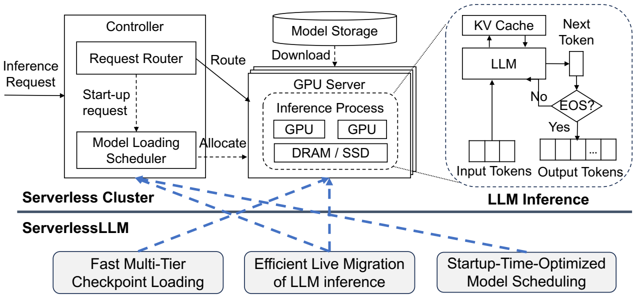

Figure 1: Overview of GPU serverless clusters, LLM inference and new designs introduced by ServerlessLLM.

multiplexing of models within a GPU cluster, improving resource utilization, and generating a software premium for managing infrastructure on behalf of users.

Serverless inference systems are especially advantageous for LLM applications with dynamic and unpredictable workloads. These may include newly launched products without clear predictions of user engagement (e.g., the launch of the ChatGPT service) or those facing spontaneous and unpredictable demands, which are typical in sectors such as healthcare, education, legal, and sales. Unlike global-scale LLM services, these applications are activated only when users access the LLM service.

2.2 Serverless Cluster and LLM Inference

We introduce the key components in GPU serverless clusters in Figure 1. Upon receiving a new inference request, the controller dispatches it to GPU-equipped nodes in a cluster running LLM inference service instances, and to cloud storage hosting model checkpoints. The controller typically consists of two main components: the *request router* and the *model loading scheduler*. The request router directs incoming requests to nodes already running LLM inference processes, or instructs the model loading scheduler to activate LLM inference processes on unallocated GPUs. The selected GPU node initiates a GPU process/container, setting up an inference library (e.g., HuggingFace Accelerate [32] and vLLM [42]). This inference process involves downloading the requested model's checkpoint from a remote model storage and loading it into the GPU, passing through SSD and DRAM.

The LLM inference process often handle requests that include user-specified input prompts, i.e., a list of tokens, as shown in Figure 1. This process iteratively generates tokens based on the prompt and all previously generated tokens, continuing until an end-of-sentence token (denoted as EoS) is produced, resulting in non-deterministic total inference time [55]. During each iteration, the LLM caches intermediate computations in a KV-cache to accelerate subsequent token generation [42, 56]. The tokens generated by each iteration are continuously streamed back to the requesting client, making LLM applications interactive by nature. Their performance is thus measured by both first-token latency (i.e., the time to return the first token) and per-token latency (i.e., the average time to generate a token).

2.3 Challenges with Serverless LLM Inference

The deployment of LLMs on serverless systems, although promising, often incurs significant latency overheads. This is largely due to the substantial proportions of cold-start in serverless clusters, as demonstrated by public data: the Azure Trace [64] shows that over 40% of functions exhibit a cold-start rate exceeding 25%, and approximately 25% of functions experience a cold-start rate greater than 60%, within a 5-minute keep-alive interval. These figures align with the findings from our experiments, underscoring the impact of cold-starts in real-world settings. Consequently, many serverless providers, including Bloomberg, have publicly acknowledged experiencing extremely high latencies, often reaching tens of seconds, when initializing state-of-the-art LLMs for inference on their platforms.

We observe several primary reasons for the prolonged LLM cold-start latency:

(1) LLM checkpoints are large, prolonging downloads. LLM checkpoints are significantly larger than conventional DNN checkpoints, which leads to longer download times. For instance, Grok-1 [82] checkpoints are over 600 GB, DBRX [72] are 250GB, and Mixtral-8x22B [71] are about 280GB [1] Downloading such large checkpoints from remote storage becomes costly. For example, acquiring an LLM checkpoint with a size of 130GB (e.g., LLaMA-2-70B [76]) from S3 or blob storage takes a minimum of 26 seconds using a fast commodity network capable of 5GB/s [19].

(2) Loading LLM checkpoints incurs a lengthy process. Even when model checkpoints are stored locally on NVMe SSDs, loading these checkpoints into GPUs remains a complex process including model initialization, GPU memory allocation, tensor creation, and tensor data copy, typically taking tens of seconds (as detailed in §7.2). For instance, loading the OPT-30B model into 4 GPUs requires 34 seconds using PyTorch, and loading LLaMA-2-70B into 8 GPUs takes 84 seconds. This loading latency far exceeds the time required for generating a token during the inference process, which is usually less than 100ms [55]. Consequently, the prolonged first-token latency can significantly disrupt user experience.

2.4 Existing Solutions and Associated Issues

To improve the latency performance when supporting LLMs, existing solutions show a variety of issues:

(1) Over-subscribing GPUs. The prevalent solutions [13, 84], aimed at circumventing model download and loading times

[1] Model size calculated in float16 precision.

in serverless inference clusters, frequently involve oversubscribing GPUs to accommodate peak demand scenarios. For instance, AWS Serverless Inference [13] maintains a certain number of GPU instances in a warmed state to alleviate the impacts of slow cold starts. While this strategy is effective for managing conventional smaller models, such as ResNet and BERT, it proves challenging for LLMs, which require substantially greater resources from costly GPUs.

(2) Caching checkpoints in host memory. Several solutions [33, 39] have been developed that cache model checkpoints in the host memory of GPU servers to eliminate the need for model downloads. This approach is typically effective for smaller conventional models (e.g., up to a few GBs [39]). However, solely relying on host-memory-based caching proves inadequate for LLMs. LLMs can easily exceed hundreds of GBs in size, challenging the capacity of host memory to store a sufficient number of their checkpoints adequately. The limited size of host memory leads to significant cache misses, resulting in frequent model downloads, as further discussed in §7.4.

(3) Deploying additional storage servers. Various strategies [19] recommend the deployment of additional storage servers within a local cluster to cache model checkpoints. Despite these enhancements, recent trace studies [19] indicate that model downloads can exceed 20 seconds through an optimized pipeline, even when connected to local commodity storage servers equipped with a 100 Gbps NIC. Although the integration of faster networks (e.g., 200 Gbps Ethernet or InfiniBand) could reduce this latency, the associated costs of implementing additional storage servers and high-bandwidth networks are substantial [18, 31]. For instance, utilizing network-optimized AWS ElasticCache servers [1] to support a 70B model can lead to a 100% increase in costs. Specifically, cache.c7gn.16xlarge servers, which provide 210GB of memory and 200 Gbps of network performance, are priced at $16.3/h, equivalent to the cost of an 8-GPU g5.48xlarge server.

3 Exploiting In-Server Multi-Tier Storage

ServerlessLLM addresses the challenges highlighted in the previous sections—namely, high model download times and lengthy model loading—using a design approach that is cost-effective, scalable, and long-term viable.

3.1 Design Intuitions

Our design is inspired by the simple observation that GPU servers used for inference feature a multi-tier storage hierarchy with substantial capacity and bandwidth. From a capacity standpoint, these servers are equipped with extensive memory capabilities. For example, a contemporary 8-GPU server can support up to 4 TBs of main memory, 64 TBs on NVMe SSDs, and 192 TBs on SATA SSDs [52]. Additionally, we observe that in the serverless inference context, a significant portion of the host memory and storage devices in GPU servers remains underutilized.

Regarding bandwidth, GPU servers typically house multiple GPUs, each connected to the host memory via a dedicated PCIe connection, providing significant aggregated bandwidth between the memory and GPU. NVMe and SATA SSDs also connect through their respective links and can be configured in RAID to enhance throughput. For instance, an 8-GPU server utilizing PCIe 5.0 technology can achieve an aggregated bandwidth of 512 GB/s between the host memory and GPUs, and around 60 GB/s from NVMe SSDs (RAID 0) to host memory.

Building on these observations, we propose a design approach that leverages the unused in-server multi-tier storage capacity to store models locally and load them more rapidly, thus reducing latency. This approach is (i) *cost-effective*, as it reutilizes existing, underutilized storage resources in GPU servers; (ii) *scalable*, given that the available local storage capacities and bandwidth can naturally increase with the addition of more inference servers; and (iii) *long-term viable*, as upcoming GPU servers will include even greater capacities and bandwidth (*e.g.*, each Grace-Hopper GPU features 1 TB on-chip DRAM and a 900GB/s C2C link between on-chip DRAM and HBM).

3.2 Design Concerns and Overview

In implementing our design, we identify three crucial concerns that must be addressed.

(1) Support complex multi-tiered storage hierarchy. Current checkpoint and model loading tools such as PyTorch [58], TensorFlow [75], and ONNX Runtime [62] are primarily designed to enhance the training and debugging phases of model development. However, these tools are not optimized for read performance, which becomes critically important in a serverless inference environment. In these settings, model checkpoints are stored once but need to be frequently loaded and accessed across multiple GPUs. This insufficient optimization for read operations results in significant loading delays. While solutions like Safetensors [36] can enhance loading performance, as demonstrated in Section 7, they still fail to fully leverage the capabilities of a multi-tiered storage hierarchy.

(2) Strong locality-driven inference. Supporting efficient model loading alone is insufficient; we also need approaches that can effectively schedule requests onto GPU servers with locally stored checkpoints. Implementing locality-driven LLM inference, however, presents challenges. Current ML model serving systems such as ClockWork [33] and Shepherd [90] take checkpoint locality into account. Yet, they either depend on accurate predictions of model inference time, which is problematic with LLMs, or they preempt ongoing model inferences, causing significant downtime and redundant computations. Therefore, ServerlessLLM must adopt a new approach that is tailored to the unique characteristics of LLM inference (*i.e.*, this workload is interactive and features long, unpredictable durations), necessitating the support for inference live migration, which is further detailed in Section 5.

(3) Scheduling models for optimized startup time. ServerlessLLM is designed to minimize the model startup latency. The cluster scheduler (or controller) plays a crucial role in scheduling models onto GPU resources to answer incoming inference requests. However, the scheduler needs to carefully consider the checkpoint's locality in the entire cluster. Many factors may influence the overall startup latency, such as the difference in the bandwidth offered by each layer in the memory hierarchy. There may be instances where it is beneficial to move the current inference execution to a new GPU than to allocate the request to a GPU where the model may have to be loaded from the storage media. Hence, ServerlessLLM needs to accurately estimate the startup times considering the cluster's checkpoint locality status and accordingly allocate resources to minimize startup time.

Overview. ServerlessLLM addresses these concerns with three novel designs, as depicted in Figure 1. Firstly, it facilitates fast multi-tier checkpoint loading (Section 4) to fully utilize the storage capacity and bandwidth of each GPU server. It also coordinates GPU servers and the cluster controller for efficient live migration of LLM inference (Section 5), ensuring locality-driven inference with minimal resource overhead and user disruption. Lastly, ServerlessLLM features a startup-time-optimized model scheduling policy (Section 6) implemented in its controller, effectively analyzing the checkpoint storage status of each server within a cluster, and it chooses a server for initiating a model, minimizing its startup time.

4 Fast Multi-Tier Checkpoint Loading

In this section, we introduce the design of fast multi-tier checkpoint loading in ServerlessLLM, with several key objectives: (i) to fully utilize the bandwidth and capacity of multi-tier local storage on GPU servers, (ii) to ensure predictable loading performance, critical for ServerlessLLM's readiness in low-latency inference clusters, and (iii) to maintain a generic design that supports checkpoints from various deep learning frameworks.

4.1 Loading-Optimized Checkpoints

Our design is motivated by the observation that LLM checkpoints are often written frequently during training and debugging but loaded infrequently. Conversely, in serverless inference environments, checkpoints are uploaded once and loaded multiple times. This discrepancy has inspired us to convert these checkpoints into a loading-optimized format.

To ensure our design is generic for different frameworks,

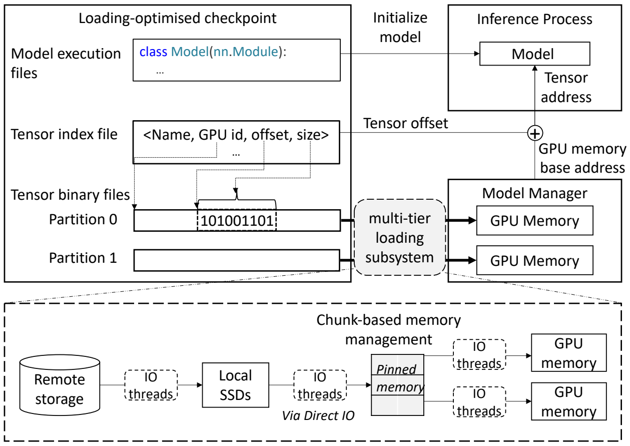

Figure 2: Components in fast multi-tier checkpoint loading.

we operate under a set of assumptions that are common in checkpoints. The checkpoints have: (i) *Model execution files* which define the model architecture. Depending on the framework, the format varies; TensorFlow typically uses protobuf files [74], while PyTorch employs Python scripts [57]. Beyond architecture, these files detail the size and shape of each tensor and include a model parallelism plan. This plan specifies the target GPU for each tensor during checkpoint loading. (ii) *Model parameter files* which stores the binary data of parameters in an LLM. Tensors within these files can be arranged in any sequence. Runtimes such as PyTorch may also store tensor shapes as indices to calculate the offset and size for each tensor.

To ensure fast loading performance, we implement two main features for the converted checkpoints: (i) *Sequential chunk-based reading*: To ensure efficient sequential reading, tensors for each GPU are grouped in partitions (shown in Figure 2). These files contain only the binary data of model parameters and exclude metadata such as tensor shapes, facilitating large chunk reading. (ii) *Direct tensor addressing*: We create a tensor index file (shown in Figure 2) that maps tensor names to a tuple of GPU id, offset, and size, facilitating the efficient restoration of tensors. The tensors are aligned with memory word sizes, facilitating direct computation of memory address.

We observe that decoupling the loading and inference processes can further enhance loading performance. This separation allows checkpoint loading to be pre-scheduled and overlapped with the initialization of the inference process. For this, ServerlessLLM uses a model manager to load tensor data, while allowing the inference process to focus on initializing the model by setting the data pointers for each tensor. More specifically, the model manager allocates memory on GPUs and loads the binary data of the checkpoint via a fast multi-tier loading subsystem (see details in 4.2). The inference process initializes the model object and sets the GPU memory address for each tensor. It acquires the base addresses for each GPU (i.e., CUDA IPC handles) from the model manager and reads the tensor offset from the tensor index file, facilitating the computation of the tensor GPU memory address (i.e., *base* + *offset*). To ensure the model is fully initialized before inference, the inference process and the model manager perform a synchronization.

4.2 Multi-Tier Loading Subsystem

To achieve fast and predictable checkpoint loading performance, we design a multi-tier loading subsystem, integrated within the model manager. This subsystem incorporates several techniques:

Chunk-based data management. For fast loading performance, we have implemented chunk-based data management with three main features: (i) *Utilizing parallel PCIe links*. To mitigate the bottleneck caused by a single PCIe link from storage when loading multiple models into GPUs, we employ parallel DRAM-to-GPU PCIe links to facilitate concurrent checkpoint loading across GPUs. (ii) *Supporting application-specific controls*. Our memory pool surpasses simple caching by providing APIs for the allocation and deallocation of memory. This enables fine-grained management of cached or evicted data chunks, based on specific requirements of the application. (iii) *Mitigating memory fragmentation*. We address latency and space inefficiencies caused by memory fragmentation by using fixed-size memory chunks.

Predictable data path. We have created an efficient data path in our model manager with two main strategies: (i) *Exploiting direct file access*. We use direct file access (e.g., ‘O_DIRECT’ in Linux) to avoid excessive data copying by directly reading data into user space. This method outperforms memory-mapped files (mmap), currently adopted in high-speed loaders such as Safetensors [36], which rely on system cache and lack consistent performance guarantees (critical for predictable performance). (ii) *Exploiting pinned memory*. We utilize pinned memory to eliminate redundant data copying between DRAM and GPU. This approach allows direct copying to the GPU with minimal CPU involvement, ensuring efficient use of PCIe bandwidth with a single thread.

Multi-tier loading pipeline. We have developed a multi-tier loading pipeline to support various storage interfaces and improve loading throughput. This pipeline has three features: (i) *Support for multiple storage interfaces*. ServerlessLLM offers dedicated function calls for various storage interfaces, including local storage (e.g., NVMe, SATA), remote storage (e.g., S3 object store [12]), and in-memory storage (pinned memory). It utilizes appropriate methods for efficient data access in each case. (ii) *Support for intra-tier concurrency*. To leverage modern storage devices’ high concurrency, ServerlessLLM employs multiple I/O threads for reading data within each storage tier, improving bandwidth utilization. (iii) *Flexible pipeline structure*. We use a flexible task queue-based pipeline design, supporting new storage tiers to be efficiently integrated. I/O threads read storage chunks and enqueue their indices (offset and size) for the I/O threads in the next tier.

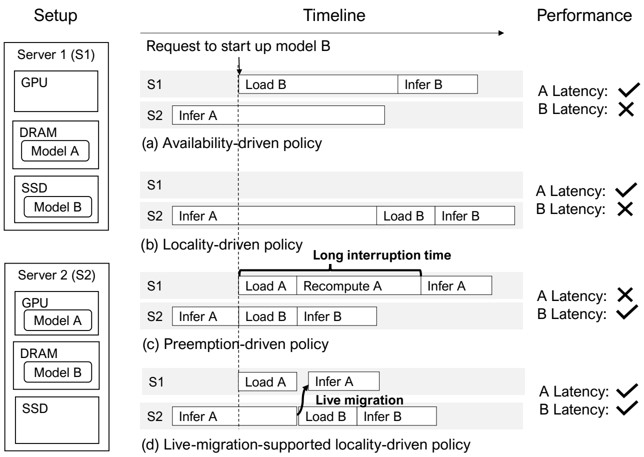

Figure 3: Analysis of different locality-driven policies

5 Efficient Live Migration of LLM Inference

In this section, we describe why live migration is the key to effective locality-driven LLM inference, and how to make such a live migration process particularly efficient.

5.1 Need for Live Migration

We consider a simple example to analyze the performance of different current approaches in supporting the checkpoint locality. In this example, we have two servers (named Server 1 and Server 2) and two models (named Model A and Model B), as illustrated in Figure 3. Server 1 currently has Model A in DRAM and Model B in SSD and its GPU is idle, while Server 2 currently has Model B in DRAM, and its GPU is running the inference of Model A.

In Figure 3, we analyze the performance of potential policies for starting up Model B. Our analysis is based on their impact on the latency performance of both Model A and B:

- *Availability-driven policy* chooses Server 1 currently with an available GPU, and it is agnostic to the location of Model B. As a result, the Model B’s startup latency suffers while the Model A remains unaffected.
- *Locality-driven policy* opts for the locality in choosing the server and thus launching Model B on Server 2. However, it waits for Model A to complete, making Model B suffer from a long queuing delay. Furthermore, the locality policy leaves Server 1 under-utilized, preventing all servers from being fully utilized.

- *Preemption-driven policy* preempts Model A on Server 2 and startups Model B. It identifies that Server 1 is free and reinitiates Model A there. This policy reduces Model B's latency but results in significant downtime for Model A when it performs reloading and recomputation.
- *Live-migration-supported locality-driven policy* prioritizes locality without disrupting Model A. It initially preloads Model A on Server 1, maintaining inference operations. When Model A is set on Server 1, its intermediate state is transferred there, continuing the inference seamlessly. Following this, Model B commences on Server 2, taking advantage of locality. This policy optimizes latency for both Models A and B.

According to the examples above, live migration stands out in improving latency for both Model A and Model B among all locality-driven policies.

5.2 Making Live Migration Efficient

We aim to achieve efficient live migration of LLM inference, incurring minimal resource overhead and minimal user interruption. We initially considered using the snapshot method from Singularity [68], which involves snapshotting the LLM inference. However, this method is slow due to lengthy snapshot creation and transfer times (e.g., typically 10s seconds or even minutes). Dirty-page-based migration might be considered to accelerate virtual machine migration, but this approach is currently not supported in GPU-enabled containers and virtual machines. Hence, we decided to explore live migration methods that can be easily implemented in applications.

To make the live migration method effective for LLM inference, we aim to achieve two objectives: (i) the migrated inference state must be minimal to reduce network traffic, and (ii) the destination server must quickly synchronize with the source server's progress to minimize migration times.

For (i), we propose to migrate tokens (typically 10-100s KB) instead of the large KV-Cache (typically 1-10s GB), as recomputing the KV-Cache based on the migrated tokens on the destination GPU is generally much faster than transferring the dirty state over the network. In certain conditions (e.g., given high-bandwidth network and short input sequences), migrating KV-Cache might also be fast yet it still increases cluster network traffic compared to migrating tokens.

For (ii), we leverage an insight from LLM inference: recomputing the KV-Cache for current tokens on the destination GPU is significantly faster (usually an order of magnitude shorter) than generating an equivalent number of new tokens on the source GPU. This approach facilitates efficient convergence of multi-round token-based migration, with the quantity of tokens generated on the source diminishing with each round. For example, time to recompute the KV-Cache for 1000 tokens equals to the time to generate about 100 new tokens according to [70].

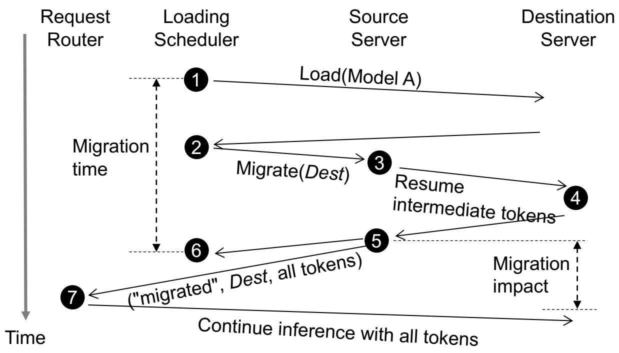

Figure 4: Live migration process for LLM inference

5.3 Multi-Round Live Migration Process

We implement the above proposal as a multi-round live migration process. In each migration round (step ❸, ❹ and ❺), the destination server (referred to as the *dest* server) recomputes the KV cache using the intermediate tokens sent by the source server (referred to as the *src* server). When the gap (i.e., the tokens generated after the last round) between the source server and the destination server is close enough, the *src* server stops generating and sends all tokens to the *dest* via the request router, ensuring minimal interruption on ongoing inference during migration. This migration process is depicted in Figure 4 with its steps defined below:

1. The model loading scheduler sends a model loading request to *dest* server to load model A into GPUs. If there is an idle instance of model A on *dest* server, the scheduler skips this step.
2. After loading, the scheduler sends a migration request carrying the address of *dest* server to *src* server.
3. Upon receiving a migrate request, *src* server sets itself as "migrating", sends a resume request with intermediate tokens (i.e., input tokens and the output tokens produced before step 3) to *dest* server if the inference is not completed. Otherwise, it immediately returns to the scheduler.
4. *dest* server recomputes KV cache given the tokens in the resume request.
5. Once *resume* request is done, *src* server stops inference, returns to the scheduler, and replies to the request router with all tokens (i.e., the intermediate tokens together with the remaining tokens produced between step 3 and step 5) and a flag "migrated".
6. The scheduler finishes the migration, unloads model A at *src* server and starts loading model B.
7. The request router checks the flag in the inference response. If it is "migrated", the request router replaces *src* server with *dest* server in its route table and sends all tokens to *dest* server to continue inference.

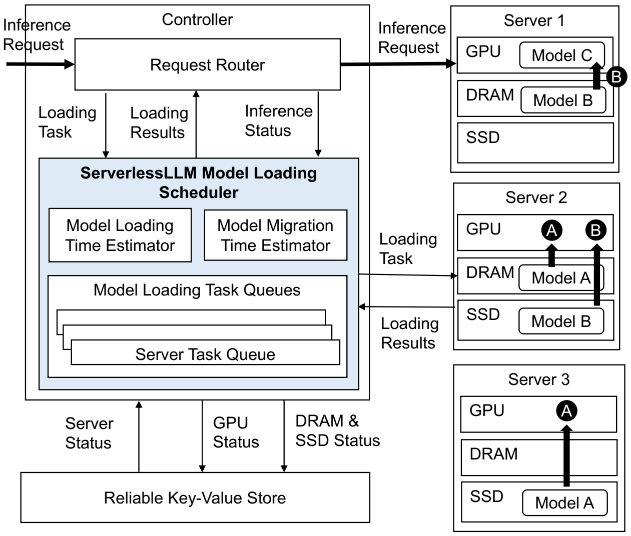

Figure 5: Overview of the model loading scheduler design

5.4 Practical Concerns

Handling inference completion. The autoregressive nature of LLM inference may lead to task completion at *src* server between steps ❸ and ❺. In such cases, *src* server informs the request router of the inference completion as usual. Additionally, it notifies the loading scheduler, which then instructs *dest* server to cease resuming, terminating the migration.

Handling server failures. ServerlessLLM can manage server failures during LLM inference migration. In scenarios where *src* server fails, if the failure happens during loading (i.e., before step ❷ in Figure 4), the scheduler aborts the migration and unloads the model from the destination. If the failure occurs during migration (i.e., between steps ❷ and ❸), the scheduler directs the destination to clear any resumed KV cache and unload the model.

In cases where *src* server fails, if the failure takes place during loading, the migration is canceled by the scheduler. Should the failure occur while resuming, the source notifies the scheduler of the failure and continues with the inference.

6 Startup-Time-Optimized Model Scheduling

In this section, we describe the design of the startup-time-optimized model scheduling implemented in ServerlessLLM's cluster scheduler (denoted as controller), as shown in Figure 5. This scheduler processes loading tasks from the request router and employs two key components: a model loading time estimator and a model migration time estimator. The former assesses loading times from various storage media, while the latter estimates times for necessary model migrations. For example, as shown in Figure 5, the scheduler calculates the time to load Model A (indicated by 🅐) from different servers' DRAM and SSD, aiding in server selection. Similarly, for Model B (🅑), it assesses whether to migrate Model C to another server or load Model B from Server 2's SSD.

To ensure robust time estimation, the ServerlessLLM scheduler employs distinct loading task queues for each server, effectively mitigating the impact of contentions caused by concurrent loading activities. Upon assigning a task, it promptly updates the server status—including GPU and DRAM/SSD states—in a reliable key-value store (e.g., , etcd [30] and ZooKeeper [38]). This mechanism enables ServerlessLLM to maintain continuity and recover efficiently from failures.

6.1 Estimating Model Loading Time

To estimate the time needed to load models from different storage tiers, we consider three primary factors: (i) *queuing time* (q), which is the wait time for a model in the server's loading task queue. This occurs when other models are pending load on the same server; (ii) *model size* (n), the size of the model in bytes, or its model partition in multi-GPU inference scenarios; (iii) *bandwidth* (b), the available speed for transferring the model from storage to GPUs. ServerlessLLM tracks bandwidth for network, SSD, and DRAM, allowing us to calculate loading time as $q + n/b$. Here, q accumulates from previous estimations for the models already in the queue.

For precise estimations, we have implemented: (i) Sequential model loading per server, with single I/O queues for both Remote-SSD and SSD-DRAM paths (since these paths are shared by multiple GPUs on a server), reducing bandwidth contention which complicates estimation; (ii) In multi-tier storage, ServerlessLLM uses the slowest bandwidth for estimation because of ServerlessLLM's pipeline loading design. For example, when SSD and DRAM are both involved, SSD bandwidth is the critical bottleneck since it is orders of magnitude slower than DRAM; (iii) The scheduler monitors the loading latency returned by the servers. It leverages the monitoring metrics to continuously improve its estimation of the bandwidth through different storage media.

6.2 Estimating Model Migration Time

For live migration time estimation, our focus is on model resuming time (as shown in step ❹ in Figure 4), as this is significantly slower (seconds) than token transfer over the network (milliseconds). We calculate model resuming time considering: (i) *input tokens* (t_{in}), the number of tokens in the LLM's input prompt; (ii) *output tokens* (t_{out}), the tokens generated so far; and (iii) *model-specific parameters* (a and b), which vary with each LLM's batch sizes and other factors, based on LLM system studies like vLLM [42]. With all the above factors, we can compute the model resuming time as $a \times (t_{in} + t_{out}) + b$.

However, obtaining real-time output tokens from servers for the scheduler can lead to bottlenecks due to excessive server interactions. To circumvent this, we developed a method where the scheduler queries the local request router for the inference status of a model, as illustrated in Figure 5. With the inference duration (d) and the average time to produce a token (t), we calculate $t_{out} = d/t$.

For selecting the optimal server for model migration, ServerlessLLM employs a dynamic programming approach to minimize migration time.

6.3 Practical Concerns

Selecting best servers. Utilizing our time estimations, ServerlessLLM evaluates all servers for loading the forthcoming model, selecting the one offering the lowest estimated startup time. The selection includes the server ID and GPU slots to assign. If no GPUs are available, even after considering migration, the loading task is held pending and retried once the request router informs the scheduler to release GPUs.

Handling scheduler failures. ServerlessLLM is built to withstand failures, utilizing a reliable key-value store to track server statuses. On receiving a server loading task, its GPU status is promptly updated in this store. Post server's confirmation of task completion, the scheduler updates the server's storage status in the store. Once recorded, the scheduler notifies the request router of the completion, enabling request routing to the server. In the event of a scheduler failure, recovery involves retrieving the latest server status from the key-value store and synchronizing it across all servers.

Scaling schedulers. The performance of the loading scheduler has been significantly enhanced by implementing asynchronous operations for server status reads, writes, and estimations. Current benchmarks demonstrate its capability to handle thousands of loading tasks per second on a standard server. Plans for its distributed scaling are earmarked for future development.

Resource fairness. ServerlessLLM treats all models with equal importance and it ensures migrations do not impact latency. While we currently adopt sequential model loading on the I/O path, exploring concurrent loading on servers with a fairness guarantee is planned for future work.

Estimator accuracy. Our estimator can continuously improve their estimation based on the monitored loading metrics returned by the servers. They offer sufficient accuracy for server selection, as shown in Section 7.

7 Evaluation

This section offers a comprehensive evaluation of ServerlessLLM, covering three key aspects: (i) assessing the performance of our loading-optimized checkpoints and model manager, (ii) examining the efficiency and overheads associated with live migration for LLM inference, and (iii) evaluating ServerlessLLM against a large-scale serverless workload, modelled on real-world serverless trace data.

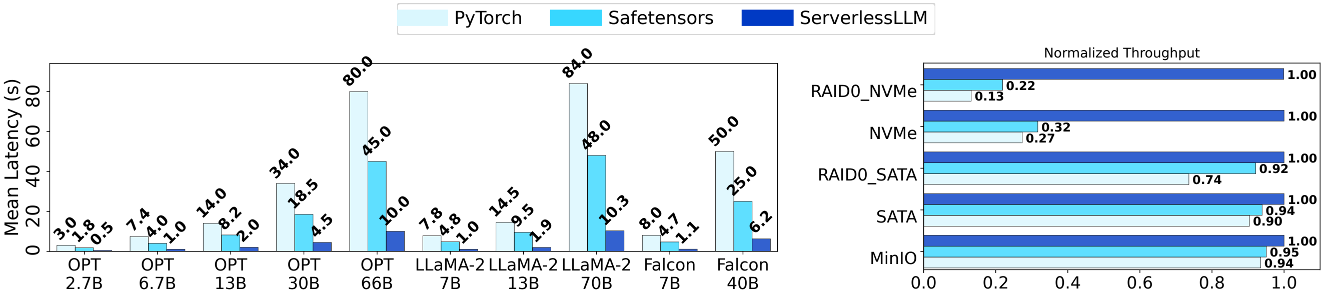
7.1 Evaluation Setup

Setup. We have two test beds: (i) a GPU server has 8 NVIDIA A5000 GPUs, 1TB DDR4 memory and 2 AMD EPYC 7453 CPUs, two PCIe 4.0-capable NVMe 4TB SSDs (in RAID 0) and two SATA 3.0 4TB SSDs (in RAID 0). This server is connected to a storage server via 1 Gbps networks on which we have deployed MinIO [51], an S3 compatible object store; (ii) a GPU cluster with 4 servers connected with 10 Gbps Ethernet connections. Each server has 4 A40 GPUs, 512 GB DDR4 memory, 2 Intel Xeon Silver 4314 CPUs and one PCIe 4.0 NVMe 2TB SSD.

Models. We use state-of-the-art LLMs, including OPT [91], LLaMA-2 [76] and Falcon [11] in different sizes. For cluster evaluation (§7.3 and §7.4) on test bed (ii), following prior work [44], we replicate OPT-6.7B/OPT-13B/OPT-30B models for 32/16/8 instances respectively (unless otherwise indicated) that are treated as different models during evaluation.

Datasets. We use real-world LLM datasets as the input to models. This includes GSM8K [25] that contains problems created by human problem writers, and ShareGPT [83] that contains multilanguage chat from GPT4. Since the models we used can handle at most 2048 context lengths, we truncate the input number of tokens to the max length. We also randomly sample 4K samples from each dataset to create a mixed workload, emulating real-world inference workloads.

Workloads. Since there are no publicly available LLM serverless inference workloads, we use Azure Serverless Trace [64] which is a representative serverless workload used in recent serverless studies [61] and model-serving studies [44, 90]. We designate functions to models and creates bursty request traces (CV=8 using Gamma distribution), following the workload generation method used in AlpaServe [44]. We then scale this trace to the desired requests per second (RPS). For cluster evaluation, we replicate each model based on its popularity and distribute them across nodes' SSDs using round-robin placement until the total cluster-wide storage limit is reached. Optimization of checkpoint placement is considered a separate issue and is not addressed in this paper. For all experiments (unless we indicate otherwise), we report the model startup latency, a critical metric for serverless inference scenarios. When migration or preemption is enabled, this latency is added with pause latency, accounting for the impacts of delays.



(a) Checkpoint loading speed.

(b) Normalized bandwidth utilization.

Figure 6: Checkpoint loading performance.

7.2 ServerlessLLM Checkpoint Loading

We now evaluate the model manager's effectiveness in reducing the model loading latency. For our experiments, we test the checkpoint read on test bed (i). We record reads from 20 copies of each model checkpoint to get a statistically significant performance report. We clear the page and inode caches after checkpoint copies are made to ensure a cold start. For each type of model, we randomly access the 20 copies to simulate real-world access patterns.

Loading performance. We aim to quantify the performance gains achieved by the ServerlessLLM checkpoint manager. We compare PyTorch [58] and Safetensors [36], representing the read-by-tensor checkpoint loading and mmap-based checkpoint loading, respectively. We use all types of models with all checkpoints in FP16 and run the test on RAID0-NVMe SSD having a throughput of 12 GB/s.

Figure 6a shows the performance comparison in terms of mean latency for all the models[2]. We observe that ServerlessLLM is 6X and 3.6X faster than PyTorch and Safetensors, respectively, for our smallest model (OPT-2.7B). We observe similar results with the largest model (LLaMA-2-70B) where ServerlessLLM is faster than PyTorch and Safetensors by 8.2X and 4.7X respectively. Safetensors is slower than ServerlessLLM due to a lot of page faults (112K for LLaMA-2-7B) on cold start. In contrast, ServerlessLLM's checkpoint manager leverages direct I/O and realizes chunk-based parallel loading, all contributing to the significant improvement in loading throughput. PyTorch is about 2X slower than Safetensors in our evaluation, consistent with the results in a public benchmark [37] reported by Safetensors. The primary reason is that PyTorch first copies data into host memory and then into GPU memory.

Furthermore, we observe that the loading performance of ServerlessLLM is agnostic to the type of the model. For example, the performance of both OPT-13B and LLaMA-2-13B is similar signifying the fact that the performance is only dependent on the checkpoint size.

Loading performance with LoRA adapters. ServerlessLLM also supports loading LoRA adapters [34] in PEFT format [49]. We conducted experiments using the same setting in [65]. For an adapter (rank=32, size=1GB) of LLaMA-70B model, ServerlessLLM achieves 83.5ms loading latency which is 4.4X faster than Safetensors whose loading latency is 370ms. This demonstrates ServerlessLLM's loader design efficiency in small checkpoint loading.

Harness full bandwidth of the storage devices. We now move to understand if ServerlessLLM can utilize the entire bandwidth that a storage medium offers to achieve low latency. We use the same setup as described above. We choose LLaMA-2-7B to represent the SOTA LLM model. We use FIO [17] with the configuration of asynchronous 4M direct sequential read with the depth of 32 as the optimal baseline and optimized throughput using the result in all storage media. We test various settings of FIO to make sure the configuration chosen has the highest bandwidth on each storage media. For object storage over the network, we use the official MinIO benchmark to get the maximum throughput.

Figure 6b shows the bandwidth utilization across different storage devices, normalized relative to the measurements obtained using FIO and MinIO. The storage device from bottom to top is ascending in maximum bandwidth. We observe that ServerlessLLM's model manager is capable of harnessing different storage mediums and saturating their entire bandwidth to get maximum performance. Interestingly, we observe that ServerlessLLM is well suited for faster storage devices such as RAID0-NVMe compared to Pytorch and Safetensors. It shows that existing mechanisms are not adaptive to newer and faster storage technology. Despite the loading process passing through the entire memory hierarchy, ServerlessLLM is capable of saturating the bandwidth highlighting the effectiveness of pipelining the loading process.

Performance breakdown. We now move to highlight how each optimization within the model manager contributes towards the overall performance. We run an experiment using RAID0-NVMe with various OPT models. We start from the basic implementation (ReadByTensor) and incrementally add

[2] The number after the model name represents the number of parameters in the figure and B stands for Billion.

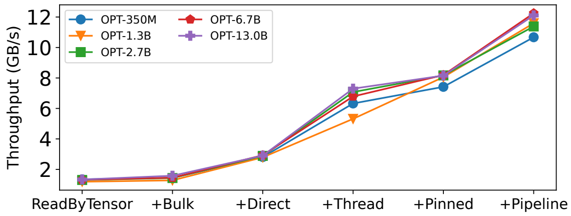


Figure 7: Performance breakdown of checkpoint loaders.

optimizations until the Pipeline implementation. Figure 7 shows the performance breakdown for each model. We observe similar contributions by different optimizations for all the models despite having different checkpoint size.

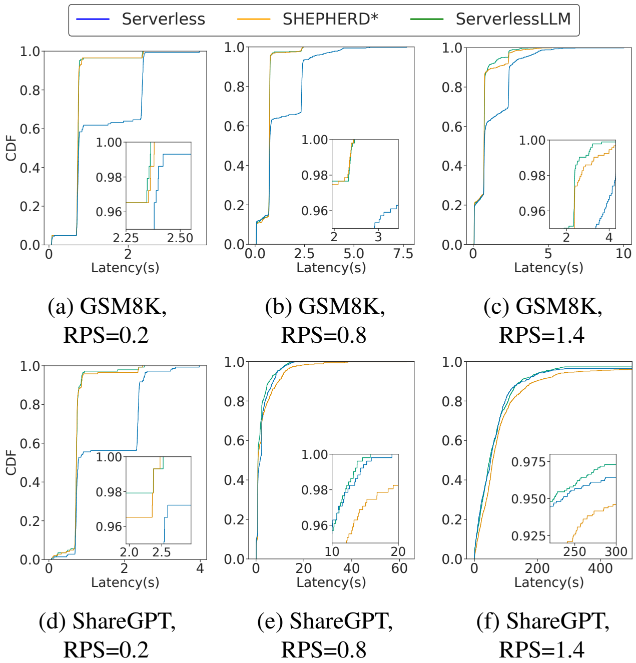
Bulk reading improves 1.2x throughput, mitigating the throughput degradation from reading small tensors one after another (on average one-third of the tensors in the model are less than 1MB). Direct IO improves 2.1x throughput, bypassing cache and data copy in the kernel. Multi-thread improves 2.3x throughput, as multiple channels within the SSD can be concurrently accessed. Pinned memory provides a further 1.4x throughput, bypassing the CPU with GPU DMA. Pipeline provides a final 1.5x improvement in throughput, helping to avoid synchronization for all data on each storage tier.

We run ServerlessLLM in a container to limit the CPU cores it can use. We find that with 4 CPU cores, ServerlessLLM can achieve maximum bandwidth utilization. We set a sufficiently large chunk size in bulk reading (16MB) to involve less number of reads and also pinned memory-based chunk pool does not need extra CPU cycles for data copy.

7.3 ServerlessLLM Model Scheduler

In this section, we evaluate the performance of the ServerlessLLM's cluster scheduler on test bed (ii). We compare ServerlessLLM against two schedulers – the de-facto serverless scheduler and Shepherd [90] scheduler. The serverless scheduler randomly chooses any GPU available and does not comprise any optimization for loading time. We implement Shepherd scheduler and use ServerlessLLM's loading time estimation strategy to identify the correct GPU. We call the modified scheduler as Shepherd*. Therefore, in principle, Shepherd* and ServerlessLLM will choose the same GPU. However, Shepherd* will continue to rely on preemption, while ServerlessLLM will rely on live migration to ensure lower latency times.

Figure 8a shows the result of a scenario where we run all three schedulers against OPT-6.7B model and GSM8K and ShareGPT dataset while increasing the requests per second. ShareGPT dataset's average inference time is 3.7X longer than GSM8K. Figure 8a and Figure 8d show the case where there is no locality contention for both datasets. The serverless scheduler cannot take advantage of locality-aware scheduling unlike ServerlessLLM and Shepherd* leading to longer latency. For 40% of the time, the model is loaded from SSD due to random allocation of the GPUs. As there is no migration or preemption, the performance of Shepherd and ServerlessLLM is similar.



(a) GSM8K, RPS=0.2

(b) GSM8K, RPS=0.8

(c) GSM8K, RPS=1.4

(d) ShareGPT, RPS=0.2

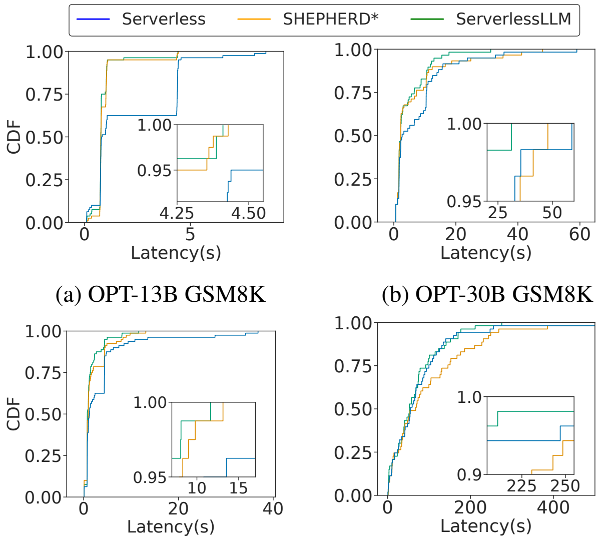
(e) ShareGPT, RPS=0.8

(f) ShareGPT, RPS=1.4

Figure 8: Impacts of RPS on model loading schedulers.

When the schedulers are subjected to medium requests per second, for GSM8K (Figure 8b, without locality-aware scheduling, the loading times start causing queueing latency leading with Serverless scheduler resulting in increasing the P99 latency by 1.86X. As there is no migration or preemption, the performance of Shepherd and ServerlessLLM is similar. With a longer inference time with ShareGPT (Figure 8e, we even observe 2X higher P99 latency with Shepherd* compared to ServerlessLLM due to preemption. As ServerlessLLM relies on live migration in case of locality contention, ServerlessLLM performs better than the other schedulers despite the number of migrations is higher (114 out of 513 total requests) than the number of preemptions (40 out of 513 total requests).

On further stressing the system by increasing the requests per second to 1.4, for GSM8K, one can clearly observe the impact of live migration and preemption. ServerlessLLM outperforms Shepherd* and Serverless schedulers by 1.27X and 1.95X on P99 latency respectively. There are 9 preemptions and 53 migrations respectively for a total of 925 requests. As discussed in Section 5.1, preemptions lead to longer latency compared to migrations. We also observe that with Shepherd*, model checkpoints are read from SSD 2X times more than with ServerlessLLM. With ShareGPT (figure 8f, we observe that the GPU occupancy reaches 100% leading to requests



(a) OPT-13B GSM8K

(b) OPT-30B GSM8K

(c) OPT-13B ShareGPT

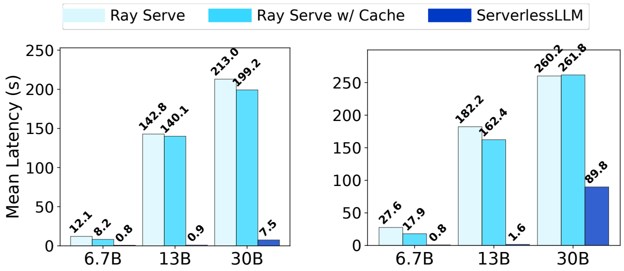
(d) OPT-30B ShareGPT

Figure 9: Impacts of datasets and models on model loading schedulers.

timeouts with all the three schedulers[3]. Shepherd behaves the worst compared to Serverless and ServerlessLLM schedulers, i.e., 1.43X and 1.5X higher P95 latency respectively. ServerlessLLM and Shepherd* issue 64 migrations and 166 preemptions, respectively for a total of 925 requests. In this scenario, ServerlessLLM's effectiveness is constrained by resource limitations.

We further stress the system by running even larger models (OPT-13B and OPT-30B) with GSM8K and ShareGPT datasets. Figure 9 shows the results for those experiments. locality-aware scheduling is more important for larger models as caching them in the main memory can reap better performance. As ServerlessLLM and Shepherd* are both locality-aware, they can make better decisions while scheduling the requests leading to better performance. As Serverless scheduler makes decisions randomly, for GSM8K, we observe that for 35-40% times, the model is loaded from SSD leading to poor performance. We see similar behavior for ShareGPT, OPT-13B experiment too. For the OPT-30B ShareGPT case, the model size is 66 GB. Hence, only two models can be stored in the main memory at any given time reducing the impact of locality-aware scheduling. Even in this extreme case, ServerlessLLM still achieves 35% and 45% lower P99 latency compared to Serverless and Shepherd* respectively.

Time Estimation. The GPU time estimation error is bounded at 5ms, while the SSD loading error is bounded at 40ms. However, we do observe instability in CUDA driver calls. For instance, when migrating a model, we noted that cleaning up GPU states (e.g., KV cache) using `torch.cuda.empty_cache()` can lead to inaccurate estimations, resulting in an average underestimation of 25.78 ms. While infrequent, we observed a maximum underestimation of 623 ms during GPU state cleanup in one out of 119 migrations (as depicted in Figure 8e).



(a) GSM8K

(b) ShareGPT

Figure 10: Impacts of datasets and models on overall serving systems.

7.4 Entire ServerlessLLM in Action

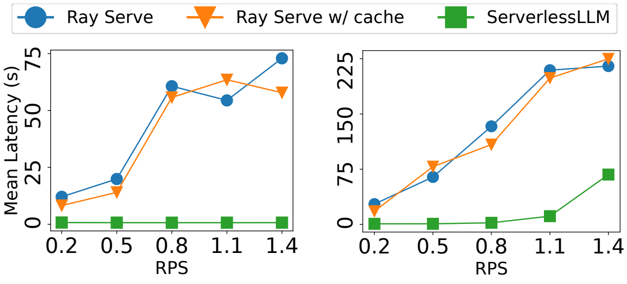
We aimed to deploy the entire ServerlessLLM with a serverless workload on test bed (ii). Here, we compare ServerlessLLM against state-of-the-art distributed model serving systems: (i) Ray Serve (Version 2.7.0), a version we have extended to support serverless inference scenarios with performance that can match SOTA serverless solutions such as KServe; (ii) Ray Serve with Cache, a version we improved to adopt a local SSD cache on each server (utilizing the LRU policy as in ServerlessLLM) to avoid costly model downloads; and (iii) KServe (Version 0.10.2), the SOTA serverless inference system designed for Kubernetes clusters.

For best performance, Ray Serve and its cache variant are both enhanced by storing model checkpoints on local SSDs and estimating download latency by assuming an exclusively occupied 10 Gbps network. For each system, we set the maximum concurrency to one and set the keep-alive period equal to its loading latency, following prior work [60]. We launch parallel LLM inference clients to generate various workloads, where each request has a timeout threshold of 300 seconds.

Effectiveness of loading-optimized checkpoints. We aimed to assess the effectiveness of loading-optimized checkpoints within a complete serverless workload, employing various model sizes and datasets to diversely test the checkpoint loaders.

In this experiment, as depicted in Figure 10, Ray Serve and Ray Serve with Cache utilize Safetensors. Owing to the large sizes of the models, the SSD cache cannot accommodate all models, necessitating some to be downloaded from the storage server. With OPT-6.7B and GSM 8K, ServerlessLLM starts models in an average of 0.8 seconds, whereas Ray Serve takes 12.1 seconds and Ray Serve with Cache 8.2 seconds, demonstrating an improvement of over 10X. Even

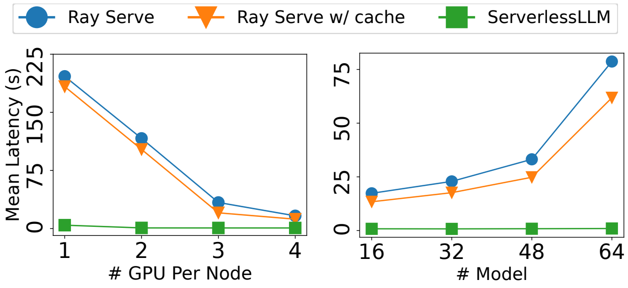
[3] Based on the average inference time of OPT-6.7B on ShareGPT dataset, the maximum theoretically RPS is 1.79.



(a) GSM8k

(b) ShareGPT

Figure 11: Impacts of RPS on overall serving systems.



(a) Impacts of # GPUs per node

(b) Impacts of # models

Figure 12: System scalability and resource efficiency.

with a faster network (i.e., 100 Gbps), the average latency of Ray Serve could drop to 3.8 seconds, making it still 4.7 times slower than ServerlessLLM. The significance of the model loader becomes more pronounced with larger models, as ServerlessLLM can utilize parallel PCIe links when loading large models partitioned on multiple GPUs from pinned memory pool. For instance, with OPT-30B, ServerlessLLM still initiates the model in 7.5 seconds, while Ray Serve's time escalates to 213 seconds and Ray Serve with Cache to 199.2 seconds, marking a 28X improvement.

This considerable difference in latency substantially affects the user experience in LLM services. Our observations indicate that ServerlessLLM can fulfill 89% of requests within a 300-second timeout with OPT-30B, whereas Ray Serve with Cache manages only 26%.

With the ShareGPT dataset (Figure 10b), which incurs a 3.7X longer inference time than GSM 8K, the challenge for model loaders becomes even more intense. For models like 6.7B and 13B, ServerlessLLM achieves latencies of 0.8 and 1.6 seconds on average, respectively, compared to Ray Serve and Ray Serve with Cache, which soar to 182.2 and 162.4 seconds. When utilizing OPT-30B, ServerlessLLM begins to confront GPU limitations (with all GPUs occupied and migration unable to free up more resources), leading to an increased latency of 89.9 seconds. However, this is still a significant improvement over Ray Serve with Cache, which reaches a latency of 261.8 seconds

Effectiveness of live migration and loading scheduler. In evaluating the effectiveness of LLM live migration and the loading scheduler, we created workloads with varying RPS levels. Scenarios with higher RPS highlight the importance of achieving load balancing and locality-aware scheduling since simply speeding up model loading is insufficient to address the resource contention common at large RPS levels.

From Figure 11a, it is evident that ServerlessLLM, equipped with GSM8K, consistently maintains low latency, approximately 1 second, even as RPS increases. In contrast, both Ray Serve and Ray Serve with Cache experience rising latency once the RPS exceeds 0.5, which can be attributed to GPU resource shortages. Their inability to migrate LLM inference for locality release or to achieve load balancing, unlike ServerlessLLM, results in performance degradation.

With the more demanding ShareGPT workload, as shown in Figure 11b, ServerlessLLM maintains significant performance improvements — up to 212 times better — over Ray Serve and Ray Serve with Cache across RPS ranging from 0.2 to 1.1. However, at an RPS of 1.4, ServerlessLLM's latency begins to rise, indicating that despite live migration and optimized server scheduling, the limited GPU resources eventually impact ServerlessLLM's performance.

Resource efficiency. A major advantage of the low model startup latency in ServerlessLLM is its contribution to resource savings when serving LLMs. We vary the number of GPUs available on each server to represent different levels of resource provisioning. As shown in Figure 12a, ServerlessLLM scales well with elastic resources. With just one GPU per server, ServerlessLLM already achieves a 4-second latency by efficient migrations and swaps. In contrast, Ray Serve with Cache requires at least four GPUs per server to attain a 12-second latency, which is still higher than ServerlessLLM's performance with only one GPU per node. With larger clusters, the resource-saving efficiency of ServerlessLLM is expected to become even more pronounced, as larger clusters offer more options for live migration and server scheduling.

The resource efficiency of ServerlessLLM is further evident when maintaining a fixed number of GPUs while increasing the number of LLMs in the cluster. In Figure 12b, with a limited number of models, Ray Serve with Cache can match ServerlessLLM in latency performance. However, as the number of models grows, the performance gap widens, showcasing ServerlessLLM's potential suitability for large-scale serverless platforms.

KServe comparison. In our study, we assess KServe and ServerlessLLM within a Kubernetes cluster. Given that our four-server cluster is unsuitable for a Kubernetes deployment, we instead utilize an eight-GPU server, simulating four nodes with two GPUs each. Since KServe performs slower than the other baselines considered in our evaluation, we only briefly mention KServe's results without delving into details.

With KServe, the GPU nodes initially exhibited a first token latency of 128 seconds. This latency was primarily due to KServe taking 114 seconds to download an OPT-6.7B model checkpoint from the local S3 storage over a 1 Gbps network. However, after applying the same enhancement as those for Ray Serve, we reduced the first token latency to 28 seconds. Despite this improvement, KServe's best latency was significantly higher than those achieved by ServerlessLLM. Notably, ServerlessLLM was the only system able to reduce the latency to within one second.

8 Related Work

Serverless inference systems. Extensive research has focused on optimizing ML model serving in serverless architectures, targeting batching [10, 84, 89], scheduling [60, 87], and resource efficiency [24, 43]. Industry solutions like AWS SageMaker and Azure ML [50], along with the open-source KServe [16], demonstrate practical implementations. Despite these advancements, serverless inference systems still perform suboptimally with LLMs, as our paper demonstrates.

Serverless cold-start optimizations. Cold-start latency is a significant issue in serverless systems, addressed through various strategies including fast image pulling [79], lightweight isolation [45, 53], snapshot and restore [15, 22, 28, 67, 77], resource pre-provision [64], elastic resource provisioning [48, 78], and fork [9, 80]. These approaches mainly focus on reducing startup times for containers or VMs without loading large external states. Recent research has explored optimizing cold-starts by facilitating faster model swaps between GPUs and host memory [39, 88], though scalability with LLMs is still challenging. In contrast, ServerlessLLM effectively minimizes cold-start latency through LLM-specific innovations, such as optimized checkpoint formats and loading pipelines, live migration, and a cluster scheduler tailored to LLM inference characteristics.

Exploiting locality in serverless systems. Locality plays a crucial role in various optimization strategies for serverless systems. This includes leveraging host memory and local storage for data cache [41, 59, 69], optimizing the reading of shared logs [40], and enhancing communication efficiency in serverless Directed Acyclic Graphs (DAGs) [46, 47]. ServerlessLLM, distinct from existing methods, introduces a high-performance checkpoint cache for GPUs, markedly improving checkpoint loading from multi-tier local storage to GPU memory. Recent studies [8, 86] have also recognized the need for leveraging locality in orchestrating serverless functions. Beyond these studies, ServerlessLLM leverages LLM-specific characteristics in improving the locality-based server's selection and launching locality-driven inference.

LLM serving systems. Recent advancements in LLM serving have improved inference latency and throughput. Orca [85] uses continuous batching for better GPU utilization during inference. AlpaServe [44] shows that model parallelism can enhance throughput while meeting SLO constraints, though it has yet to be tested on generative models. vLLM [42] introduces PagedAttention for efficient KV cache management. SplitWise [55] improves throughput by distributing prompt and token generation phases across different machines. Some approaches [14, 66] also use storage devices to offload parameters from GPUs to manage large LLM sizes. However, these systems often overlook model loading challenges, leading to increased first token latencies when multiple models share GPUs. ServerlessLLM addresses this by focusing on minimizing loading latency to complement these throughput and latency optimizations.

9 Conclusion

This paper describes ServerlessLLM, a low-latency serverless inference system purposefully designed for LLMs. The design of ServerlessLLM uncovers significant opportunities for system research, including designing new loading-optimized checkpoints, discovering the need to support live migration when conducting locality-driven LLM inference, and enabling a serverless cluster scheduler to be aware of the locality of checkpoints in a cluster when optimizing its model scheduling decision. We believe our work can be extended to ensure fairness of resources across the cluster and explore the possibility of smart checkpoint placement. We look forward to addressing these issues in the future. We consider ServerlessLLM as the first step towards unlocking the potential of serverless computing for LLMs. We will continue to develop the open-source version of ServerlessLLM. Given its versatility, we envision it as a platform to test new research ideas.

10 Acknowledgments

We sincerely thank our shepherd, Amar Phanishayee, and the OSDI reviewers for their insightful feedback, which helped improve the quality of this paper. We also extend our thanks to Boris Grot for his feedback. We acknowledge Zhaonan Zhang, Mingyu Dai, and Yusen Fei for their work in the early stages of this project. We are grateful for the GPU resources provided by the School of Informatics and the Edinburgh International Data Facility. This work is supported by UK EPSRC and gifts from Tencent.

InfiniGen: Efficient Generative Inference of Large Language Models with Dynamic KV Cache Management

Wonbeom Lee[†] Jungi Lee[†] Junghwan Seo Jaewoong Sim

Seoul National University

Abstract

Transformer-based large language models (LLMs) demonstrate impressive performance across various natural language processing tasks. Serving LLM inference for generating long contents, however, poses a challenge due to the enormous memory footprint of the transient state, known as the key-value (KV) cache, which scales with the sequence length and batch size. In this paper, we present InfiniGen, a novel KV cache management framework tailored for long-text generation, which synergistically works with modern offloading-based inference systems. InfiniGen leverages the key insight that a few important tokens that are essential for computing the subsequent attention layer in the Transformer can be speculated by performing a minimal rehearsal with the inputs of the current layer and part of the query weight and key cache of the subsequent layer. This allows us to prefetch only the essential KV cache entries (without fetching them all), thereby mitigating the fetch overhead from the host memory in offloading-based LLM serving systems. Our evaluation on several representative LLMs shows that InfiniGen improves the overall performance of a modern offloading-based system by up to 3.00× compared to prior KV cache management methods while offering substantially better model accuracy.

1 Introduction

Large language models (LLMs) have opened a new era across a wide range of real-world applications such as chatbots [40, 76], coding assistants [11, 43], language translations [1, 68], and document summarization [64, 74]. The remarkable success of LLMs can largely be attributed to the enormous model size, which enables effective processing and generation of long contents. For instance, while the maximum sequence length of the first version of GPT was restricted to 512 tokens [51], the latest version, GPT-4, can handle up to 32K tokens, which is equivalent to approximately 50 pages of text [3]. Some recently announced models such as Claude 3 [6] and Gemini 1.5 [53] can even process up to 1 million tokens, significantly expanding the context window by several orders of magnitude.

In addition to the well-studied challenge of the model size, deploying LLMs now encounters a new challenge due to the substantial footprint of the transient state, referred to as the *key-value (KV) cache*, during long context processing and generation. For generative LLM inference, the keys and values of all preceding tokens are *stored* in memory to avoid redundant and repeated computation. Unlike the model weights, however, the KV cache scales with the output sequence length, often consuming even more memory capacity than the model weights. As the demand for longer sequence lengths (along with larger batch sizes) continues to grow, the issue of the KV cache size will become more pronounced in the future.

Meanwhile, modern LLM serving systems support offloading data to the CPU memory to efficiently serve LLMs within the hardware budget [5, 57]. These offloading-based inference systems begin to support even offloading the KV cache to the CPU memory, thereby allowing users to generate much longer contexts beyond the GPU memory capacity. However, transferring the massive size of the KV cache from the CPU memory to the GPU becomes a new performance bottleneck in LLM inference.

In this work, we propose InfiniGen, a KV cache management framework designed to synergistically work with modern offloading-based inference systems. InfiniGen builds on two key design principles. First, it speculates and chooses the KV cache entries that are critical to produce the next output token, dropping the non-critical ones, by conducting a minimal *rehearsal* of attention computation for Layer i at Layer $i-1$. Second, it leverages the CPU memory capacity and maintains the KV cache pool on the CPU, rather than on the GPU, to ensure that the critical KV cache values can be identified for all outputs and layers with a large *window size* while alleviating the concerns about limited GPU memory capacity for long content generation.

In particular, InfiniGen manipulates the model weights *offline* to make the speculation far more efficient and precise, by

[†] Equal contribution

skewing the Transformer architecture query and key matrices to emphasize certain important columns. During the prefill stage, while the prompt and input of an inference request are initially processed, InfiniGen generates *partial* weights for use in the subsequent decoding (i.e., output generation) stage. At Layer $i-1$ of the decoding stage, InfiniGen speculates on the attention pattern of the next layer (Layer i) using the attention input of Layer $i-1$, a partial query weight, and a partial key cache of Layer i. Based on the speculated attention pattern, InfiniGen prefetches the essential KV cache entries from the CPU memory for attention computation at Layer i. By dynamically adjusting the number of KV entries to prefetch, InfiniGen brings only the necessary amount of the KV cache to the GPU, thereby greatly reducing the overhead of the KV cache transfer. In addition, InfiniGen manages the KV cache pool by dynamically removing the KV cache entries of infrequently used tokens.

We implement InfiniGen on a modern offloading-based inference system [57] and evaluate it on two representative LLMs with varying model sizes, batch sizes, and sequence lengths. Our evaluation shows that InfiniGen achieves up to a 3.00× speedup over the existing KV cache management methods while offering up to a 32.6 percentage point increase in accuracy. In addition, InfiniGen consistently provides performance improvements with larger models, longer sequence lengths, and larger batch sizes, while prior compression-based methods lead to saturating speedups.

In summary, this paper makes the following contributions:

- We present InfiniGen, a dynamic KV cache management framework that synergistically works with modern offloading-based LLM serving systems by intelligently managing the KV cache in the CPU memory.

- We propose a novel KV cache prefetching technique with ephemeral pruning, which speculates on the attention pattern of the subsequent attention layer and brings only the essential portion of the KV cache to the GPU while retaining the rest in the CPU memory.

- We implement InfiniGen on a modern offloading-based inference system and demonstrate that it greatly outperforms the existing KV cache management methods, achieving up to 3.00× faster performance while also providing better model accuracy.

2 Background

This section briefly explains the operational flow and the KV caching technique of large language models and introduces the singular value decomposition (SVD) as a method of skewing matrices for a better understanding of our proposed framework, which we discuss in Section 4.

2.1 Large Language Models

Large language models (LLMs) are composed of a stack of Transformer blocks, each of which contains an attention layer followed by a feed-forward layer [61]. The input tensor (X) of the Transformer block has a dimension of $N \times D$, where N is the number of query tokens, and D is the model dimension. This input tensor (X) is first layer-normalized (LayerNorm), and the layer-normalized tensor (X_a) is fed into the attention layer as input. The attention input (X_a) is multiplied by three different *weight* matrices (W_Q, W_K, W_V) to generate Query (Q), Key (K), and Value (V) matrices. Each weight matrix has a dimension of $D \times D$. Thus, Query, Key, and Value have a dimension of $N \times D$. These matrices are reshaped to have a dimension of $H \times N \times d$, where H is the number of attention heads and d is the head dimension; note that $D = H \times d$.

Each head individually performs attention computation, which can be formulated as follows: $\mathrm{softmax}(QK^T)V$.[1] The attention output, after a residual add (adding to the input tensor X) and layer normalization, is fed into the feed-forward layer. The feed-forward network (FFN) consists of two consecutive linear projections and a non-linear activation operation between them. The output of FFN after a residual add becomes the output of a Transformer block, which has the *same* dimensionality as the input of the Transformer block (i.e., $N \times D$). This allows us to easily scale LLMs by adjusting the number of Transformer blocks.

2.2 Generative Inference and KV Caching

Generative LLM inference normally involves two key stages: the *prefill* stage and the *decoding* stage. In the prefill stage, LLMs summarize the context of the input sequence (i.e., input prompt) and produce a *new* token that serves as the initial input for the decoding stage. Subsequently, using this new token, LLMs run the decoding stage to generate the next token. The newly generated token is then fed back into the decoding stage as input, creating an *autoregressive* process for token generation. In this work, we refer to each token generation in the decoding stage as an *iteration*.

To generate a new token that aligns well with the context, LLMs need to compute the relationship between the last token and all the previous ones, including the tokens from the input sequence, in the attention layer. A naïve approach to this is to recompute the keys and values of all the previous tokens at every iteration. However, this incurs a significant overhead due to redundant and repeated computation. Furthermore, the computation overhead linearly grows with the number of the previous tokens; i.e., the overhead becomes larger for longer sequences.

To avoid such overhead, the keys (K) and values (V) of all the previous tokens are typically *memoized* in memory,

[1] In this work, we refer to the results of QK^T and $\mathrm{softmax}(QK^T)$ as *attention scores* and *attention weights*, respectively.

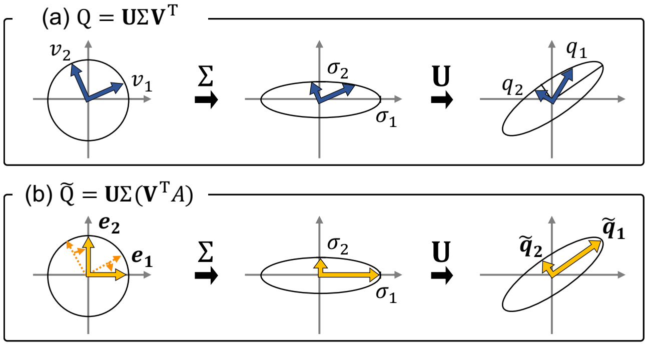

Figure 1: Transformation from matrix $\mathbf{V}^T$ to matrix Q in terms of SVD. The orthogonal matrix A maximizes the difference in magnitude between the column vectors of Q.

which is known as the *KV cache*. The KV cache then keeps updated with the key and value of the generated token at each iteration. As such, the dimension of the KV cache at the i-th iteration can be expressed as $H \times (N+i) \times d$. If batched inference is employed, the size of the KV cache also grows linearly to the batch size. By employing the KV cache, we can avoid repeated computation and produce the key and value of only one token at each iteration. Note that in the decoding stage, the input to the Transformer block (X) has a dimension of $1 \times D$, and the dimension of the attention score matrix becomes $H \times 1 \times (N+i)$ at the i-th iteration.

2.3 Outliers in Large Language Models

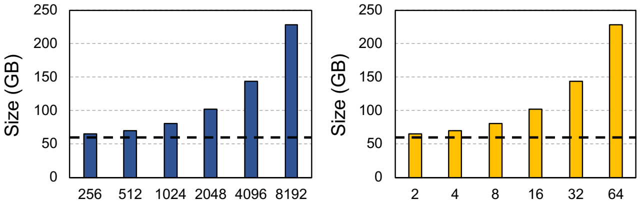
Large language models have outliers in the Transformer block input tensors. The outliers refer to the elements with substantially larger magnitudes than the other elements. The outliers in LLMs appear in a few fixed channels (i.e., columns in a 2D matrix) across the layers. Prior work has shown that outliers are due to the intrinsic property of the model (e.g., large magnitudes in a few fixed channels of layer normalization weights) [19, 65].

2.4 Singular Value Decomposition

We observe that skewing the query and key matrices to make a small number of channels much larger than others and using only those channels to compute the attention score matrix can effectively predict which tokens are important. In essence, we multiply the Q and K matrices with an orthogonal matrix A to make it align with the direction that Q stretches the most, to produce the respective skewed matrices $\tilde{Q}$ and $\tilde{K}$. We explain in detail why we use an orthogonal matrix in Section 4.2.

To find such an orthogonal matrix A, we employ the singular value decomposition (SVD), which is a widely used matrix factorization technique in linear algebra. For a real matrix Q of size $m \times n$, its SVD factorization can be expressed as follows:

$$Q = \mathbf{U}\Sigma\mathbf{V}^T,$$



(a) Sequence Length

(b) Batch Size

Figure 2: Total size of the KV cache and model weights of OPT-30B for different sequence lengths and batch sizes. The batch size of (a) is 16, and the sequence length of (b) is 2048. The dotted line represents the size of the model weights.

where $\mathbf{U}$ and $\mathbf{V}$ are orthogonal matrices of size $m \times m$ and $n \times n$, respectively.[2] Σ is an $m \times n$ diagonal matrix, which has nonzero values $(\sigma_1, \sigma_2, ..., \sigma_k)$ on the diagonal, where $k = \min(m,n)$. In terms of linear transformation, it is well known that a transformation of a vector $v \in \mathbb{R}^n$ by a real matrix B (i.e., the product of B and v) is a rotation and/or reflection in $\mathbb{R}^n$ if the B matrix is orthogonal. If B is an $m \times n$ diagonal matrix, each dimension of v is stretched by the corresponding diagonal entry of B and is projected to $\mathbb{R}^m$.

For example, Figure 1 shows how the column vectors v_1 and v_2 of $\mathbf{V}^T$ would transform to column vectors q_1 and q_2 of Q, when m and n are 2. In Figure 1(a), the orthogonal unit vectors v_1 and v_2 are first stretched to the points on an ellipse whose semi-axis lengths correspond to the diagonal entries in Σ. The vectors are then rotated and/or reflected to q_1 and q_2 by matrix $\mathbf{U}$. On the other hand, Figure 1(b) shows how orthogonal matrix A performs rotation to make the resulting $\tilde{q}_1$ much larger than $\tilde{q}_2$. Specifically, A rotates vectors v_1 and v_2 to e_1 and e_2, which map to the semi-axes of the ellipse. In this way, the vectors are stretched to the maximum and minimum by the matrix Σ. This process emphasizes the magnitude of $\tilde{q}_1$ over $\tilde{q}_2$, which allows us to effectively predict the attention score using only $\tilde{q}_1$ while omitting $\tilde{q}_2$.

3 Motivation

In this section, we first explain that the KV cache size becomes a critical issue for long-text generation in LLM inference, and it becomes more problematic when deploying modern offloading-based inference systems (Section 3.1). We then discuss why the existing KV cache management methods cannot fundamentally address the problem in the offloading-based inference system (Section 3.2).

3.1 KV Cache in LLM Inference Systems

As discussed in Section 2.2, today's LLM serving systems exploit KV caching to avoid redundant computation of key and

[2] Note that this $\mathbf{V}$, typeset with a different font, is one of the resulting matrices of SVD and is distinct from the V of the Value matrix in the Transformer attention layer.

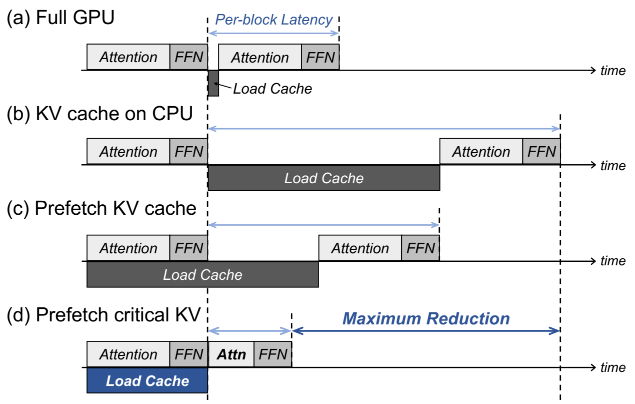


Figure 3: Comparison between different execution styles of Transformer blocks.

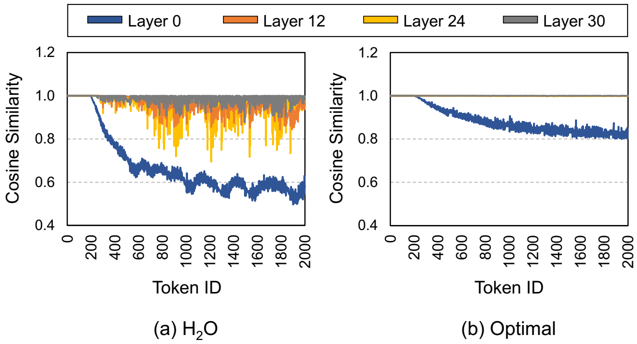

Figure 4: Cosine similarity between the attention weights of the base model with full cache and (a) H_2O or (b) Optimal. H_2O and Optimal use 200 tokens for attention computation. We use OPT-6.7B and a random sentence with 2000 tokens from the PG-19 dataset [52].

value projections during the decoding stage. While this is an effective solution for short sequence generation with a single client request, the KV cache quickly becomes a key memory consumer when we generate long sequences or employ modern request batching techniques [57, 71].

Figure 2 shows the combined size of LLM weights and the KV cache across different sequence lengths and batch sizes. As depicted in the figure, the model size remains constant regardless of sequence lengths or batch sizes, whereas the KV cache size linearly scales with them. Note that modern LLM serving systems, such as NVIDIA Triton Inference Server [45] and TensorFlow Serving [47], already support *batched* inference for better compute utilization and higher throughput in serving client requests. When individual requests are batched, each request retains its own KV cache, thereby increasing the overall KV cache size for the inference. Even for a single client request, beam search [59] and parallel sampling [20] are widely used to generate better outputs or to offer clients a selection of candidates [11, 24]. The techniques also increase the size of the KV cache like batched inference as multiple sequences are processed together. Consequently, the KV cache size can easily exceed the model size for many real-world use cases, as also observed in prior work [37, 49, 57, 78]. This can put substantial pressure on GPU memory capacity, which is relatively scarce and expensive.

LLM Inference Systems with Offloading. Modern LLM serving systems such as DeepSpeed [5] and FlexGen [57] already support offloading the model weights or the KV cache to the CPU memory. When it comes to offloading-based inference systems, the KV cache size becomes more problematic due to the low PCIe bandwidth between the CPU and GPU, which becomes a new and critical bottleneck.

Figure 3 depicts a high-level timing diagram between different execution styles of Transformer blocks. Figure 3(a) represents the case when the KV cache entirely resides in the GPU memory (Full GPU). In this case, the load latency of the KV cache (Load Cache) involves a simple read operation from the GPU memory, which is negligible due to the high bandwidth of GPU memory. However, the maximum batch size or sequence length is limited by the GPU memory capacity, which is relatively smaller than the CPU memory.

To enable a larger batch size or a longer sequence length, we can offload the KV cache to CPU memory (KV cache on CPU), as shown in Figure 3(b). While offloading-based inference systems alleviate the limitation on the batch size and sequence length, transferring hundreds of gigabytes of the KV cache to the GPU for attention computation significantly increases the overall execution time of Transformer blocks due to the limited PCIe bandwidth.

Even when we apply a conventional prefetching technique (Prefetch KV cache), as shown in Figure 3(c), only part of the load latency can be hidden by the computation of the preceding Transformer block. Note that although compressing the KV cache via quantization could potentially reduce the data transfer overhead in offloading-based systems [57], it does not serve as a fundamental solution as quantization does not address the root cause of the KV cache problem, which is the linear scaling of KV entries with the sequence length. This necessitates intelligent KV cache management to mitigate the performance overhead while preserving its benefits.

3.2 Challenges in KV Cache Management

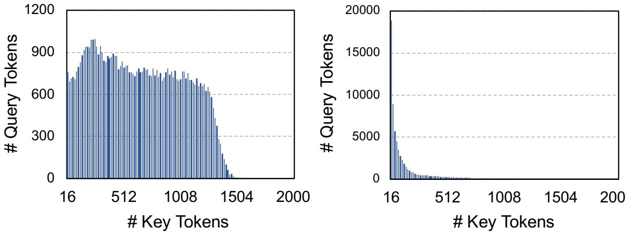
The fundamental approach to mitigating the transfer overhead of the KV cache from the CPU to GPU is to reduce the volume of the KV cache to load by identifying the *critical* keys and values for computing attention scores, as shown in Figure 3(d). It is widely recognized that the keys and values of certain tokens are more important than others in attention computation [9, 10, 14, 33, 63]. As explained in Section 2.1, after computing the attention score, the softmax operation is applied, which emphasizes a few large values of tokens. Therefore, skipping attention computation for some less critical tokens does not significantly degrade the model accuracy, provided the token selection is appropriate.

In this context, several recent works propose to reduce the KV cache size through key/value evictions at runtime within a constrained KV cache budget [37, 78]. However, all the prior works assume the *persistence* of attention patterns across iterations; that is, if a token is deemed unimportant in the current iteration (i.e., having a low attention weight), it is likely to remain unimportant in the generation of future tokens. Under the assumption, they evict the tokens with a low attention weight from the KV cache at each iteration when the KV cache size exceeds its budget. The keys and values of the evicted tokens are *permanently* excluded from the subsequent iterations while being removed from the memory. Although the recent works on managing the KV cache can be applied to offloading-based inference systems, we observe that they do not effectively address the challenges in KV cache management below and thus have subpar performance with offloading-based inference systems.

C1: Dynamic nature of attention patterns across iterations. Figure 4 shows the cosine similarity between the attention weights of the baseline model, which uses the KV cache of all prior tokens for computing attention weights (i.e., a maximum of 2000 tokens in the experiment), and two different KV cache management methods (H_2O and Optimal) with a KV cache budget of 200 tokens.[3] H_2O [78] is a state-of-the-art technique that retains only a small percentage of important tokens in the KV cache to reduce its size. It *assesses* the importance of each token in every iteration and *removes* unimportant ones before the next iteration to keep the KV cache size in check (i.e., using a narrow assessment window). In contrast, Optimal represents the scenario where we choose the same number of tokens as H_2O from the KV cache at each iteration but retain all prior keys and values (i.e., using a wider assessment window). In other words, Optimal selects 200 tokens out of the entire sequence of previous tokens at each iteration.

The figure indicates that despite H_2O-like approaches assuming that the attention pattern does not change across iterations, this is not the case in practice. The tokens deemed unimportant in the current iteration could become important in subsequent iterations. Consequently, H_2O exhibits high similarity until around 200 iterations (i.e., within the KV cache budget), but as the sequence length extends beyond the KV cache budget, it starts to struggle with the dynamic nature of the attention pattern, resulting in lower cosine similarity than the Optimal case. Note that while we only show the scenario of a KV cache budget of 200 out of a total sequence length of 2000 tokens for brevity, this issue would become more pronounced as the sequence length surpasses it.

C2: Adjusting the number of KV entries across layers. Figure 4 also illustrates that the impact of the KV cache eviction *varies* across the layers in LLMs. For Layer 0, both H_2O and Optimal show a significant drop in cosine similarity as the token ID increases. This implies that Layer 0 has a *broader* attending pattern than other layers; i.e., the attention weights are relatively similar between key tokens. Thus, the selected 200 tokens with the large attention weight do *not* adequately represent the attention pattern of the baseline model for this layer, as they are likely only slightly larger than the others, not strongly so. In such cases, it becomes necessary to compute the attention weight with a larger number of tokens.



(a) Layer 0

(b) Layer 18

Figure 5: Histogram that shows the number of key tokens needed to achieve 0.9 out of 1.0 total attention weight for (a) Layer 0 and (b) Layer 18 of the OPT-6.7B model. The bin width is set to 16. We observe that the distribution dynamically changes across the layers.

To estimate how many keys/values from the KV cache need to be retained, we sort the attention weight for each query token in descending order and sum the key tokens until the cumulative weight reaches 0.9. Figure 5 presents a histogram of the number of query tokens (y-axis) requiring the number of key tokens (x-axis) needed to reach a weight of 0.9 (out of the total attention weight of 1.0) in two different layers: Layer 0 and Layer 18. Layer 0 shows a broad distribution, indicating a significant variation in the number of key tokens required to achieve a weight of 0.9 for each query token. In contrast, Layer 18 exhibits a highly skewed distribution, suggesting that the majority of the query tokens in this layer require only a few key tokens to reach a weight of 0.9. This implies that we need to *dynamically* adjust the number of key tokens participating in attention computation across different layers to make efficient use of the KV cache budget.

C3: Adjusting the number of KV entries across queries. H_2O sets the number of key/value tokens to retain as a fixed percentage of the input sequence length. The KV cache budget remains constant regardless of how many tokens have been generated. By analyzing the data from Figure 5 on Layer 18, we observe that this fixed KV cache budget has some limitations. For instance, with an input sequence length of 200 and a 20% KV cache budget, H_2O maintains 40 key/value tokens throughout token generations. However, most of the subsequent query tokens require more than 40 tokens to effectively represent the attention weight of the baseline model; for example, the 500^{th}, 1000^{th}, 1500^{th}, and 2000^{th} tokens need 80, 146, 160, and 164 key tokens, respectively, to reach a cumulative attention weight of 0.9. This implies an inadequate amount of the key/value tokens to properly represent the attention weight of the baseline model. Furthermore, the

[3] The cosine similarity measures how much each row of the attention weight is similar to the case of the full KV cache. If they are similar, the generated tokens will also be similar. Thus, a low cosine similarity indicates low accuracy far from the baseline model with the full KV cache.

number of key tokens required to reach 0.9 varies even for the adjacent query tokens; for instance, the 998th, 999th, 1000th, 1001st, and 1002nd tokens need 172, 164, 146, 154, and 140 key tokens, respectively. Fixing the KV cache budget without accounting for the variance between query tokens inevitably results in ineffective KV cache management. Therefore, we need to *dynamically* adjust the amount of the key/value tokens loaded and computed for each query token to efficiently manage the KV cache.

Summary. Prior works aiming to reduce the KV cache size through token eviction inherently have some challenges. Given the dynamic attention pattern across iterations, permanently excluding evicted tokens from future token generation can result in a non-negligible drop in accuracy. Instead, we need to dynamically *select* critical tokens from the KV cache while avoiding the outright eviction of less important ones. Furthermore, the fixed size of the KV cache budget in prior works leads to inefficient KV cache management. The number of key/value tokens required for each layer differs, and each query token demands a varying number of key/value tokens to effectively represent the attention pattern of the baseline model. Failing to account for these variations may result in ineffective KV cache management. Thus, we need to dynamically adjust the number of key/value tokens to select from the KV cache while considering the variances between layers and query tokens.

4 InfiniGen Design

In this section, we present InfiniGen, a KV cache management framework for offloading-based inference systems. We first show the high-level overview of our proposed KV cache management solution (Section 4.1) and discuss the opportunities of KV cache prefetching that we observe (Section 4.2). We then explain our prefetching module (Section 4.3), which builds on the offloading-based inference systems, and discuss how InfiniGen manages the KV cache on CPU memory regarding the memory pressure (Section 4.4).

4.1 Overview

Figure 6 shows an overview of our KV cache management framework, InfiniGen, which enables offloading the KV cache with low data transfer overhead. The key design principle behind InfiniGen is to exploit the abundant CPU memory capacity to increase the *window size* when identifying the important tokens in the KV cache. As such, the majority of the tokens for the KV cache are kept in the CPU memory as we generate new tokens, not completely discarding them unlike prior works [37, 78]. However, we do not bring the entire KV cache to the GPU for attention computation, but load and compute with only the keys and values of a *few important tokens*, dropping other unimportant ones dynamically. To do so, we maintain the KV cache pool in the CPU memory and selectively and speculatively load a few of tokens.

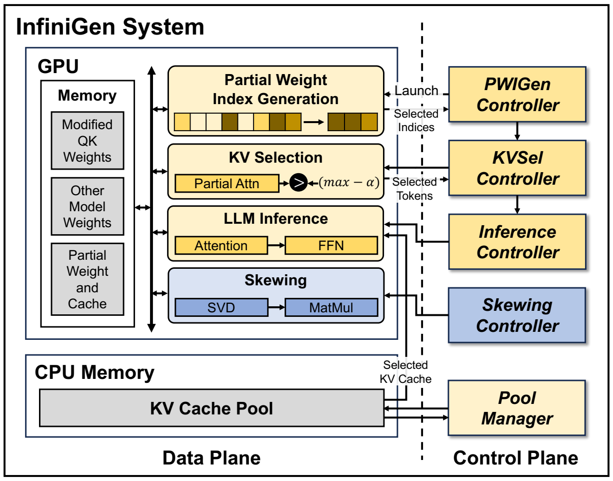


Figure 6: Overview of InfiniGen design.

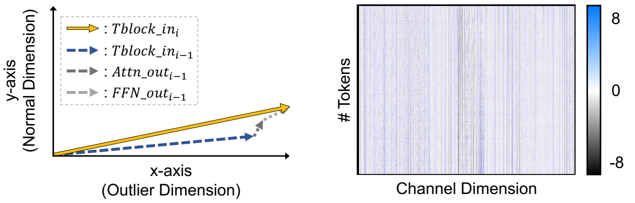
In detail, we use the attention input of the *previous* Transformer layer to speculate and prefetch the keys and values of the important tokens for the *current* layer. The speculation is done by performing a minimal rehearsal of attention computation of the current layer in the preceding layer. This allows for reducing the waste of PCIe bandwidth by only transferring the keys and values critical for attention computation while preserving model accuracy. In addition, although the KV cache is offloaded to CPU memory, which is much cheaper and larger than GPU memory, we manage the KV cache pool size so as not to put too much pressure on CPU memory.

As shown in Figure 6, there are two major components in the InfiniGen runtime. The first includes the Partial Weight Index Generation Controller, KV Selection Controller, and Inference Controller. These controllers cooperate to speculate and prefetch the critical KV cache entries while serving LLM inference. Additionally, to aid in prefetching, the Skewing Controller performs offline modifications on the model weights. We explain each operation in Section 4.3. The second component is the Pool Manager. It manages the KV cache pool on CPU memory under CPU memory pressure, which we discuss in Section 4.4.

4.2 Prefetching Opportunities

In the following, we first explain why using the attention input of the previous layer for speculation makes sense. We then show how we modify the query and key weight matrices to make our speculation far more effective.

Attention Input Similarity. Our prefetching module builds on the key observation that the attention inputs of consecutive attention layers are highly similar in LLMs. There are two major reasons behind this. The first is the existence of *outliers* in LLMs, as discussed in Section 2.3, and the second is due to layer normalization (LayerNorm).



(a) Input Similarity (b) Query

Figure 7: (a) Visualization of input similarity between consecutive Transformer blocks. (b) Query matrix of Layer 18 of the OPT-13B model. We only show channels from 3000 to 4000 for a clearer view of column-wise patterns.

To begin with, the input to the Transformer block i ($\texttt{Tblock\_in}_\texttt{i}$) can be formulated as follows:

$$\begin{aligned} Attn\_out_{i-1} &= Attn(LN(Tblock\_in_{i-1})) \\ FFN\_out_{i-1} &= FFN(LN(Tblock\_in_{i-1} + Attn\_out_{i-1})) \\ Tblock\_in_i &= Tblock\_in_{i-1} + Attn\_out_{i-1} + FFN\_out_{i-1}, \end{aligned} \tag{1}$$

where $\texttt{Tblock\_in}_{\texttt{i}-1}$ is an input for Layer $i-1$, which is first layer-normalized (*LN*) and is fed into the attention layer in the Transformer block. After performing attention, we obtain the output ($\texttt{Attn\_out}_{\texttt{i}-1}$), which is added to $\texttt{Tblock\_in}_{\texttt{i}-1}$ because of the residual connection. Then, the sum of $\texttt{Tblock\_in}_{\texttt{i}-1}$ and $\texttt{Attn\_out}_{\texttt{i}-1}$ is again layer-normalized and is fed into the FFN layer. Afterward, we obtain the FFN output ($\texttt{FFN\_out}_{\texttt{i}-1}$), which is added to the sum of $\texttt{Tblock\_in}_{\texttt{i}-1}$ and $\texttt{Attn\_out}_{\texttt{i}-1}$ again due to the residual connection. Finally, the sum of $\texttt{Tblock\_in}_{\texttt{i}-1}$, $\texttt{FFN\_out}_{\texttt{i}-1}$, and $\texttt{Attn\_out}_{\texttt{i}-1}$ is used as input to the next Transformer block ($\texttt{Tblock\_in}_\texttt{i}$).

Now, we show why the attention input of Layer i is similar to the one of Layer $i-1$ with the example in Figure 7(a). In the figure, there are four vectors, each of which corresponds to a term in Equation 1. The x-axis represents an outlier channel among the model dimension, while the y-axis represents a normal channel (i.e., other than the outlier channel). In practice, there exist more normal channels and only a few outlier channels in the input tensors, but we only present one channel each for both outlier and normal channels for clarity.

$\texttt{Tblock\_in}_{\texttt{i}-1}$ is highly skewed along the outlier channel (x-axis) due to a few outlier channels containing significantly large values compared to those in the normal channels. In contrast, $\texttt{Attn\_out}_{\texttt{i}-1}$ and $\texttt{FFN\_out}_{\texttt{i}-1}$ have relatively small values for both outlier and normal channels (i.e., short vectors). This is because the attention and FFN inputs are *layer-normalized*, reducing the magnitude of each value. The small magnitude of the attention and FFN inputs naturally results in their output values being relatively small compared to $\texttt{Tblock\_in}_{\texttt{i}-1}$. Consequently, $\texttt{Tblock\_in}_\texttt{i}$ is highly influenced by $\texttt{Tblock\_in}_{\texttt{i}-1}$, rather than $\texttt{Attn\_out}_{\texttt{i}-1}$ or $\texttt{FFN\_out}_{\texttt{i}-1}$. Highly similar inputs between consecutive Transformer blocks lead to similar inputs across the attention layers, as the attention input is a layer-normalized one of the Transformer block input.

Table 1: Average cosine similarity between the Transformer block input of Layer i ($\texttt{Tblock\_in}_\texttt{i}$) and the other three tensors ($\texttt{Tblock\_in}_{\texttt{i}-1}$, $\texttt{Attn\_out}_{\texttt{i}-1}$, $\texttt{FFN\_out}_{\texttt{i}-1}$) across the layers. We use a random sentence with 2000 tokens from the PG-19 dataset [52].

Tensors	OPT-6.7B	OPT-13B	OPT-30B	Llama-2-7B	Llama-2-13B
$\texttt{Tblock\_in}_{\texttt{i}-1}$	**0.95**	**0.96**	**0.97**	**0.89**	**0.91**
$\texttt{Attn\_out}_{\texttt{i}-1}$	0.29	0.28	0.36	0.31	0.27
$\texttt{FFN\_out}_{\texttt{i}-1}$	0.34	0.28	0.35	0.37	0.34

Table 1 shows the cosine similarity between $\texttt{Tblock\_in}_\texttt{i}$ and the other three tensors ($\texttt{Tblock\_in}_{\texttt{i}-1}$, $\texttt{Attn\_out}_{\texttt{i}-1}$, $\texttt{FFN\_out}_{\texttt{i}-1}$). As shown in the table, $\texttt{Tblock\_in}_\texttt{i}$ is highly dependent on the $\texttt{Tblock\_in}_{\texttt{i}-1}$ rather than others. InfiniGen leverages this key observation to speculate on the attention pattern of Layer i using the attention input of Layer $i-1$. Note that $\texttt{Tblock\_in}$ gradually changes across the layers; the inputs to distant layers are distinct.

Skewed Partial Weight. We observe that the attention score highly depends on a few columns in the query and key matrices. Figure 7(b) shows the values in a query matrix of Layer 18 of the OPT-13B model, where the column-wise patterns indicate that there exist certain columns with large magnitudes in the matrix; we observe the same patterns in the key and query matrices across different layers and models. The large magnitude columns have a great impact on the attention pattern because the dot product between the query and key is highly affected by these few columns. The column-wise pattern in the attention input indicates that there is little variance between each row in the outlier channels. Thus, the dot product between any row of the attention input and a column of the weight matrix could have a similarly large magnitude, which induces the outlier channels in the query and key matrices.

Going one step further, if we make a few columns in the query and key matrices have much larger magnitude than others, a much smaller number of columns significantly affects the attention pattern. We can do this by multiplying the query and key weight matrices with the same orthogonal matrix A. Since the transpose of the orthogonal matrix is the inverse of itself, the proposed operation does not change the final result, as shown in Equation 2 (i.e., this is mathematically equivalent to QK^T, not an approximation):

$$\begin{aligned} \tilde{Q} = X_a \times W_Q \times A, &\qquad \tilde{K} = X_a \times W_K \times A \\ \tilde{Q} \times \tilde{K}^T &= X_a \times W_Q \times A \times (X_a \times W_K \times A)^T \\ &= X_a \times W_Q \times A \times A^T \times W_K^T \times X_a^T \\ &= X_a \times W_Q \times W_K^T \times X_a^T \\ &= X_a \times W_Q \times (X_a \times W_K)^T \\ &= Q \times K^T, \end{aligned} \tag{2}$$

where $\tilde{Q}$ and $\tilde{K}$ are skewed query and key matrices, while W_Q and W_K are query and key weight matrices. X_a denotes the attention input. We set the orthogonal matrix A whose direction

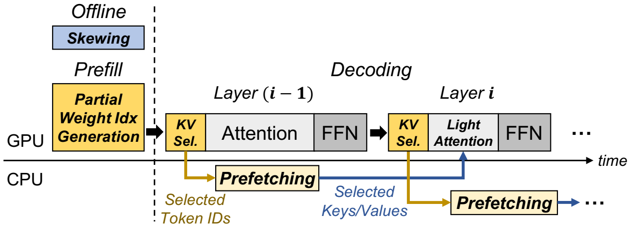


Figure 8: Operation flow of the prefetching module of InfiniGen.

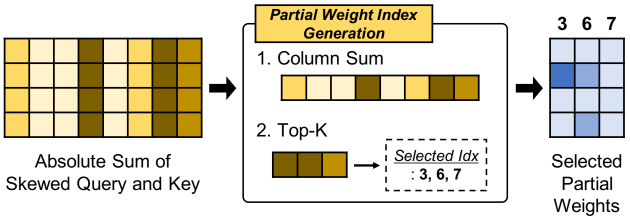

Figure 9: Partial weight generation in the prefill stage.

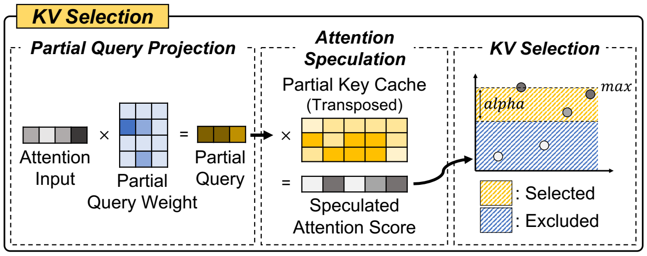

Figure 10: Attention score speculation in the decoding stage.

aligns with the direction that the query matrix stretches the most. Specifically, we first decompose the query matrix using SVD and obtain $\mathbf{U}$, Σ, and $\mathbf{V}$. We then set A to orthogonal matrix $\mathbf{V}$ to align the column vectors with the standard unit vectors as $\mathbf{V}^T\mathbf{A} = \mathbf{V}^T\mathbf{V} = I$, where I is an identity matrix. We formulate the skewed query matrix as follows:

$$\tilde{Q} = Q \times A = \mathbf{U}\Sigma\mathbf{V}^T \times A = \mathbf{U}\Sigma\mathbf{V}^T \times \mathbf{V} \tag{3}$$

In this way, we can make a few columns with large magnitudes in $\tilde{Q}$ without altering the result of computation, as discussed in Section 2.4.

4.3 Efficiently Prefetching KV Cache

Prefetching Scheme. Figure 8 shows the operation flow of the prefetching module in InfiniGen. In the offline phase, InfiniGen modifies the *weight* matrices to generate skewed query and key matrices. To achieve this, InfiniGen first runs the forward pass of the model once with a sample input. During this process, InfiniGen gathers the query matrix from each layer and performs singular value decomposition (SVD) of each query matrix. The skewing matrix (A_i) of each layer is obtained using the decomposed matrices of the query matrix, as shown in Equation 3. This matrix is then multiplied with each of the query and key weight matrices in the corresponding layer. Importantly, after the multiplication, the dimensions of the weight matrices remain unchanged. Note that the skewing is a *one-time* offline process and does not incur any runtime overhead because we modify the weight matrices that are invariant at runtime. As we exploit the column-wise pattern, which stems from the intrinsic property of the model rather than the input, whenever we compute the query and key for different inputs after the skewing, the values exhibit a high degree of skewness, thereby improving the effectiveness of our prefetching module. Note that skewing does not alter the original functionality. Even with the skewing, the attention layer produces identical computation results.

Prefill Stage. In the prefill stage, InfiniGen selects several important columns from the query weight matrix and the key cache to speculate on the attention pattern, and generates *partial* query weight and key cache matrices used in the decoding stage. Figure 9 shows how InfiniGen creates these partial matrices. Because we multiply each column in the query matrix with the corresponding row in the transposed key matrix, it is essential to select the *same* column indices in the query weight matrix and the key cache to obtain a proper approximation of the attention score. However, the indices of the outlier columns of the skewed query ($\tilde{Q}$) and key ($\tilde{K}$) matrices may not align exactly. To obtain partial matrices that capture the outliers, we first take the element-wise absolute values of the skewed query and key matrices, then add these two matrices together. This helps us calculate the sum of each column and perform top-k operation only once while accommodating the outlier columns of both query and key matrices. We then sum the elements in each column and select the top-k columns in the matrix; we choose 30% of the columns in our work. Using the sum of column values captures the global trend of each column while minimizing the effect of variance in each row. The selected columns better approximate the attention pattern because of the use of skewed query and key matrices.

Decoding Stage. In the decoding stage, InfiniGen speculates on the attention pattern of the next layer and determines the critical keys and values to prefetch. Figure 10 shows how InfiniGen computes the *speculated* attention score. At Layer $i-1$, we use the partial query weight matrix and key cache of Layer i, which are identified in the prefill stage, along with the attention input of Layer $i-1$. After multiplying the partial query and partial key cache, InfiniGen selects tokens with high attention scores.

We set the threshold considering the maximum value of the speculated attention score. We select only the tokens with an attention score greater than the maximum score subtracted by *alpha*. It is noted that subtraction from the attention score results in division after softmax. For example, assume that the attention score of the 3rd token is the maximum attention score minus 5. Once we apply softmax to the attention scores, the attention weight of the 3rd token is the maximum attention weight divided by $e^5 \approx 148.4$. Even though we do not use this token, it does not noticeably hurt the accuracy of the model since it accounts for less than 1% of importance ($\approx 1/148.4$) after softmax. Thus, InfiniGen only prefetches the keys and values of the tokens with an attention score larger than the highest attention score minus *alpha*. As multiple attention heads are computed in parallel, we ensure that each head in the same layer fetches the same number of tokens by averaging the number of tokens between the maximum score and the threshold across the heads.

By reducing the amount of KV cache to load and compute, InfiniGen effectively reduces the loading latency (i.e., data transfer from CPU to GPU) while maintaining an output quality similar to that of the original model with a full KV cache. Moreover, as InfiniGen does not require a fixed number of tokens to load from CPU memory, it utilizes only the necessary PCI interconnect bandwidth. InfiniGen initiates speculation and prefetching from Layer 1 because the outliers, which are essential for exploiting input similarity, emerge during the computation in Layer 0.

4.4 KV Cache Pool Management

We manage the KV cache as a pool, offloading to the CPU memory and prefetching only the essential amount to the GPU. While CPU memory is more affordable and larger than GPU memory, it still has limited capacity. Hence, for certain deployment scenarios, it might be crucial to confine the size of the KV cache pool and remove less important KV entries that are infrequently selected by query tokens. We extend the design to incorporate a user-defined memory size limit. During runtime, when the size of the CPU memory reaches a user-defined limit, the KV cache pool manager selects a victim KV entry for eviction. Subsequently, the manager overwrites the selected victim with the newly generated key and value, along with updating the corresponding partial key cache residing in the GPU. It is noted that the order of KV entries can be arbitrary, as long as the key and value of the same token maintain the same relative location in the KV cache pool.

The policy of selecting a victim is important since it directly impacts model accuracy. We consider a counter-based policy along with two widely used software cache eviction policies: FIFO [7, 69, 70] and Least-Recently-Used (LRU) [2]. The FIFO-based policy is easy to implement with low overhead but results in a relatively large accuracy drop since it simply evicts the oldest residing token. The LRU-based policy generally exhibits a smaller decrease in accuracy but often entails a higher runtime overhead. In general, LRU-based policy uses a doubly linked list with locks to promote accessed objects to the head, which requires atomic memory updates for accessed KV entries. In the case of the counter-based policy, the pool manager increments a counter for each prefetched KV entry and selects a victim with the smallest count in the KV cache pool. If any counter becomes saturated, all the counter values are reduced by half. We observe that the counter-based policy and the LRU-based one show comparable model accuracy, which we discuss in Section 5.2. We opt for a counter-based approach due to its simpler design and to avoid atomic memory updates for better parallelism.

5 Evaluation

5.1 Experimental Setup

Model and System Configuration. We use Open Pre-trained Transformer (OPT) models [77] with 6.7B, 13B, and 30B parameters for evaluation. The 7B and 13B models of Llama-2 [60] are also used to demonstrate that InfiniGen works effectively across different model architectures. We run the experiments on a system equipped with an NVIDIA RTX A6000 GPU [44] with 48GB of memory and an Intel Xeon Gold 6136 processor with 96GB of DDR4-2666 memory. PCIe 3.0 ×16 interconnects the CPU and GPU.

Workload. We evaluate using few-shot downstream tasks and language modeling datasets. We use five few-shot tasks from the lm-evaluation-harness benchmark [23]: COPA [54], OpenBookQA [42], WinoGrande [55], PIQA [8], and RTE [62]. The language modeling datasets used are WikiText-2 [41] and Penn Treebank (PTB) [38]. Additionally, randomly sampled sentences from the PG-19 dataset [52] are used to measure the speedup with long sequence lengths.

Baseline. We use two inference environments that support KV cache offloading: CUDA Unified Virtual Memory (UVM) [4] and FlexGen [57]. On UVM, all data movements between the CPU and GPU are implicitly managed by the UVM device driver, thereby enabling offloading without requiring intervention from the programmer. In contrast, FlexGen uses explicit data transfers between the CPU and GPU. For the FlexGen baseline, unless otherwise specified, we explicitly locate all the KV cache in the CPU memory. The model parameters are stored in the GPU memory as much as possible, with the remainder in the CPU memory. We compare InfiniGen with two different KV cache management methods: H_2O [78] and Quantization [57]. H_2O, a recent method in KV cache management, maintains the KV cache of the important or recent tokens by assessing the importance of each token and discarding others. Quantization-based compression applies group-wise asymmetric quantization to the KV cache.

Key Metric. We evaluate accuracy (%) to assess the impact of approximation when InfiniGen, H_2O, and Quantization are used. For the language modeling tasks with WikiText-2 and PTB, we use perplexity as a metric; lower perplexity means better accuracy. To present performance improvements, we measure the wall clock time during inference with varying batch sizes and sequence lengths. The partial weight ratio is set to 0.3. We set alpha to 4 for OPT and 5 for Llama-2, resulting in using less than 10% of the KV cache on average across the layers. For each layer, we allow sending up to 20% of the total KV cache to the GPU if it contains more candidates.

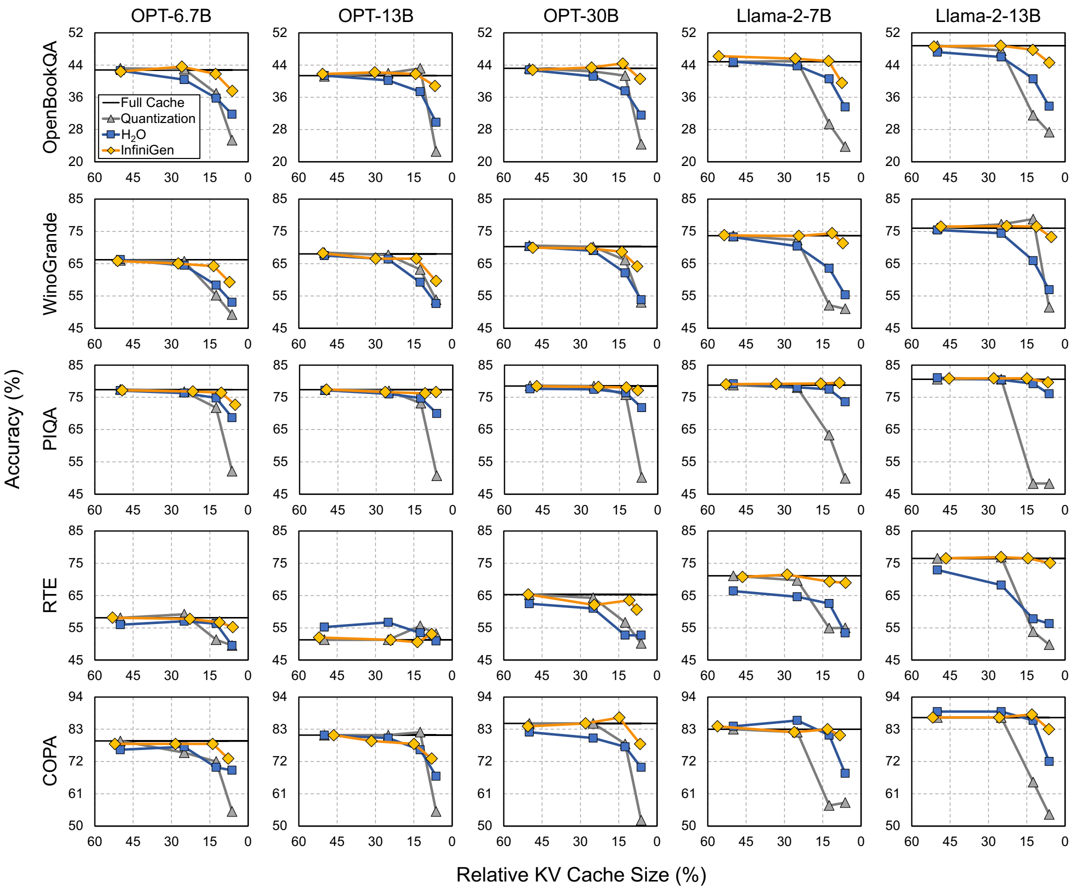

Figure 11: Accuracy of LLMs on 5-shot tasks in lm-evaluation-harness.

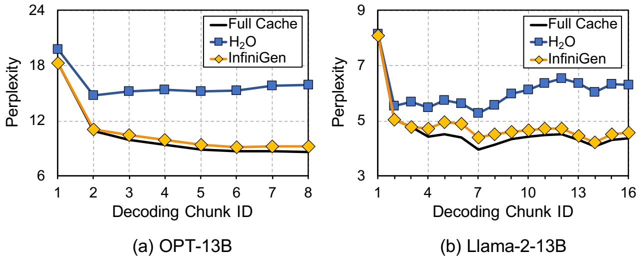

(a) OPT-13B

(b) Llama-2-13B

Figure 12: Perplexity of OPT-13B and Llama-2-13B for WikiText-2 dataset. Lower is better. Perplexity is computed for each decoding chunk that contains 256 tokens.

The partial weight ratio and alpha are determined based on a sensitivity study for each model to balance accuracy and inference latency, which we discuss in Section 6.1.

5.2 Language Modeling

Accuracy on lm-evaluation-harness. Figure 11 shows the accuracy of the baselines and InfiniGen across different models with 5-shot tasks. The relative KV cache size indicates the size of the KV cache involved in the attention computation compared to the full-cache baseline (e.g., a 10% relative KV cache size means that 10% of the full KV cache size is used). InfiniGen consistently shows better accuracy across the models and tasks when the relative KV cache size is less than 10%, whereas the others exhibit a noticeable accuracy drop due to insufficient bit widths (Quantization) or permanent KV cache elimination (H_2O). This implies that our proposed solution can effectively reduce the KV cache transfer overhead while preserving model accuracy. For relative KV cache sizes larger than 10%, the accuracy with InfiniGen closely matches that of the full-cache baseline. In some cases, InfiniGen even shows slightly better accuracy than the full-cache baseline. This is likely because reducing the amount of the KV cache participating in the attention computation can help the model focus more on critical tokens.

Sequence Length. Figure 12 shows the perplexity of two different models with InfiniGen and the baselines, as the sequence length increases. In this experiment, H_2O is configured to use the same amount of KV cache as InfiniGen. The sequence lengths are 2048 and 4096 for OPT-13B and Llama-2-13B, respectively. For a clearer view, we evaluate perplexity with consecutive 256 tokens as a group, which is referred to as a decoding chunk in the figure. The results show that even though the sequence length becomes longer (i.e., the decoding chunk ID increases), the perplexity of InfiniGen remains consistently comparable to the full-cache baseline,

Table 2: Perplexity on WikiText-2 and PTB with 2048 sequence length with or without KV cache memory limits. Lower is better.

Scheme	OPT-6.7B		OPT-13B		OPT-30B		Llama-2-7B		Llama-2-13B	
	Wiki	PTB	Wiki	PTB	Wiki	PTB	Wiki	PTB	Wiki	PTB
100%	11.68	13.86	10.55	12.78	10.14	12.31	5.69	22.53	5.25	31.94
80-FIFO%	19.64	16.82	30.99	33.84	30.66	35.45	22.26	61.88	21.41	32.34
80-LRU%	11.68	13.85	10.55	12.78	10.14	12.31	5.69	22.53	5.25	31.94
80-Counter%	11.68	13.86	10.55	12.78	10.14	12.31	5.69	22.53	5.25	31.94

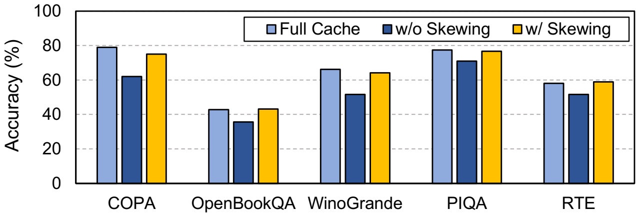

Figure 13: Accuracy on the lm-evaluation-harness benchmark with or without skewing on OPT-6.7B.

while H_2O shows an increasing divergence from the baseline. H_2O suffers from permanent KV cache elimination and may not retain a sufficient amount of KV cache in certain layers due to its fixed budget. In contrast, InfiniGen dynamically computes attention using only the essential amount of KV cache for each layer. The difference is likely to widen as the models become capable of handling much longer sequences.

Effect of Skewing. Figure 13 shows the accuracy with or without key/query skewing on the OPT-6.7B model. For the experiment, we use a fixed KV cache budget of 20%, instead of using a dynamic approach, to clearly show the effect of skewing. We observe that several language models (e.g., Llama-2) show a small drop in accuracy without skewing. For some models such as OPT-6.7B, however, we see a large accuracy drop if we do not apply the skewing method as shown in Figure 13. This indicates that in the case of OPT-6.7B, the partial weight does not adequately represent the original matrix without skewing. After applying our skewing method, we achieve accuracy similar to the full-cache baseline. Our skewing method effectively skews key and query matrices such that a few columns can better represent the original matrices.

KV Cache Pool Management. Table 2 shows the perplexity of five different models with or without limiting the memory capacity for WikiText-2 and PTB. We compare FIFO-based, LRU-based, and Counter-based victim selection policies in Section 4.4 under the 80% memory limit of a full KV cache. We also present the perplexity results with no memory limit (100%). The FIFO-based approach shows the worst model performance because it simply deletes the oldest KV entry regardless of its importance. The LRU and Counter-based approaches show perplexity that is almost similar to that with no memory limit. We choose a Counter-based victim selection policy instead of an LRU-based approach because the LRU-based approach typically needs to maintain a doubly linked list queue with locks for atomic memory updates.

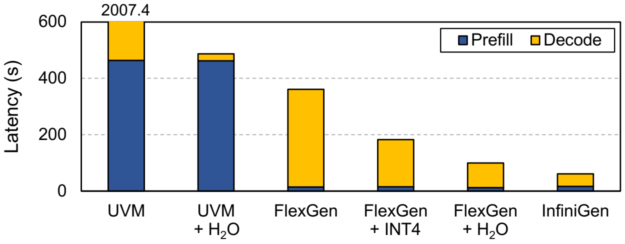

Figure 14: Inference latency on OPT-13B with a sequence length of 2048 (1920 input and 128 output tokens) and a batch size of 20.

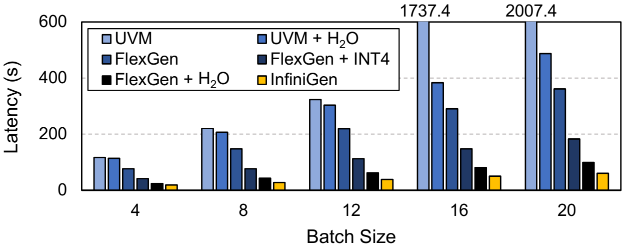

Figure 15: Inference latency for 5 different batch sizes on OPT-13B with a sequence length of 2048 (1920 input and 128 output tokens).

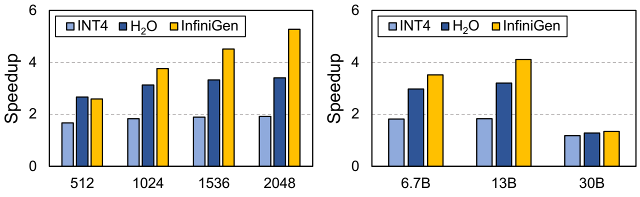
5.3 Performance

In this section, we refer to H_2O (with a KV cache budget of 20%) and 4-bit quantization implemented on top of FlexGen as H_2O and INT4.

Inference Latency. Figure 14 shows the inference latency including the prefill and decoding stages. We use the OPT-13B model with 1920 input tokens, 128 output tokens, and a batch size of 20. InfiniGen achieves 1.63×-32.93× speedups over the baselines. The performance benefit mainly comes from the significantly reduced amount of KV cache to load from the CPU memory due to our dynamic approach.

UVM shows an extremely long latency because the working set size (i.e., the size of the model parameters and KV cache) is larger than the GPU memory capacity, thereby leading to frequent page faults and data transfers between the CPU and GPU. The prefill stage of UVM + H_2O also shows a long latency due to the page faults and data transfers. However, because all required data are migrated to the GPU memory after the prefill stage, UVM + H_2O shows a substantially shorter decoding latency. FlexGen loads the full KV cache with high precision (i.e., FP16) from the CPU memory for every attention computation. On the other hand, INT4 and H_2O load relatively small amounts of the data from the CPU because of the low-bit data format (INT4) or a smaller size of the KV cache (H_2O). However, they still load larger amounts of data than InfiniGen; even with low precision, INT4 loads the KV cache of all the previous tokens; H_2O always loads the same amount of data no matter how many tokens are actually important in each layer. As a result, InfiniGen achieves better performance than both of them.

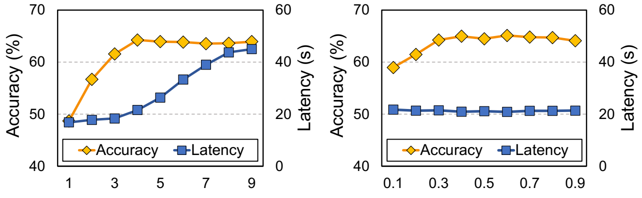
Batch Size. Figure 15 shows the inference latency across different batch sizes. The results show that InfiniGen achieves



(a) Sequence Length

(b) Model Size

Figure 16: Speedup over the FlexGen baseline across (a) sequence lengths and (b) model sizes.



(a) Alpha Value

(b) Partial Weight Ratio

Figure 17: Accuracy and inference latency across (a) alpha values and (b) partial weight ratios.

lower latency than others across the batch sizes (1.28×-34.64×). As the batch size increases, the performance gap between InfiniGen and others becomes larger. UVM and UVM + H_2O show increasing latency mainly due to frequent page faults in the prefill stage. For UVM, the latency also rapidly increases at a batch size of 16 because the working set size exceeds the GPU memory capacity for *both* prefill and decoding stages. As the batch size keeps increasing, UVM + H_2O will face the same problem as well.

The latency of FlexGen almost linearly increases with the batch size because the KV cache transfer occupies the majority of the inference latency. As we increase the batch size from 4 to 20, the throughput (tokens per second) of InfiniGen increases from 27.36 to 41.99, while INT4 and H_2O offer a small increase in throughput (from 12.22 to 14.02 and from 21.31 to 25.70 each). By dynamically adjusting the amount of the KV cache to load, InfiniGen achieves scalable performance across the batch sizes.

Sequence Length. Figure 16(a) shows the speedup of INT4, H_2O, and InfiniGen over FlexGen on OPT-13B across different sequence lengths. With a batch size of 8, we use four different input/output configurations. Each configuration comprises 128 output tokens and 384, 896, 1408, 1920 input tokens (i.e., a total number of tokens ranging from 512 to 2048). The speedup of InfiniGen continues to increase across the sequence lengths (up to 5.28×), whereas INT4 and H_2O show saturating speedups (up to 1.92× and 3.40×). This suggests that neither INT4 nor H_2O provides a scalable solution for KV cache management. INT4 shows a negligible increase in speedup due to the inherent growth in the size of the KV cache. Similarly, H_2O lacks scalability due to its fixed ratio of the KV cache budget; as the sequence length increases, H_2O stores and loads more KV cache.

Even though the sequence length increases, the number of tokens that each token attends to does not increase linearly. For instance, in the OPT-13B model, we count the number of important tokens with attention scores larger than $(max - 4)$ and identify that, on average, 37, 60, 66, and 73 tokens are assessed as *important* for sequence lengths of 512, 1024, 1536, and 2048, respectively. H_2O, which employs 20% of a fixed KV cache budget, loads 409 tokens for the sequence length of 2048, while only 73 tokens are relatively important. In contrast, InfiniGen naturally captures this trend (i.e., a non-linear increase in the number of important tokens) by dynamically observing the speculated attention score.

Model Size. Figure 16(b) shows the speedup of INT4, H_2O, and InfiniGen over FlexGen on three different model sizes. We use 1920 input tokens and 128 output tokens with a batch size of 4 for the experiment. The results show that InfiniGen outperforms others across the model sizes. As the model size increases from 6.7B to 13B, the speedup of InfiniGen also increases by 1.17×, while others do not lead to a noticeable increase in speedup. For most of the layers, InfiniGen loads a smaller amount of KV cache than H_2O because a relatively small number of tokens are needed. Thus, InfiniGen performs better than H_2O as the model size becomes larger due to the increased number of Transformer blocks. For the 30B model, the model parameters do not fit in the GPU memory. As such, we offload 30% of the model parameters to the CPU. In this case, the size of the offloaded parameters is 1.7× larger than the KV cache size. Even so, InfiniGen shows a 1.34× speedup over FlexGen, while others achieve 1.18× and 1.28× each.

6 Analysis and Discussion

6.1 Sensitivity Study

We use the OPT-6.7B model with 1920 input tokens, 128 output tokens, and a batch size of 8. The accuracy is evaluated with the WinoGrande task in lm-evaluation-harness.

Threshold and Alpha. As discussed in Section 4.3, we load the KV cache of the tokens with a speculated attention score greater than the threshold (i.e., the maximum attention score minus alpha). Increasing alpha results in fetching more KV entries to the GPU, thus increasing inference latency but also improving accuracy. Figure 17(a) shows such trade-offs between accuracy and inference latency for nine different alpha values with a partial weight ratio of 0.3. The results show that more KV entries are fetched and involved in attention computation as alpha increases, thereby leading to better accuracy. For the alpha values beyond 4, however, since most important tokens are already included, the accuracy does not further increase, while the cost for KV transfers and attention computation keeps increasing. This trend is similarly observed in other models, and we thus opt for an alpha value of 4 or 5 to strike a balance between inference latency and accuracy.

Partial Weight Ratio. Figure 17(b) shows the accuracy and

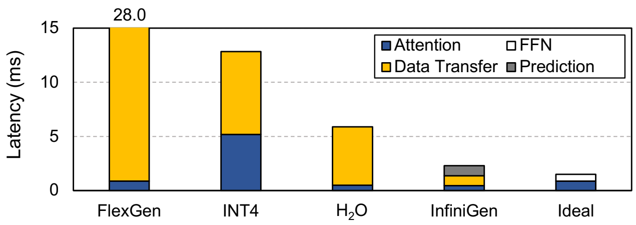


Figure 18: Latency breakdown of a Transformer block for OPT-13B with a sequence length of 2048 and a batch size of 8.

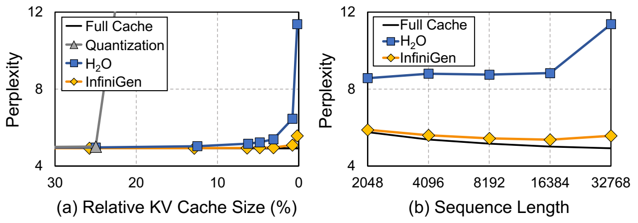
inference latency across different partial weight ratios with an alpha value of 4. As shown in the figure, the amount of partial weights has a negligible impact on inference latency because the cost for computing the speculated attention score is relatively small. Note that the amount of KV cache to transfer is *not* related to the partial weight ratio. However, increasing the partial weight ratio results in higher memory consumption for partial weights and key cache (e.g., doubling the ratio doubles the memory consumption overhead). The accuracy also does not noticeably differ beyond a ratio of 0.3. In our work, we opt for a partial weight ratio of 0.3 to achieve better accuracy while considering memory consumption overhead.

6.2 Overhead

Prefetching Overhead. Figure 18 shows the latency breakdown of executing a single Transformer block for the OPT-13B model; FFN is not shown in the figure for schemes other than Ideal because it is fully overlapped with data transfer time. Ideal is a scenario where all the computations (i.e., attention and FFN) are performed on the GPU without any data transfer between the CPU and GPU. As shown in the results, the key performance bottleneck of FlexGen and H_2O is the data transfer overhead, which occupies 96.9% and 91.8% of the execution time, respectively. For INT4, due to the quantization and dequantization overhead, attention computation also occupies a large portion of the execution time in addition to the data transfer. InfiniGen, on the other hand, considerably improves the inference speed over FlexGen by reducing the amount of data transfer with our dynamic KV cache prefetching. Furthermore, InfiniGen is only 1.52× slower than Ideal, while others show 3.90×-18.55× slowdowns.

Memory Consumption. InfiniGen uses the partial query weight and key cache for speculation. For a ratio of 0.3, the sizes of the partial query weight and key cache are only 2.5% and 15% of the total model parameters and total KV cache, respectively. While we simply store them in the GPU during our experiments, we can manage the storage overhead in various optimized ways if needed. For example, we can store only the column indices of the partial query weight and retrieve the column vectors from the full query weight matrix (which already resides in the GPU) as needed for partial query projection. Additionally, we can place the partial key cache in the CPU and perform speculation on the CPU after fetching the partial query from the GPU. Even a naïve method of lowering the partial ratio would likely still provide better accuracy compared to other methods while reducing storage overhead. In summary, by minimally sacrificing inference performance, we can greatly reduce the storage overhead on the GPU if necessary.



(a) Relative KV Cache Size (%)

(b) Sequence Length

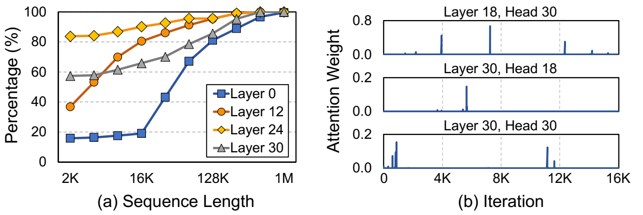
Figure 19: Perplexity of Llama-2-7B-32K across (a) relative KV cache sizes with a sequence length of 32768 and (b) sequence lengths while retaining 64 tokens. Lower is better. Llama-2-7B-32K is a fine-tuned version capable of processing up to 32K tokens using position interpolation [12]. Quantization is omitted in (b) since the KV cache cannot be compressed below 6.25% (i.e., 1 bit).

6.3 Long Context Window

Figure 19 shows the perplexity of the Llama-2-7B-32K model, which can process up to 32K tokens, across the relative cache sizes and sequence lengths. We use the WikiText-2 dataset for the experiment. As the context window size increases for future LLMs, the relative portion of the KV cache that the GPU can retain would decrease due to the limited capacity of GPU memory.

Figure 19(a) shows that InfiniGen maintains perplexity levels close to the full-cache baseline even as the relative KV cache size decreases, without leading to a noticeable increase in perplexity even with much smaller cache sizes. In contrast, other methods increase perplexity compared to the full-cache baseline and significantly diverge at certain sizes due to insufficient bit widths for preserving adequate information on all keys and values (Quantization) or the permanent removal of KV cache entries (H_2O). As shown in Figure 19(b), the perplexity gap between InfiniGen and H_2O widens for longer sequence lengths, which is likely to increase further for sequence lengths beyond 32K. This implies that InfiniGen can scale to longer sequences and better preserve model accuracy compared to others.

We further speculate on how InfiniGen would benefit in an era of million-token context windows by analyzing a model capable of handling 1 million tokens. Figure 20(a) shows that the percentage of query tokens that attend to less than 1% of key tokens increases as the sequence length becomes longer. InfiniGen can adapt to this changing trend by dynamically adjusting the amount of the KV cache to load, whereas prior fixed-budget/pruning approaches would not easily adjust the effective KV cache size. Figure 20(b) further shows that the attention weights of key tokens can change across iterations;



(a) Sequence Length

(b) Iteration

Figure 20: Analysis of 1 million tokens using Llama-3-8B-1048K. (a) Percentage of query tokens that attend to less than 1% of the key tokens across the sequence lengths. (b) Attention weight of sampled key tokens from different layers and heads across the last 16K iterations out of 1 million tokens.

the sampled key tokens show sudden *spikes* after thousands of iterations with significantly low attention weights (e.g., the 7425th iteration out of the last 16K iterations in Layer 18, Head 30). We observe that the prior approaches that permanently eliminate tokens while they are unimportant could lose the critical contexts if they become important again at later iterations. In contrast, InfiniGen can preserve model performance by keeping the temporarily unimportant KV entries for potential future use.

7 Related Work

DNN Serving Systems. A systematic approach to enabling an efficient and fast model serving system is an important topic that has been widely studied by both academia and industry. Some prior works focus on distributed systems with predictable latency for service-level objectives (SLOs) [15, 16, 25, 56]. Other works improve parallelism and throughput of the system through preemption [28, 75], fine-grained batching [17, 21, 71], or memory optimizations [18, 35, 58].

Several other works aim at achieving high throughput execution with limited GPU memory by offloading parameters to secondary storage (e.g., CPU memory and disk). Some of them build on CUDA Unified Memory [46] with prefetching [31, 39], while others explicitly move tensors in and out as needed for computation [29, 30, 48, 72, 73]. FlexGen [57] is a recent LLM serving system that enables high-throughput inference on a single GPU by offloading weights and KV cache to CPU memory and disk. InfiniGen is orthogonal to FlexGen and can work in conjunction with it to efficiently offload and prefetch the KV cache.

KV Cache Management. vLLM [35] mitigates the KV cache memory waste from fragmentation and duplication. StreamingLLM [67] enables LLMs to generate longer sequence lengths than the trained ones. However, since neither vLLM nor StreamingLLM reduces the size of the KV cache, data transfers still incur a significant overhead in offloading-based inference systems. InfiniGen complements the KV cache management to reduce the data transfer overhead, which is a major bottleneck in offloading-based systems.

Efficient LLM Inference. There are lines of research that exploit *quantization* or *sparsity* to make LLMs efficient through algorithmic methods [13, 19, 22, 34, 66] or hardware-software co-design [26, 27, 36, 50]. Regarding sparsity, most algorithm-based works focus on reducing the model size by exploiting the sparsity of weights. Alternatively, H_2O and Sparse Transformer [13] leverage the row-wise (i.e., token-level) sparsity in the KV cache by *permanently* removing certain KV entries. On the other hand, most hardware-software co-design studies focus on relaxing the quadratic computational complexity in the prefill stage by skipping non-essential key tokens with the aid of specialized hardware. However, they often do not reduce memory access as they identify the important key tokens only after scanning all the elements of the key tensors.

Kernel fusion [18, 32] is another approach to mitigating the quadratic memory overhead of attention in the prefill stage. InfiniGen can be implemented with kernel fusion techniques to alleviate the overhead of KV cache access in the decoding stage. To our knowledge, this is the *first* work to enable efficient LLM inference by prefetching only essential KV entries in offloading-based inference systems.

8 Conclusion

The size of the KV cache poses a scalability issue in high-throughput offloading-based inference systems, even surpassing the model parameter size. Existing KV cache eviction policies show a large accuracy drop and do not efficiently use the interconnect bandwidth when they are employed in offloading-based LLM systems. We propose InfiniGen, an offloading-based dynamic KV cache management framework that efficiently executes inference of large language models. InfiniGen exploits the attention input of the previous layer to speculatively prefetch the KV cache of important tokens. We manipulate the query and key weights to make the speculation more efficient. InfiniGen shows substantially shortened inference latency while preserving language model performance. It also shows much better scalability regarding the batch size, sequence length, and model size compared to prior solutions.

Llumnix: Dynamic Scheduling for Large Language Model Serving

Biao Sun[*†], Ziming Huang[*†], Hanyu Zhao[*], Wencong Xiao, Xinyi Zhang[†], Yong Li, Wei Lin

Alibaba Group

Abstract

Inference serving for large language models (LLMs) is the key to unleashing their potential in people's daily lives. However, efficient LLM serving remains challenging today because the requests are inherently heterogeneous and unpredictable in terms of resource and latency requirements, as a result of the diverse applications and the dynamic execution nature of LLMs. Existing systems are fundamentally limited in handling these characteristics and cause problems such as severe queuing delays, poor tail latencies, and SLO violations.

We introduce Llumnix, an LLM serving system that reacts to such heterogeneous and unpredictable requests by *runtime rescheduling* across multiple model instances. Similar to context switching across CPU cores in modern operating systems, Llumnix reschedules requests to improve load balancing and isolation, mitigate resource fragmentation, and differentiate request priorities and SLOs. Llumnix implements the rescheduling with an efficient and scalable live migration mechanism for requests and their in-memory states, and exploits it in a dynamic scheduling policy that unifies the multiple rescheduling scenarios elegantly. Our evaluations show that Llumnix improves tail latencies by an order of magnitude, accelerates high-priority requests by up to 1.5×, and delivers up to 36% cost savings while achieving similar tail latencies, compared against state-of-the-art LLM serving systems. Llumnix is publicly available at `https://github.com/AlibabaPAI/llumnix`.

1 Introduction

Large language models (LLMs) such as the GPT series [15, 49] are bringing generative AI to an unprecedented level. Their human-level generation capabilities are being quickly adopted in a wide range of domains, inspiring many imaginations for future applications, and expected to have profound influences on how people live and work.

Inference serving of LLMs plays a key role in LLM-powered services, becoming a critical workload in datacenters. Such services are typically backed by multiple instances of the LLM deployed on a GPU cluster. The system involves a *scheduler* and an *inference engine*, where a request is first dispatched by the scheduler to a model serving instance, then gets executed by the inference engine inside. The requests are typically batched for execution on each instance to increase throughput and cost efficiency.

We observe unique characteristics of LLMs that call for new design philosophy of the serving infrastructure. The first is *workload heterogeneity*. LLMs are designed to be universal, by learning as much knowledge as possible from whatever domains. People can query the same LLM in totally different situations or even build custom applications atop LLMs for various scenarios; for all of these, a context-specific input (*i.e.*, prompt) is all you need [15]. Such universality and application diversity lead to heterogeneity of the inference requests, in terms of input lengths, output lengths, expected latencies, *etc*. For instance, the task of summarizing long text can introduce significant input lengths, where the latency of returning the first token (word) is often important to user experience [38].

The second characteristic is *execution unpredictability*. Serving an LLM request needs to run the model for multiple iterations, each producing a single output token; however, it is not known a priori how many tokens will be generated eventually. Moreover, the iterative generation also brings considerable GPU memory consumption that dynamically grows with the tokens. As such, the execution time and the resource demand of a request are both unpredictable.

These characteristics make an LLM inherently a *multi-tenant* and *dynamic* environment, serving heterogeneous and unpredictable workloads on multiple instances. This behavior is fundamentally different from traditional DNN models, where the requests are homogeneous and the execution is one-shot, stateless, and deterministic. Instead, we find LLMs more similar to modern operating systems hosting processes with dynamic working sets and different priorities on multiple cores. Managing such systems has complex goals, which goes

[*] Equal contribution.

[†] Work done during internship at Alibaba Group.

beyond what existing inference serving systems are designed for. Although there has been a series of LLM-tailored inference engines that shows superior performance, such systems concentrate on the sole goal of maximizing throughput within a single instance [34, 46, 67]. The request scheduling across instances, on the other hand, has received relatively little attention; the common practice today is still to use generic scheduling systems or policies inherited from the era of traditional DNNs [4, 28, 35, 47, 53]. Such a clear gap introduces challenges in the following aspects that are crucial in multi-tenant environments and online services.

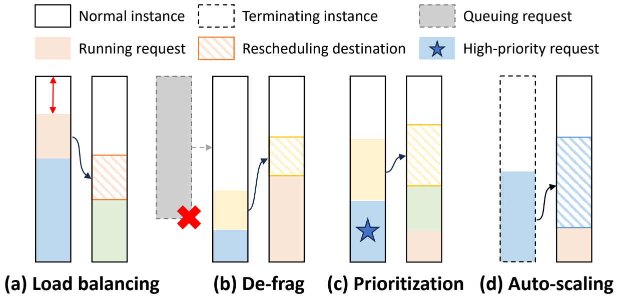
Isolation. The system can hardly provide performance isolation to requests as their memory consumption grows unpredictably. Memory contention incurs performance interference and even preemptions of certain requests in a batch [34], leading to highly unstable latencies and service-level objective (SLO) violations, significantly sacrificing user experiences.

Fragmentation. The varying request lengths and memory demands inevitably result in memory fragmentation across instances, which introduces conflicting scheduling objectives. The running requests prefer load balancing to reduce preemptions and interference, but such load balancing fragments the free memory space across instances at the same time. The fragmentation can cause long queuing delays of new requests that instead require a large space on one instance for the input sequences. This conflict is difficult for the scheduler to reconcile with unpredictable arrivals and lengths of requests.

Priorities. Requests from different applications and scenarios naturally come with different latency objectives. Online chatbots [6, 8] are interactive applications and are therefore with tight SLO constraints. On the contrary, offline applications, such as evaluation [51], scoring [36], or data wrangling [43], are less sensitive to latency. Such different latency objectives are also a consequence of the commercial purpose of earning more profits from LLMs via diversified service classes (*e.g.*, ChatGPT Plus [2]). However, existing LLM inference systems [34, 67] often treat all requests for a model equally and cannot differentiate their priorities, which has limitations in meeting different latency objectives of requests.

We introduce Llumnix, a new scheduling system for LLM serving that addresses the challenges above via *runtime rescheduling* of requests across model instances. Analogous to context switching across CPU cores in OS process management, rescheduling enables Llumnix to *react* to the unpredictable workload dynamics at runtime, instead of having to address all the complex scheduling concerns and tradeoffs with the one-shot dispatching of requests. Llumnix reschedules requests for multiple purposes (Figure 1): load balancing for reducing preemptions and interference, de-fragmentation for mitigating queuing delays, prioritization of urgent requests by creating even higher degree of isolation, saturating or draining out instances during auto-scaling more quickly.

Llumnix reschedules requests via an efficient and scalable *live migration* mechanism of requests along with their GPU memory states across instances. Straightforward rescheduling approaches could introduce substantial downtimes to rescheduled requests, especially for long sequences. By contrast, Llumnix introduces *near-zero* downtime that is *constant* to sequence lengths, by carefully coordinating the computation and the memory transfer to hide the cost.



(a) Load balancing (b) De-frag (c) Prioritization (d) Auto-scaling

Figure 1: Example rescheduling scenarios in Llumnix.

To exploit such great scheduling flexibility of migration, Llumnix adopts a distributed scheduling architecture that enables continuous rescheduling with high scalability. Llumnix further introduces a dynamic scheduling policy under this architecture that unifies all the rescheduling scenarios with different goals elegantly. This unification is achieved via a concept called *virtual usage*: Llumnix just needs to define a set of rules for setting the virtual usages of GPU memory for requests in different scenarios, and then use a simple load-balancing policy based on the virtual usages.

We have implemented Llumnix as a scheduling layer on top of inference engines. Llumnix currently supports a representative system, vLLM [34], as the underlying engine. Evaluation on a 16-GPU cluster using realistic workloads shows that Llumnix improves P99 first-token latency by up to 15× and P99 per-token generation latency by up to 2×, compared against a state-of-the-art scheduler INFaaS [53]. Llumnix also accelerates high-priority requests by 1.5×, and achieves 36% cost saving when delivering similar tail latencies.

In summary, this paper makes the following contributions.

- We reveal the unique characteristics and scheduling challenges of LLM serving that necessitate new scheduling goals such as isolation, de-fragmentation, and priorities.
- We propose request rescheduling as a key measure to achieve these goals and realize it with an efficient migration mechanism of requests and their GPU memory states.
- We design a distributed scheduling architecture and an accompanying scheduling policy that exploit request migration to achieve the multiple goals in a unified manner.
- We implement and evaluate Llumnix to show its advantages over state-of-the-art inference serving systems.

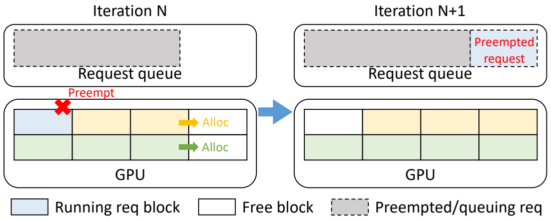


Figure 2: Request queuing and preemption using continuous batching and dynamic memory allocation.

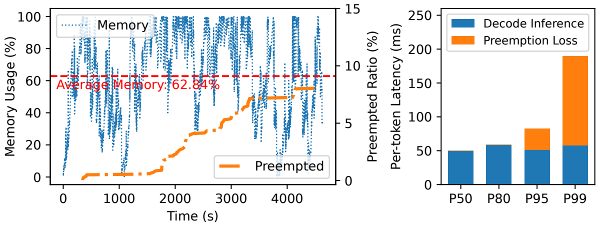

Figure 3: Request preemptions in LLaMA-7B serving.

2 Background

Application diversity of LLMs. Recent LLMs are becoming *task-agnostic*. That is, the same model can work for various tasks with context-specific inputs (*a.k.a.* the "prompts") provided. This is achieved by both increasingly larger model and dataset sizes and advanced pre-training approaches such as few-shot learning [14]. Task-agnostic models enable diverse applications, from chatbots, search engines, summarization, coding, AI assistants, to AI agents, to name a few.

The diverse applications lead to requests with different requirements for the serving. An important aspect is the *sequence lengths*. LLMs are racing to support longer sequence lengths — for example, from March to November 2023, the maximum sequence lengths of the GPT family have scaled from 32k [1] (GPT-4 [49]) to 128k (GPT-4 Turbo [50]). We expect this trend to continue as longer sequences are necessary for broader applications of LLMs. Consider an intuitive example of the tasks for summarizing and writing an article: they require sufficiently long input and output lengths, respectively. Another aspect is *expected latencies*. A real product example is that OpenAI introduces a subscription plan called ChatGPT Plus [2] to offer faster responses of common ChatGPT services. In general, different applications and situations also naturally have different levels of urgency. For example, more interactive applications like personal assistants expect shorter latencies than tasks like summarizing an article.

Autoregressive generation. The inference for state-of-the-art LLMs is *autoregressive*: the model iteratively accepts the input sequence plus all the previous output tokens to generate the next output token, until an "end-of-sequence" (EOS) token is generated. The phase for generating the first token and that for each new token afterwards are usually referred to as *prefill* and *decode*, respectively. LLM services typically return the generated tokens in a streaming manner. Therefore, the prefill and decode latencies are both user-perceivable and important to user experiences. The prefill latency determines how long it takes to start receiving the response, which can be dominated by the queuing delay. The decode latency determines the speed of receiving the following tokens subsequently.

During the autoregression, the intermediate results (key and value tensors used in the attention operation [59]) for each token are involved in the generation of all following tokens. Therefore, the inference engine typically stores these states in GPU memory for reuse, known as the *KV cache* [52].

Batching and memory management. State-of-the-art inference engines apply the *continuous batching* technique [34,67] to handle the varying sequence lengths and dynamic arrivals of requests. That is, a new/completed request can join/leave the running batch immediately, instead of waiting for all the running requests to complete. Batching also raises concern about memory management of KV cache. Since the memory demand of KV cache is not known a priori, it would clearly limit the batch size and batching benefits if the memory is reserved to the maximum length. For example, a LLaMA-2-13B [58] model supports sequence lengths up to 4k, which translates to 3.2 GB KV cache for a single request; while the memory of current GPUs remain tens of GBs, let alone the space for model weights (26 GB for LLaMA-2-13B). Therefore, recent work (vLLM [34]) proposed *dynamic memory allocation* for KV cache to increase batch size and throughput, enabled by a technique named PagedAttention: the KV cache tensors are stored in dynamically allocated blocks as the KV cache grows. Figure 2 presents an example of using continuous batching with dynamic memory allocation. The running requests are chosen based on the free memory blocks, hence there is a queuing request (the gray one) at iteration N as the memory is insufficient. At the next iteration, the system runs out of memory for the new blocks of the running requests. Therefore, the system preempts certain running requests (the blue one), which then goes back to the queue.

3 Motivation

We motivate the design of Llumnix with a series of key characteristics of LLM serving as follows.

Unpredictable memory demands and preemptions. With dynamic memory allocation, request preemptions are inevitable as a result of the unpredictable memory demands, which can significantly increase the latencies of the preempted requests. Figure 3 shows an experiment of LLaMA-7B model serving using vLLM on an A10 GPU running a trace of 2,000 requests generated from a Poisson distribution. The input and output lengths follow a power-law distribution with a mean

[1] 1k stands for 1,024 when describing sequence length in this paper.

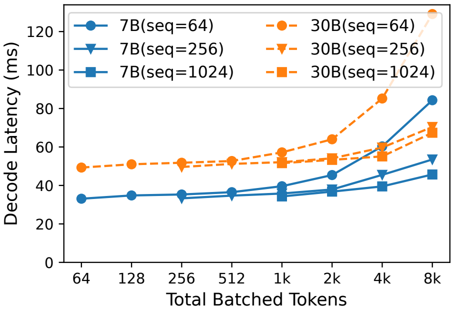

Figure 4: Latencies of one decode step of LLaMA-7B and LLaMA-30B with different sequence lengths and batch sizes.

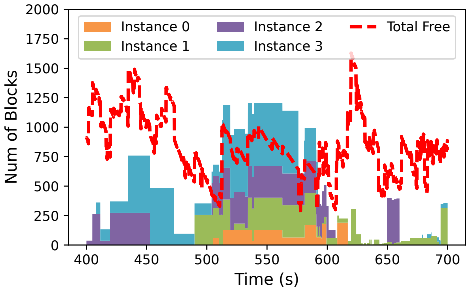

Figure 5: Total free memory vs. demands of the head-of-line queuing requests across four LLaMA-7B instances.

value of 256 tokens (details in §6). We control the request rate (0.42 req/s) to get a moderate memory load (62% on average) with some spikes due to the varying sequence lengths. Under such load, we still observe 8% of the requests being preempted. We quantify the preemption loss by measuring the latency penalty caused by preemption, including the extra queuing time and the recomputing for previous KV cache. We show different percentiles of per-token decode latency (averaged across all decode iterations of a request). We do not use the end-to-end latency because it depends on the number of iterations. We observe that the P99 per-token decode latency is much worse than the P50 (3.8×), and the preemption loss accounts for 70% for the P99 request. In particular, the P99 request experiences a total preemption loss of 50 seconds (preempted twice), showing severe service stalls and degradation of user experiences due to preemptions.

Performance interference among requests. We also observe performance interference of requests in a batch to each other, due to resource competition on GPU compute and memory bandwidth resources. Figure 4 shows the times for a decode step of LLaMA-7B (1-GPU) and LLaMA-30B (4-GPU) using different sequence lengths and batch sizes (the X-axis shows the total number of tokens in a batch for each data point). The decode speed decreases with more requests and higher interference, and the gap between the same sequence length is up to 2.6×.

Memory fragmentation. Considering the aforementioned problems, it would be better to spread requests across instances to reduce preemptions and interference. However, such spreading will make the available memory of the cluster fragmented across instances simultaneously. Here fragmentation refers to *external* fragmentation, *i.e.*, unallocated memory on an instance. Dynamic allocation techniques like PagedAttention [34] can eliminate external fragmentation during the *decode* phase, where the blocks are allocated one at a time. However, external fragmentation remains a significant problem for the *prefill* phase, which requires many blocks on an instance in one allocation to accommodate the KV cache of all tokens in the inputs. Therefore, external fragmentation can cause long queuing delays of new requests, especially those with long inputs.

Figure 5 shows an experiment of four LLaMA-7B instances, where the trace also uses the input/output length distribution with mean value 256 and a Poisson distribution with a request rate of 1.9 req/s. We implement a spreading dispatching policy that dispatches new requests to the instance with the lowest memory load for load balancing. We demonstrate the fragmentation by showing the total free memory blocks across the cluster, against the demand of the head-of-line queuing request on each instance. For most of the time span, the total free memory can accommodate the queuing requests on at least three instances (sometimes all of them). The request are queuing despite enough total memory because they exceed the free space on their own instances, which demonstrates the fragmentation and also the potential of defragmentation to reduce queuing delays.

Different emergency and priorities of requests. With requirements of products like ChatGPT Plus and the diverse application scenarios of LLMs, we foresee more applications with different latency sensitivities. However, existing systems usually treat all requests equally, where the latency-sensitive could easily be interfered by other normal ones, *e.g.*, excessive queuing delays or performance interference. This calls for a systematic approach to differentiating the request priorities for an LLM to meet their respective latency objectives.

Opportunity: request rescheduling across instances. This paper explores a new dimension that is missing in current LLM serving systems: the multiple model instances of a deployment and their interaction. A simple intuition is that when the aforementioned problems occur on a certain instance, it is possible that the whole cluster still has enough space for avoiding preempting requests, accommodating new requests, or mitigating interference. This is also a natural consequence of the varying request lengths and memory loads across instances. However, existing systems cannot exploit such free space on other instances because requests are tied on the same instance once scheduled throughout the autoregressive execution. Llumnix unifies the request scheduling component and the model inference engine to explore the potentials of fine-grained coordination among inference instances.

4 Llumnix Design

4.1 Overview

Llumnix builds upon the key idea of rescheduling LLM inference requests at runtime across model instances. Llumnix inherits continuous batching [67] and dynamic memory allocation [34] from state-of-the-art systems for high throughput. Beyond that, Llumnix exploits request rescheduling to react to the unpredictable workload dynamics in various situations with different scheduling goals, as illustrated in Figure 1.

A first goal is *load balancing* (Figure 1-a) to reduce request preemptions and interference on high-load instances. Although the dispatching can also consider load balancing of memory usage, it could be sub-optimal as the final memory usages of requests are unknown at the arrivals, due to the unpredictability of output lengths. Rescheduling complements it by reacting to the real usage growths of requests. Meanwhile, as shown before, load balancing can also lead to higher memory fragmentation and longer queuing delays of long inputs probably. Therefore, Llumnix also reschedules requests for *de-fragmentation* (1-b), *i.e.*, creating contiguous space on an instance by moving requests onto others. Although these two goals remain a tradeoff, Llumnix has a much larger space to balance them with rescheduling. Another goal is *prioritization* (1-c) of certain requests by rescheduling co-located requests away for lower load and avoiding interference. Such rescheduling provides "decicated" resources to high-priority requests dynamically, without the need for reserving machines statically. Finally, Llumnix also reschedules requests during *auto-scaling*, *e.g.*, to drain out an instance to be terminated (1-d) or saturate a new instance more quickly.

Realizing such highly dynamic rescheduling efficiently is challenging, considering the large request context states (*i.e.*, the KV cache). Naïve solutions include recomputing or copying the KV cache of the rescheduled requests, however with high computation stalls and downtime, reaching over 50× of the decoding cost (§6.2). What's more, the KV cache states increase with sequence lengths, limiting the scheduling flexibility under the trend of growing context lengths [50]. Such a high inference delay in generating next tokens greatly degrades the user experiences of LLM serving and thus prohibits request rescheduling. Llumnix addresses this challenge with a *live migration* mechanism that pipelines and coordinates the KV cache copying and the token generation computation, thereby bringing negligible downtime (§4.2).

To exploit the benefits of migration, Llumnix adopts a scalable architecture that combines global and local scheduling to decentralize the scheduling decisions and the coordinated migration actions, facilitating continuous rescheduling at scale (§4.3). Under this architecture, we further design an efficient heuristic scheduling policy that centers around the *virtual usage* concept to abstract the requirements of the different scheduling goals in a unified manner (§4.4).

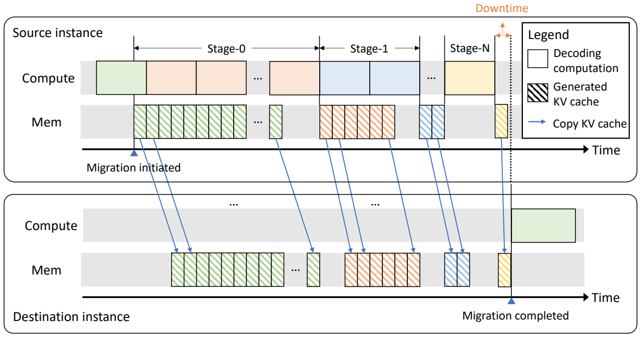

Figure 6: Llumnix adopts multi-stage migration to overlap the computation and KV cache copying for minimal downtime.

4.2 Live Migration of LLM Requests

The significant KV cache states of requests can potentially introduce great cost and serving stalls during rescheduling. Llumnix addresses this challenge by exploiting a key characteristic of LLM inference: the KV cache is *append-only*. LLM inference iteratively concatenates the output token of the current iteration with the input tokens, which is set as the input for the next iteration. In this way, inference engines also keep appending the calculated KV state of the current iteration to the KV cache parameters, leaving the parameters generated by previous iterations remain constant.

The live migration mechanism of Llumnix utilizes the inherent append-only characteristic of KV cache to pipeline the KV cache copying with the decoding computation. Because the KV cache already generated won't be modified in the following iterations, Llumnix can safely copy the KV cache of previous tokens in parallel with the computation for new tokens. In this way, Llumnix achieves *near-zero* and *constant* downtime to the rescheduled request. As shown in Figure 6, when migration is initiated, the source instance starts to copy the KV cache blocks of completed iterations, and continues the computation at the same time (stage 0). When the copying for the previous KV cache blocks is done, there will be a few more iterations (*i.e.*, blocks in Figure 6) computed in stage 0. Then, it switches to stage 1 to copy the KV cache generated by stage 0, while continuing the computation afterwards. The copying is generally much faster than the computation, thus the number of new blocks is typically small such that we can copy them in a very short period. To the end, only one iteration of computation is conducted for the KV cache migration (*i.e.*, stage-N). Therefore, Llumnix suspends the computation for the request by draining it out of the current batch and copies the remaining block, which introduces the downtime of this request. Once it is finished, the migration completes and the request resumes on the destination instance. Although the total copying duration of the whole sequence depends on the sequence length, the downtime for the request is only the period of copying the KV cache generated by one iteration,

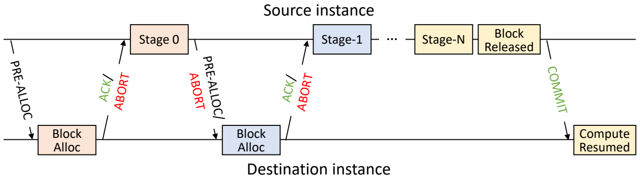

Figure 7: Handshake during migration.

which is negligible regardless of the sequence length.

The request migration approach of Llumnix borrows the key concept introduced in virtual machine (VM) live migration [17], which gradually reduces the working set to minimize the downtime. Llumnix does not require the dirty page tracing in VM migration as the working set (*i.e.*, KV cache) is append-only and does not change during migration. However, LLM serving further introduces additional challenges. Firstly, as both the source and destination instances are continually processing requests, the request might run out of memory during migration. Secondly, the request can complete in the middle of migration, due to the unpredictable execution (*i.e.*, generating EOS token) and the continuous batching [67]. To handle such exceptions and guarantee correctness during the asynchronous computation and memory copying, Llumnix introduces fine-grained coordination between the participating instances with a *handshake* process (Figure 7). Before each stage, the source instance issues a pre-allocate request with the number of blocks to migrate to make sure that the destination has enough space. The destination will try to allocate and reserve the blocks; if it succeeds or fails, the destination will notify the source to proceed or abort the migration and clean the states, respectively. Similarly, after each stage, the source instance also checks whether the request being migrated has completed or been preempted — if it has, the source will notify the destination to abort and release the reserved blocks; otherwise the source will go ahead to the next stage. The source or destination will also abort the migration if the other side fails. After the final stage finishes, the source releases its local blocks and notifies the destination to commit the migration and resume the execution of the request.

4.3 Distributed Scheduling Architecture

The live migration mechanism provides the foundation for runtime rescheduling of LLM inference requests. However, achieving fully dynamic scheduling is still non-trivial due to the higher scheduling pressure than in traditional schedulers. In particular, Llumnix would need to continuously track and reschedule every single running request throughout the cluster, rather than only dispatch incoming requests for one time or only manage running requests on one instance. This implies a higher scheduling frequency and a larger number of requests for the scheduler to track and schedule in each round.

Llumnix devises a scalable architecture that combines a cluster-level *global scheduler* and distributed instance-level schedulers, named *llumlet*s, to enable continuous rescheduling efficiently (Figure 8). Llumnix defines a clean separation of concerns with a narrow interface between the two levels. The global scheduler does not directly track or schedule the running requests; instead, it makes all scheduling decisions oriented to the *instances*, according to the *memory loads* of them. This way, the complexity of the global scheduler remains independent from the running requests, thereby preserving similar scalability to schedulers without dynamic scheduling. The loads are reported by the llumlets periodically, based on the request status and Llumnix's scheduling policy.

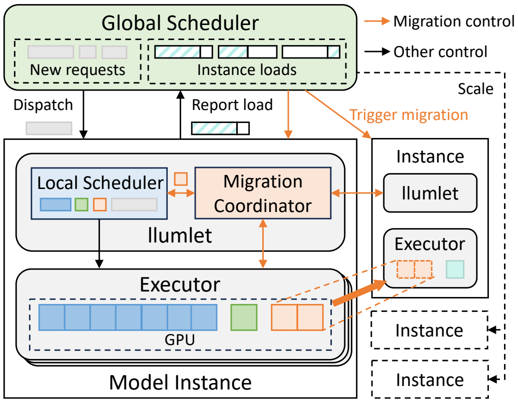

Figure 8: Llumnix architecture.

The global scheduler utilizes the load information to dispatch new requests, trigger migration across instances, and control the instance auto-scaling. In particular, for migration, the decisions are not made for specific requests; the global scheduler just pairs the source and destination instances, only based on the loads, and marks them as in the corresponding states to trigger the migration. The llumlets will decide the requests to migrate and execute the migration automatically.

The llumlet of each instance consists of a local scheduler and a migration coordinator. In addition to the functionalities of similar roles in existing systems like queuing, batching, and block management, an important new task of the local scheduler is to calculate the memory load of the instance. The load is not simply the physical memory being used; instead, it is a sum of the "virtual usages" (§4.4) of the requests. The local scheduler is also responsible for deciding the requests to migrate when triggered. Given the chosen requests, the migration coordinator will coordinate with the local scheduler and the other instance, and instruct the model executor to do the memory copying, as described before.

4.4 Dynamic Scheduling Policy

4.4.1 Goals and Definitions

Llumnix's scheduling policy is designed with the following goals. The first is to improve **prefill and decode latencies**, by reducing queuing delays, preemptions, and interference.

The second goal is **load-adaptivity** to handle varying cluster load and improve cost efficiency. We notice that the benefits of rescheduling is also relevant to cluster load, which could be limited under too high/low load. Llumnix incorporates instance auto-scaling to keep appropriate cluster load for both saving costs and maximizing the benefits of rescheduling.

Besides these two goals similar to those of existing systems, Llumnix introduces a new goal of request **priorities** that comes from the new requirements of LLMs. Priorities present a systematic approach for the same LLM to serve certain requests with higher emergency, *e.g.*, from ChatGPT Plus or more interactive applications. Llumnix provides applications with an interface for specifying request priorities to meet different SLOs, in terms of *scheduling priority* and *execution priority*. Requests with higher scheduling priorities will get scheduled earlier to reduce their queuing delays. Those with higher execution priorities will be given lower instance load and hence less interference to accelerate their execution. Currently, Llumnix supports two priority classes, high and normal, to demonstrate the ability of Llumnix to prefer high-priority requests, but our design also generalizes to more priorities.

4.4.2 Virtual Usage

To achieve the multiple goals above under the distributed scheduling architecture, Llumnix needs a scheduling policy that can express these goals using simple instance-level metrics, to improve the efficiency and scalability of the global scheduler. To this end, Llumnix introduces the *virtual usage* abstraction to unify these different, sometimes conflicting goals into a simple load metric of instances. The key observation here is that the aforementioned rescheduling scenarios fall into two categories: *load balancing*, and *creating free space on one instance* (de-fragmentation, prioritization, and draining out instances). We find that they can be unified into load balancing by assuming a virtual load on the instance: to create free space on an instance, we just need to set the virtual usages of certain requests to make the instance virtually overloaded, then a load balancing policy will be triggered to migrate the requests to other instances.

This observation leads us to a simple heuristic with load-balancing as the basis, combined with a set of rules for setting request virtual usages in different situations. We summarize the rules in the function `CalcVirtualUsage` in Algorithm 1 and illustrate example scenarios in Figure 9. In normal cases, the virtual usage of a request is just its physical memory usage to enable routine load balancing, as shown in Figure 9(a). We discuss the rules for other cases as follows.

Queuing requests. For the head-of-line queuing request on an instance, we assign a positive virtual usage to it to reflect its resource demand in terms of the required memory, although the physical usage is 0. Thus, queuing requests will increase the total virtual usage of the instance, then the policy will trigger migration for load balancing (which in effect is de-fragmentation for the queuing request), as shown in Figure 9(b). There could be a lot of heuristics to explore for setting the virtual usage, which controls the tradeoff between reducing queuing delays and load balancing — for example, gradually increasing the virtual usage of a queuing request until it reaches the real memory demand. Llumnix currently uses a simple rule that directly uses its real demand (line 4 in Algorithm 1), which favours reducing queuing delays. This rule is based on our observation that queuing delay can dominate the end-to-end latency and worth such preference. Our evaluation also shows that this rule preserves the benefits of load balancing, due to the high flexibility of migration.

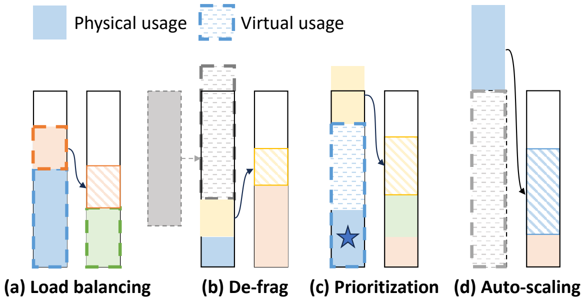

Figure 9: Llumnix combines virtual usages with a load-balancing policy to unify multiple scheduling goals.

Execution priorities. For a request with high execution priorities, Llumnix tries to prevent the instance the request is running on from exceeding a given level of real load, by reserving a memory space as headroom, as shown in Figure 9(c). This is achieved by adding such a headroom on the physical usage of a high-priority request to get the virtual usage (line 8). When there are multiple high-priority requests on an instance, this headroom is divided among them (line 10). The headroom for high-priority requests is currently defined as that required to preserve the ideal decode speed (*i.e.*, no visible interference), which is obtained through profiling. The headroom for normal requests is 0. Llumnix can also support more execution priorities by specifying the sizes for the headroom. When the headroom for a high-priority request is running up, the other normal requests will be migrated away by the load balancing policy because the instance is overloaded in terms of the total virtual usage.

Auto-scaling. When a new instance is launched, Llumnix's load balancing policy will automatically saturate it by migrating requests from other instances to it. When an instance is terminating, we artificially add a fake request with a virtual usage of infinity on it (line 7), then the remaining requests will be migrated to other instances, as shown in Figure 9(d).

4.4.3 Policies

We then describe how the specific scheduling decisions are made based on the virtual usages.

Algorithm 1: Virtual Usage and Freeness Calculation

```
Function CalcVirtualUsage(req, instance):
    if $req.isQueuing$ then
        if $req.isHeadOfLine$ then
            return $req.demand$
        return 0
    if $req.isFake$ then
        return $\infty$
    return $req.physicalUsage$+GetHeadroom($req.priority, instance$)
Function GetHeadroom(p, instance):
    return $headroomForPriority[p]/instance.numRequests[p]$
Function CalcFreeness(instance):
    if $instance.isTerminating$ then
        AddFakeReq($instance.requests$)
    $totalVirtualUsages = 0$
    for $req$ in $instance.requests$ do
        $totalVirtualUsages+=$CalcVirtualUsage($req, instance$)
    $freeness = (instance.M - totalVirtualUsage)/instance.B$
    return $freeness$
```

Dispatching. Llumnix dispatches new requests with higher scheduling priorities first. Within the same priority, it adopts a simple first-come-first-serve order. On each instance, requests are scheduled in the same order. Llumnix uses a load-balancing policy that dispatches each request to the freest instance. We introduce a metric for measuring the *freeness* of an instance defined as $F = (M - \sum V)/B$, where M is the total memory, V is the virtual usage of each request, and B is the batch size. While $(M - \sum V)$ already measures the free space, we divide it by the batch size because it determines the consumption speed, *i.e.*, the number of new tokens per iteration. Thus the metric suggests how many iterations the batch can still run for. Then Llumnix dispatches each incoming request to the instance with the highest freeness. Because the virtual usage of a request can be larger than the physical, it is possible that F is a negative value, *e.g.*, when there are queuing requests or high-priority requests. Such negative freeness values help Llumnix automatically treat such instances as overloaded and prefer dispatching requests to other instances. The freeness metric also guides the migration and auto-scaling, as shown later.

Migration. Llumnix triggers the migration policy periodically. In each round, Llumnix selects the candidate sets of source and destination instances by choosing those with freeness values smaller or greater than given thresholds, respectively. Llumnix pairs the instances from both sets by picking the two with the lowest and the highest freeness values repeatedly, and then sets them in corresponding states. The llumlet of each source instance then starts to migrate requests to the destination continuously, until it is no longer set in the source state. The llumlet prefers the requests with lower priorities and shorter sequence lengths when choosing the requests to migrate. In the next round, if an instance during migration is no longer beyond the thresholds, Llumnix will unset the migration state and the migration will stop.

Auto-scaling. Llumnix scales the instances according to the cluster load in terms of the averages freeness for the normal priority across instances. The policy maintains the average freeness within a range $[x, y]$, and adds or terminates an instance when the freeness is smaller than x or greater than y for a period, respectively. Llumnix chooses the instance with fewest running requests for termination.

5 Implementation

We implement Llumnix with 3,300 lines of Python code. Llumnix is a standalone library comprising both its own components and an interface to integrate and communicate with backend inference engines. This architecture makes Llumnix non-intrusive and extensible to different backends. Llumnix currently supports vLLM [11] as the backend, which is an open-source state-of-the-art inference engine that features continuous batching, PagedAttention, and tensor-parallel distributed inference [34, 56].

Multi-instance serving. Llumnix instantiates the multiple instances of the backend and the other components as Ray [42] actors. Ray's Python-native distributed runtime enables fine-grained coordination among these actors in a simple and efficient manner. Llumnix also launches a set of request frontend actors that exposes an OpenAI-style API endpoint [48]. Although a request can be migrated across backend instances, the generated tokens are forwarded to the frontend and then returned to end users, ensuring a steady API service.

KV cache transfer. We use the Gloo collective communication library [5] (the `Send`/`Recv` primitives) for the KV cache transfer during migration. A potential alternative is NCCL [1], which is generally faster than Gloo on GPUs but has been adopted in communication for distributed inference. However, Llumnix needs to migrate requests in parallel with the inference to minimize the downtimes, but concurrent invocations of NCCL are known to be unsafe [45]. The pipelined migration design allows us to use Gloo while maintaining negligible downtimes. Using Gloo needs to copy the KV cache between CPU and GPU memory, which is done in another CUDA stream to avoid blocking the inference computation. Note that in typical deployments, the communication-heavy tensor parallelism is limited in a single machine for high-speed transfer [44]. In such cases, migration between instances (machines) will not interfere with the tensor-parallel inference.

Block fusion. vLLM stores the KV cache in non-contiguous small blocks that are dynamically allocated. For example, the block size of a 16-bit LLaMA-7B model is 128 KB (for key or value tensors of 16 tokens in each layer), and a sequence of 1k tokens translates to 4k such blocks (32 layers). To avoid the overhead of sending these blocks using many small messages, we fuse the blocks by copying them from GPU memory to a contiguous CPU memory buffer and use Gloo to send the buffer as a whole, thereby improving the transfer efficiency.

Fault tolerance. Llumnix provides fault tolerance for each component to ensure high service availability. When the global scheduler fails, Llumnix temporarily falls back to a scheduler-bypassing mode, thus not affecting the service availability: that is, the request frontends directly dispatch requests to certain instances using simple rules, and migration is disabled. When an instance (or the co-located llumlet) fails, the requests running on it will be aborted. In particular, ongoing migration on failed instances will also be aborted (the request being migrated is not necessarily aborted, depending on if its source instance is healthy), which is handled by the handshake process. These failed actors will be automatically restarted by Ray, after which the service could go back to normal state.

6 Evaluation

We evaluate Llumnix on a 16-GPU cluster using realistic models and various workloads. Overall, our key findings include:

- Llumnix introduces near-zero downtime to requests being migrated and near-zero overhead to other running requests.
- Llumnix improves prefill latencies by up to 15×/7.7× (P99/mean) over INFaaS on 16 LLaMA-7B instances via de-fragmentation. Llumnix also improves P99 decode latency by up to 2× by reducing preemptions.
- Llumnix improves high-priority request latencies by up to 1.5× by reducing their queuing delays and accelerating their execution, while preserving similar performance of the normal requests.
- Llumnix achieves up to 36% cost saving while preserving similar P99 latencies with efficient auto-scaling.

6.1 Experimental Setup

Testbed. We use a 16-GPU cluster with 4 GPU VMs on Alibaba Cloud (type `ecs.gn7i-c32g1.32xlarge`), each with 4 NVIDIA A10 (24 GB) GPUs connected via PCI-e 4.0, 128 vCPUs, 752 GB memory, and 64 Gb/s network bandwidth.

Models. We conduct experiments using a popular model family, LLaMA [57]. We test two different specifications: LLaMA-7B, which runs on a single GPU, and LLaMA-30B, which runs on 4 GPUs of a machine using tensor parallelism. The models adopt the commonly used 16-bit precision. The version of vLLM that we based on only supports the original LLaMA with a maximum sequence length of 2k, but there have been a series of recent LLaMA variants supporting longer sequence lengths ranging from 4k to 256k [3, 7, 58, 65]. Since the model architectures and inference performance of these variants are mostly similar to those of LLaMA, we believe that our results are representative of more model types and larger sequence length ranges from a systems perspective.

Traces. Similar to prior work [34, 35, 67], we synthesize request traces to asses Llumnix's online serving performance.

Distribution			Mean	P50	P80	P95	P99
Real	ShareGPT	In	306	74	348	1484	3388
		Out	500	487	781	988	1234
	BurstGPT	In	830	582	1427	2345	3549
		Out	271	243	434	669	964
Gen	Short (S)		128	38	113	413	1464
	Medium (M)		256	32	173	1288	4208
	Long (L)		512	55	582	3113	5166

Table 1: Real and generated distributions of sequence lengths (numbers of tokens) used in our evaluation. The real distributions include those of both inputs ("In") and outputs ("Out").

We use Poisson and Gamma distributions with different request rates (requests per second) to generate request arrivals. For Gamma, we also use varying coefficients of variance (CVs) to adjust the burstiness of the requests. Each trace has 10,000 requests. We choose an appropriate range of request rates or CVs for the traces to maintain the loads within a reasonable range: nearly no queuing delays and preemptions for P50 requests, and queuing delays within a few tens of seconds for P99 requests when using Llumnix.

For the input/output lengths of requests, we use two public ChatGPT-4 conversation datasets, ShareGPT (GPT4) [10] and BurstGPT (GPT4-Conversation) [62], for an evaluation on real workloads. Considering that Llumnix targets more diversified applications, we also use generated power-law length distributions to emulate long-tail workloads that mix both frequent, short sequences (*e.g.*, for interactive applications like chatbots and personal assistants) and seldom, long sequences (*e.g.*, summarizing or writing articles). We generate multiple distributions with different long-tail degrees and mean lengths (128, 256, 512), as shown by the Short (S), Medium (M), and Long (L) distributions in Table 1. These distributions have a maximum length of 6k, thus the total sequence length of a request (input plus output) will not exceed the capacity of an A10 GPU when running LLaMA-7B (13,616 tokens). To observe the performance with different workload characteristics, we construct the traces by picking different combinations of the length distributions for inputs and outputs as follows: S-S, M-M, L-L, S-L, and L-S.

Baselines. We compare Llumnix with the following schedulers. All the baselines and Llumnix use vLLM as the underlying inference engine to focus the comparison on the request scheduling across instances.

- *Round-robin dispatching*: a simple dispatching policy to distribute requests across instances evenly, which is a typical behavior of production-grade serving systems [4, 9, 47].
- *INFaaS++*: an optimized version of INFaaS [53], a state-of-the-art scheduler for multi-instance serving. We evaluate its load-balancing dispatching and load-aware auto-scaling policies. We improve it by making it focus on the GPU

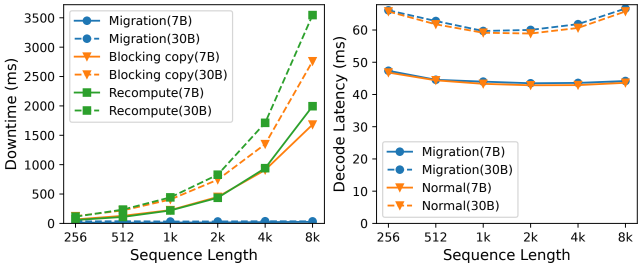

Figure 10: Downtime and overhead of migration.

memory load as it is the dominant resource in LLM serving. This load also counts in the memory required by queuing requests on each instance to reflect the queue pressure.

- *Llumnix-base*: a base version of Llumnix that is priority-agnostic (*i.e.*, treats all requests as the same priority) but enables all the other features including migration.

Key metrics. We focus on request latency, in terms of end-to-end, prefill (that of the first generated token), and decode (that since first generated token to the last, averaged over all generated tokens). We report both mean and P99 values.

6.2 Migration Efficiency

We first examine the performance of Llumnix's migration mechanism, in terms of the downtimes introduced to the migrated requests and the performance overheads for the running requests. We test both the 1-GPU LLaMA-7B and the 4-GPU LLaMA-30B models. For each model, we deploy two instances on two different machines. We use different sequence lengths, for each of which we run a batch of requests with the same total length of 8k on both instances. We migrate one of the requests from one instance to another and measure its downtime and the decode speeds of the running batches on both instances during migration.

We compare the downtime during migration with two simple approaches: recomputing, and blocking copying of the KV cache using Gloo (non-blocking for other requests). As shown in Figure 10 (left), the downtime of migration is nearly constant with increasing sequence lengths (roughly 20-30 ms), even shorter than a single decode step. In comparison, the downtimes of baselines increase with the sequence lengths, reaching up to 111× that of migration. For example, recomputing an 8k sequence for LLaMA-30B takes 3.5s, which translates to a service stall similar to 54 decode steps. We also notice that for all sequence lengths, the migration only takes two stages, which is the minimum. This is because the data copying is sufficiently fast and the number of new tokens generated during the first stage is small.

Figure 10 (right) also compares the per-step decode times during migration on the source instance with that during normal execution (results on the destination are mostly similar). We observe up to 1% performance differences for both LLaMA-7B and LLaMA-30B, showing the negligible migration overhead. Also note that such overhead exists only when there are requests being migrated (in or out) on an instance. We find that in all the serving experiments in the following sections, the average fraction of time span with ongoing migration for each instance is only roughly 10%. This implies an effective overhead that is even much smaller, which is worthwhile for the great scheduling benefits of migration.

6.3 Serving Performance

We evaluate the scheduling performance of Llumnix in online serving using 16 LLaMA-7B instances (auto-scaling is disabled except in experiments in §6.5).

Real datasets. We first compare Llumnix with round-robin and INFaaS++ using the ShareGPT and BurstGPT traces (the top two rows in Figure 11). Llumnix outperforms the baselines in end-to-end request latency by up to 2× and 2.9× for mean and P99, respectively. In particular, we observe that round-robin always performs much worse than both INFaaS++ and Llumnix: since the sequence lengths have high variance, simply distributing requests evenly can still lead to unbalanced load, impacting both prefill and decode latencies. Llumnix achieves significant gains in prefill latency over round-robin, by up to 26.6× for mean and 34.4× for P99. This is because round-robin can possibly dispatch new requests to overloaded instances, leading to long queuing delays. Llumnix also improves P99 decode latency by up to 2×, by load balancing to reduce preemptions. This margin seems smaller as the latency penalty caused by preemptions is averaged over all generated tokens. However, whenever preemption occurs, it results in a sudden service stall, which impacts user experience. Figure 11 (the rightmost column) reports the preemption loss in terms of the extra queuing and recomputing times (mean value of all requests). Llumnix reduces preemption loss by 84% on average compared to round-robin. These results highlight the importance of load balancing in LLM serving. In the following experiments using generated distributions with higher variance, round-robin showed up to two orders of magnitude worse latencies. Therefore, we omit it for the other traces for clarity of the figures and focus on the comparison between INFaaS++ and Llumnix.

Llumnix outperforms INFaaS++ in mean and P99 prefill latencies by up to 2.2× and 5.5×, and P99 decode latencies by up to 1.3×, respectively, showing the extra benefits of migration, beyond dispatch-time load balancing. Next we use more traces with different characteristics to further evaluate them for a deeper understanding of the improvements.

Generated distributions. We compare Llumnix and INFaaS++ using multiple generated distributions (bottom five rows in Figure 11). Llumnix outperforms INFaaS++ across all traces in end-to-end request latency by up to 1.5× and 1.6× for mean and P99, respectively. For prefill, the improvements are up to 7.7× for mean and 14.8× for P99. Despite dispatch-

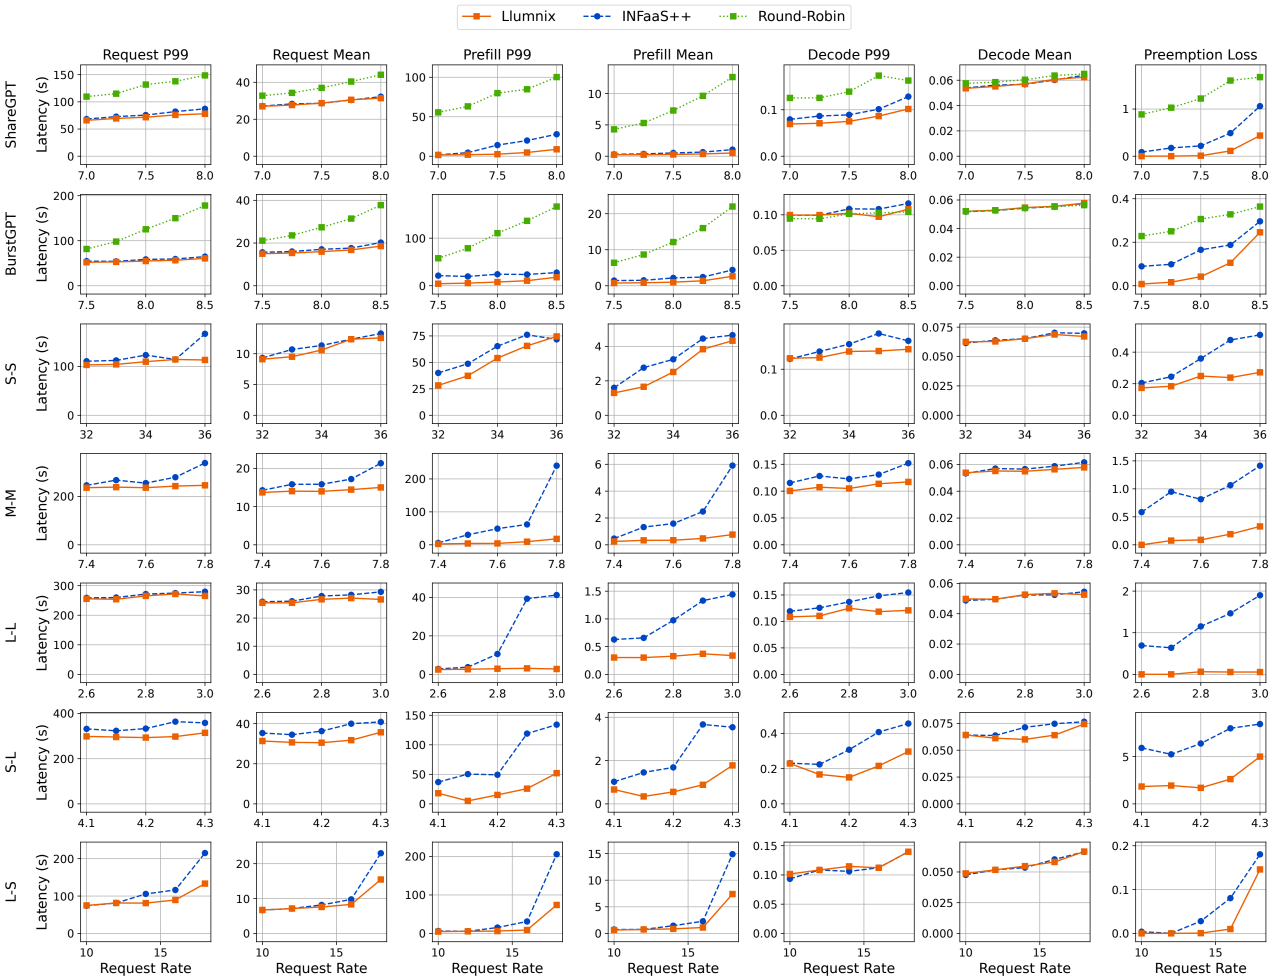

Figure 11: Request end-to-end, prefill, and decode latencies and preemption loss of serving 16 LLaMA-7B instances. Each row shows a set of experiments using a trace with a specific sequence length distribution, as annotated on the Y-axis labels.

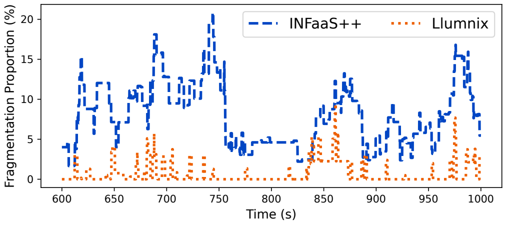

Figure 12: Memory fragmentation over time.

ing requests to instances with the lowest load, INFaaS++ can still exhibit long queuing delays due to fragmentation, especially for the long-tail requests with long inputs. Llumnix uses migration for de-fragmentation to reduce such queuing delays, showing more gains in traces with more long inputs.

To take a closer look at the memory fragmentation, we further present a case study on the experiment of the M-M trace with the request rate of 7.5. We define the fragmented memory at each moment as the portion of cluster free memory that could satisfy the demands of the head-of-line blocking requests across all instances, if no fragmentation. For example, if the total free memory is 8 GB, with three head-of-line blocking requests each requiring 3 GB, then the fragmented memory is counted as 6 GB, *i.e.*, this 6 GB memory could satisfy two queuing requests if no fragmentation. This metric suggests the memory space wasted due to fragmentation. We report the proportion of fragmented memory in the cluster total memory. In the example, if the total memory is 16 GB, then the proportion is 37.5% (6/16). Figure 12 shows the fragmentation proportion of the experiment during a busy period. We observe that INFaaS++ often shows higher than 10% fragmentation, wasting a significant amount of cluster memory. In comparison, the fragmentation is often 0 in Llumnix. The average values during this period are 0.7% and 7.9% for Llumnix and INFaaS++ respectively (92% reduction), highlighting the effect of de-fragmentation using migration.

Llumnix also improves the P99 decode latency by up to

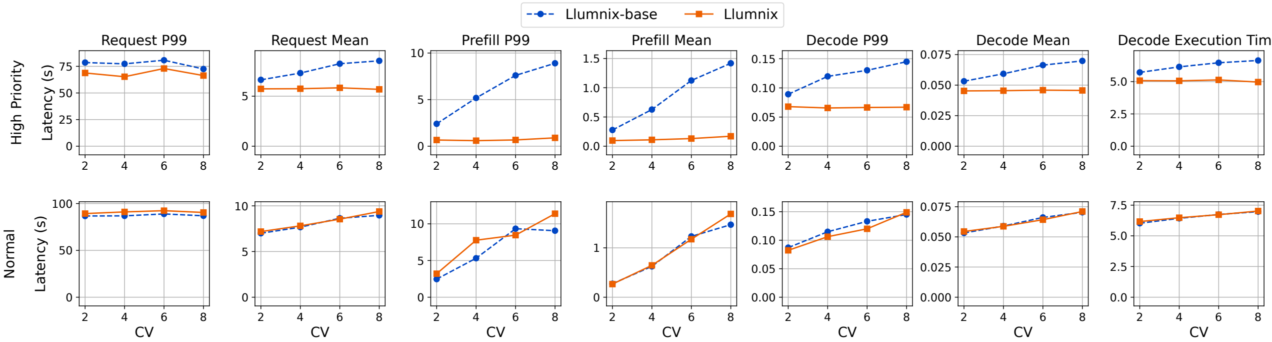

Figure 13: Performance of high-priority and normal requests, as annotated on the Y-axis labels.

2×, through migration to reduce preemptions. Although INFaaS++ already implements load balancing in dispatching to reduce preemptions, migration complements it by reacting to the real sequence lengths, which are unknown at request arrivals. As shown in Figure 11, Llumnix significantly reduces the preemption loss, in many cases down to near zero. The reduction is 70.4% on average across all experiments, which translates to an average reduction of 1.3 seconds in the end-to-end request latency.

6.4 Support for Priorities

We evaluate the support for priorities of Llumnix by randomly picking 10% of the requests and assigning high scheduling and execution priorities. We use traces with the Short-Short length distribution and Gamma arrival distribution. We vary the CV parameter to show the interference to high-priority requests due to bursty workloads and load spikes. We empirically choose a target memory load of 1,600 tokens for high-priority requests, as we observe that such load preserves near-ideal decode speed (refer to Figure 4). Llumnix translates this target load to the corresponding memory headroom for high-priority requests. We compare Llumnix with Llumnix-base, which simply treats all requests as the same priority.

As shown in the first row in Figure 13, Llumnix improves mean request latencies for the high-priority by 1.2× to 1.5× with increasing CVs. Higher CVs leads to more high-load periods, where high-priority requests can suffer more interference if not protected. Even with higher CVs, Llumnix still delivers similar latencies of high-priority requests, showing the isolation Llumnix provides to such requests. This is because Llumnix can handle changing high-priority loads by dynamically creating space for them, which is difficult in approaches like static resource reservation. For prefill latencies, Llumnix shows 2.9× to 8.6× gains for the mean, and 3.6× to 10× for the P99, respectively. This is achieved by reducing the queuing delays with high scheduling priorities. Llumnix also improves decode latencies by 1.2× to 1.5× for the mean and 1.3× to 2.2× for the P99, respectively. This improvement comes from the acceleration of the decode computation by giving lower instance loads and interference to high execution priorities, shown by the similar gains in the average decode computation time (the rightmost column). We also notice that Llumnix preserves similar performance of the normal requests (the second row in Figure 13): Llumnix increases the mean request, prefill, and decode latencies of normal requests by up to 4.5%, 13%, and 2%, respectively.

6.5 Auto-scaling

We evaluate the auto-scaling capability of Llumnix using larger ranges of request rates and Gamma CVs to show the adaptivity to load variation. By default, Llumnix uses a scaling threshold range of [10, 60], *i.e.*, Llumnix scales instances up or down when the average freeness is under 10 or above 60; recall that this metric represents the most decode steps an instance can still run for given the current batch. We let INFaaS++ use the same scaling strategy, thus both Llumnix and INFaaS++ have the same degree of aggressiveness of scaling up instances. We use a maximum instance number of 16 and the Long-Long sequence length distribution.

We first vary the request rates using Poisson distribution. As shown in the first row of Figure 14, Llumnix consistently achieves latency improvements across all request rates, *e.g.*, up to 12.2× for P99 prefill latency. We also measure the resource cost in terms of average instances used, shown in the rightmost column. Llumnix saves costs by up to 16%, because Llumnix increases the auto-scaling efficiency by saturating or draining out instances more quickly. We also test different workload burstiness with varying CVs of Gamma distribution (request rate = 2). As shown in the second row, Llumnix shows similar improvements in latencies and costs, *e.g.*, up to 11× for P99 prefill latency and 18% for the cost.

Finally, we examine the cost efficiency of Llumnix in terms of how aggressively Llumnix needs to scale out instances to preserve a certain latency objective, *e.g.*, a given P99 prefill latency. We vary the scaling up threshold *t*, and the scaling threshold range is determined as [*t*, *t*+50]. Higher values of *t* means that Llumnix tends to use more instances. Figure 15 shows the P99 prefill latencies and costs with different scaling

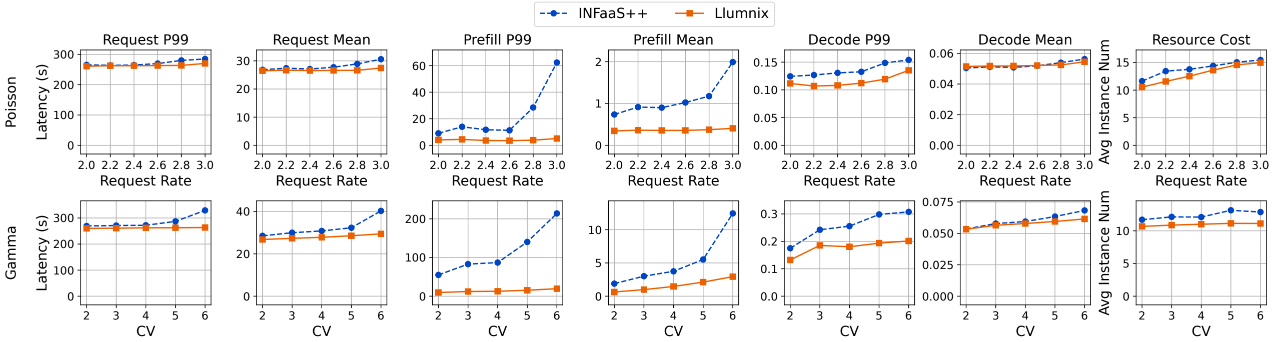

Figure 14: Auto-scaling of LLaMA-7B instances with Poisson and Gamma distributions, as annotated on the Y-axis labels.

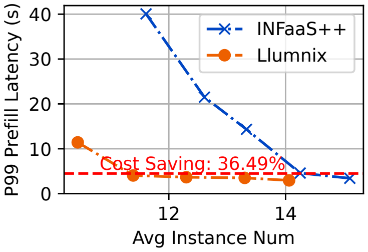

Figure 15: P99 prefill latencies vs. average numbers of instances with varying scaling thresholds.

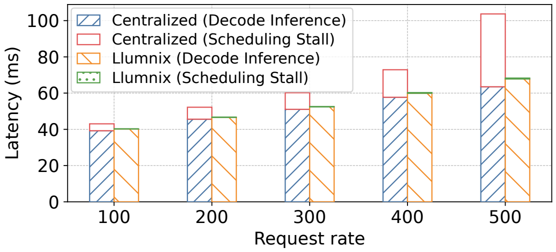

Figure 16: Per-token latencies and scheduling stalls under increasing request rates using 64 LLaMA-7B instances.

thresholds. We observe that Llumnix achieves similar P99 prefill latency (roughly 5s, the red dash line) while saving 36% of the cost compared to INFaaS++, as a result of the combination of the ability to reduce queuing delays via migration and the higher auto-scaling efficiency.

6.6 Scheduling Scalability

We conduct a scheduling stress test to examine the scalability of Llumnix with 64 LLaMA-7B instances using higher request rates. Since this cluster exceeds the size of our testbed, we replace the real GPU execution in vLLM with a simple `sleep` command, whose duration is determined by offline measurement on A10 GPUs with different sequence lengths and batch sizes. We build a simple centralized scheduler as the baseline by extending the vLLM scheduler to manage all requests across all instances. We issue requests with input and output lengths of 64 tokens with increasing request rates.

As shown in Figure 16, with increasing request rates, the baseline experiences scheduling stalls during the inference computation of up to 40ms per iteration, translating to 1.7× slowdown. Such stalls are a result of the communication between instances and the centralized scheduler synchronizing request statuses and scheduling decisions, which becomes a bottleneck under high load. By contrast, Llumnix exhibits near-zero scheduling stalls even under high request rates, showing the scalability of the distributed scheduling architecture. Llumnix offloads and distributes the intra-instance scheduling logic across llumlets so that it is done in parallel and asynchronously with the global scheduling. Moreover, llumlets only report instance-level metrics, instead of the precise status of every single request, further improving the communication efficiency.

7 Related Work

LLM inference. As transformer models show significance in model serving, recent works, such as FasterTransformer [46], TurboTransformer [25], LightSeq [61], and FlashAttention [21, 22], optimize GPU kernels to improve the inference performance. SpotServe [41] supports LLM inference using preemptible instances for improving cost efficiency. FastServe [63] optimizes request completion times using a preemptive time-slicing approach. AlpaServe [35] exploits pipeline parallelism to reduce serving latency for bursty workloads. To further increase the GPU utilization and serving throughput, Orca [67] proposes iteration-level scheduling (referred to as continuous batching in recent works and this paper) and selective batching, while vLLM [34] optimizes the memory usage with PageAttention. [55] proposes fair scheduling of requests on an LLM instance. Prior works mostly target solo-instance serving, therefore complementing to Llumnix. Llumnix explores the challenges and opportunities of deploying multi-instance LLM serving. The key append-only characteristic of KV cache is exploited to enable migration capability of requests in the inference engine. Such a mechanism opens great policy design space to offer priority and performance isolation, improve memory efficiency, and enable instance auto-scaling. We also plan to explore the interplay between the global scheduling across instances with local scheduling techniques inside each instance (*e.g.*, preemptive [63] and fair [55] scheduling) as future works.

Request scheduling. To support deep learning model deployment, numerous systems (*e.g.*, Clipper [19], Nexus [54], DVABatch [20], and TritonServer [47]) have been proposed to optimize request scheduling for DNN inference serving. To meet the SLOs of DNN inference requests, Clockwork [29] utilizes the execution predictability of traditional DNNs, while Reef [33] and Shepherd [68] perform preemptions to serve high-priority requests. AlpaServe [35] uses a simple load-balancing dispatching policy based on queue lengths. These works mostly focus on traditional DNN model serving, where a request requires only one-time inference on the model. However, LLM inference service requires autoregressive computation on models for unpredictable numbers of iterations and introduces intermediate states (*i.e.*, KV cache), showing brand new characteristics. DeepSpeed-MII [4], albeit targeting multi-instance LLM serving, uses a simple round-robin dispatching policy that ignores LLM characteristics. Llumnix steps further to incorporate request migration and ensures high throughput and low latency, provides SLO for prioritized requests, and auto-scales instances for resource efficiency with a unified load-aware dynamic scheduling policy.

Beyond multiple model instances, INFaaS [53] further supports scheduling across multiple model types/variants, considering the performance and accuracy requirements in difference applications. This is also a typical scenario for LLMs: for example, fine-tuned models for a specific task (*e.g.*, coding [3, 13, 30]); variants with different sizes or precisions ([26, 37, 39]) of the base LLM. We plan to extend Llumnix to support multiple model types in future work, considering the larger tradeoff space of latency/throughput and accuracy.

Isolation vs. fragmentation. The tradeoff between isolation and fragmentation, or that between workload packing and spreading, have been a classic scheduling challenge. That is, workload packing improves resource utilization, at the expense of potential interference between co-located workloads; spreading workloads, on the contrary, provides better isolation but also increases resource fragmentation. Many research efforts have been devoted to better balancing isolation and fragmentation in datacenters for big-data jobs and virtual machines, by identifying the interference-sensitivity of workloads and optimized scheduling policies ([16, 18, 23, 24, 27, 31, 32, 40, 60, 66]). This challenge was also identified in GPU clusters for deep learning workloads. Amaral et al proposed a topology-aware placement algorithm to address the tradeoff between packing and spreading deep learning training jobs on multi-GPU servers [12]. Gandiva [64] addresses the heterogeneous sensitivity to packing/spreading of different jobs with introspective job migration. This challenge becomes more complex for LLM serving due to the unpredictable autoregressive execution. Llumnix exploits request migration at runtime to react to the workload dynamics to better reconcile these two goals.

Migration. Gandiva [64] enables introspective migration for deep learning training jobs during scheduling. It utilizes the inherent iterative behavior of deep learning, and conducts checkpoint-resume approach on the minimal working set (*i.e.*, mini-batch boundary) to migrate model weights. Even though LLM inference is iterative as well, directly migrating the entire states of a request is unacceptable, because the latency SLO of an inference request is crucial. Moreover, the working set per request is linear to the sequence length, which can be considerable given the trend of longer contexts [49, 50]. The migration approach in Llumnix is inspired by virtual machine live migration [17]. By carrying out the majority of migration while LLM requests continue decoding tokens on GPUs, Llumnix minimizes the downtime of request migration, making the cost negligible regardless of the sequence lengths.

8 Conclusion

Llumnix, as implied by the name, represents our vision of serving LLMs as Unix. This vision originates in the observation that LLMs and modern operating systems have common natures such as the universality, multi-tenancy, and dynamism, and hence share similar requirements and challenges. This paper takes an important step towards this vision by drawing lessons from conventional OS wisdom including: definition of classic abstractions like isolation and priorities in the new context of LLM serving; implementation of the “context switching” as the key approach with inference request migration; and continuous, dynamic request rescheduling exploiting the migration. All these combined, Llumnix delivers better latency, cost efficiency, and support for differentiated SLOs, pointing to a new way of LLM serving.

A Artifact Appendix

Abstract

This artifact includes the source code and scripts to run the experiments and reproduce the evaluation results of this paper.

Scope

The artifact can be used to reproduce the results of the following experiments.

- Migration efficiency: Figure 10.
- Serving performance: Figure 11.
- Support for priorities: Figure 13.
- Auto-scaling: Figure 14 and Figure 15.

Contents

This artifact includes the following contents.

- Source code of a prototype implementation of Llumnix.
- Scripts to prepare the environment, run the experiments, plot the figures, and validate the claims in this paper automatically.
- A `README` file including detailed instructions on how to use this artifact.

Hosting

The artifact is publicly available at `https://github.com/AlibabaPAI/llumnix` (the `osdi24ae` branch). Note that this is not the same branch as the official release of Llumnix (the `main` branch). We will describe their difference later.

Requirements

The artifact runs on GPU machines, with software dependencies mostly the same as those of vLLM. To reproduce our results, you would need 4 GPU machines each with 4 A10 GPUs (24 GB). We recommend that you use the same VM type as in our experiments (`ecs.gn7i-c32g1.32xlarge` on Alibaba Cloud).

Difference from the Official Release

This artifact is a research prototype and was used during the experiments of this paper. After the paper submission, we refactored it into a new implementation that is more production-ready, *i.e.*, the official release, as described in §5. Major differences between the two versions include:

- The artifact is directly based on the vLLM code base, whereas the official release is a standalone Python library, making it more extensible and non-intrusive to backend inference engines.
- The artifact is not fault-tolerant, whereas the official release provides fault tolerance for each component.
- The official release is still being actively developed, and has supported or will support a series of new features, such as scalable API servicing via distributed request frontends, support for newer versions of vLLM and more models, further improvements of the scheduling policies, *etc*.

The artifact is sufficient to reproduce the experiment results in this paper. However, if you want to use Llumnix in production or conduct further research, we do recommend the official release.

DistServe: Disaggregating Prefill and Decoding for Goodput-optimized Large Language Model Serving

Abstract

DistServe improves the performance of large language models (LLMs) serving by disaggregating the prefill and decoding computation. Existing LLM serving systems colocate the two phases and batch the computation of prefill and decoding across all users and requests. We find that this strategy not only leads to strong prefill-decoding interferences but also couples the resource allocation and parallelism plans for both phases. LLM applications often emphasize individual latency for each phase: time to first token (TTFT) for the prefill phase and time per output token (TPOT) of each request for the decoding phase. In the presence of stringent latency requirements, existing systems have to prioritize one latency over the other, or over-provision compute resources to meet both.

DistServe assigns prefill and decoding computation to different GPUs, hence eliminating prefill-decoding interferences. Given the application's TTFT and TPOT requirements, DistServe co-optimizes the resource allocation and parallelism strategy *tailored* for each phase. DistServe also places the two phases according to the serving cluster's bandwidth to minimize the communication caused by disaggregation. As a result, DistServe significantly improves LLM serving performance in terms of the maximum rate that can be served within both TTFT and TPOT constraints on each GPU. Our evaluations show that on various popular LLMs, applications, and latency requirements, DistServe can serve 7.4× more requests or 12.6× tighter SLO, compared to state-of-the-art systems, while staying within latency constraints for $> 90\%$ of requests.

1 Introduction

Large language models (LLMs), such as GPT-4 [37], Bard [2], and LLaMA [51], represent a groundbreaking shift in generative AI. They start to reshape existing Internet services, ranging from search engines to personal assistants [4], and enable fundamentally new applications, like universal chatbots [1, 16] and programming assistants [15, 42]. Yet, these advances come with a significant challenge: processing an end-to-end LLM query can be substantially slower than a standard search query [41]. In order to meet the stringent latency requirements of various applications, service providers need to over-provision compute resources, particularly many GPUs, leading to a shortfall in cost efficiency. Therefore, optimizing the cost per LLM query while adhering to high *SLO attainment* (the proportion of requests that meet the SLOs) is becoming increasingly essential for all LLM services.

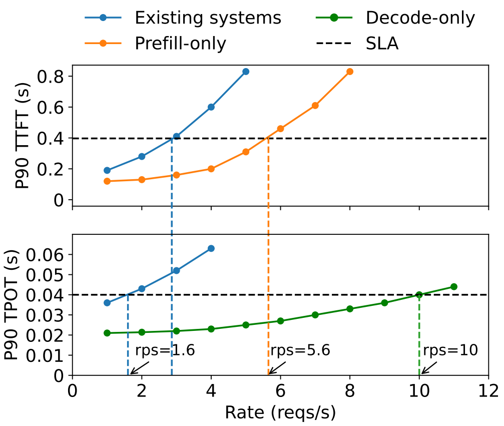

Figure 1: Performance when serving an LLM with 13B parameters under a synthetic workload with input length = 512 and output length = 64 on one NVIDIA 80GB A100. *Upper*: The P90 time-to-first-token (TTFT) latency comparing existing systems vs. a system serving only the prefill phase. *Down*: The P90 time-per-output-token (TPOT) latency comparing existing systems vs. a system serving only the decoding phase.

An LLM service responds to a user query in two phases. The *prefill phase* processes a user's prompt, composed of a sequence of tokens, to generate the first token of the response *in one step*. Following it, the *decoding phase* sequentially generates subsequent tokens *in multiple steps*; each decoding step generates a new token based on tokens generated in previous steps, until reaching a termination token. This dual-phase process distinguishes LLM services from traditional services – an LLM service's latency is uniquely measured by two key metrics: the *time to first token* (TTFT), which is the duration of the prefill phase, and the *time per output* *token* (TPOT), which represents the average time taken to generate a token for each request (except for the first token)[1]. Different applications place varying demands on each metric. For example, real-time chatbots [1] prioritize low TTFT for response promptness, while TPOT only remains important until it is faster than human reading speed (i.e., 250 words/min). Conversely, document summarization emphasizes low TPOT for faster generation of the summary.

Hence, given the application's TTFT and TPOT requirements, an effective LLM serving system should balance these needs and maximize *per-GPU goodput*, defined as the maximum request rate that can be served adhering to the SLO attainment goal (say, 90%) for each GPU provisioned – higher per-GPU goodput directly translates into lower cost per query.

As the prefill and decoding phases share the LLM weights and working memory, existing LLM serving systems typically colocate both phases on GPUs and maximize the overall system throughput – tokens generated per second across all users and requests – by batching the prefill and decoding steps across requests [31, 54]. However, to meet latency requirements, we find these systems must over-provision compute resources. To see this, Figure 1 illustrates how the P90 TTFT and TPOT shift with increasing request rates when serving a 13B LLM using existing systems [32], with workload pattern and two latency constraints set to emulate using LLM to generate a short summary for an article. Under the SLO attainment of 90%, the maximum achievable goodput on a single A100 GPU, which is constrained by the more stringent one of TTFT and TPOT requirements, is about 1.6 requests per second (rps). The performance contrasts sharply when each phase is served independently on a separate GPU, shown by the orange and green curves, which achieve per-GPU goodput of 5.6 rps for the prefill phase and 10 rps for decoding. Ideally, by allocating 2 GPUs for prefill and 1 GPU for decoding, we can effectively serve the model with an overall goodput of 10 rps, or equally 3.3 rps per GPU, which is 2.1x higher than existing systems. The gap in goodput primarily stems from the colocation of the prefill and decoding – two phases with very distinct computational characteristics and latency requirements (§2.1).

First, colocation leads to strong *prefill-decoding interference*. A prefill step often takes much longer than a decoding step. When batched together, decoding steps in the batch are delayed by the prefill steps, significantly elongating their TPOT; similarly, the inclusion of decoding steps contributes to a non-trivial increase in TTFT, as evidenced in Figure 2. Even if we schedule them separately, issues persist as they begin to compete for resources. Decoding tasks awaiting GPU execution are subject to increased queuing delays due to ongoing prefill tasks, and vice versa. Prioritized scheduling of one phase risks failing the latency requirements of the other.

Second, the prefill and decoding computation differ in latency requirements and preference for different forms of parallelism (§3). Colocating prefill and decoding, however, couples their resource allocation, and prevents implementing different parallelism strategies more suited to meeting the specific latency requirements of each phase.

To overcome these challenges, we propose to disaggregate the prefill and decoding phases of LLM inference, assigning them to separate GPUs. Our approach has two benefits. First, operating each phase independently on different GPUs eliminates prefill-decoding interference. Second, it allows to scale each phase independently with tailored resource allocation and model parallelism strategies to meet their specific latency requirements. Although disaggregation causes communication of intermediate states between GPUs, we show that the communication overhead is insubstantial (§3.3) in modern GPU clusters, and when managed appropriately, disaggregation significantly improves per-GPU goodput.

Based on the above insights, in this work, we build DistServe[2], a goodput-optimized LLM serving system by disaggregating the prefill and decoding phases. Given TTFT and TPOT requirements, DistServe first scales each phase independently by co-optimizing the GPU allocation and parallelism strategies of the prefill and decoding phase assuming serving a single model replica. The optimization ensures maximizing the per-GPU goodput and may assign different numbers of GPUs and parallelism strategies to each phase depending on their respective latency requirements. DistServe then scales this allocation to multiple instances via replication until meeting the user-required traffic rate (§4). DistServe also features an algorithm to place the prefill and decoding computation according to their allocation schemes and the cluster's bandwidth to minimize the overhead of communicating intermediate states between phases.

We implement DistServe as an orchestration layer on top of the LLM inference engine. We evaluate DistServe on various LLMs, varying the workloads based on three important real-world LLM applications: chatbots, programming assistant, and document summary. Compared to state-of-the-art solutions, DistServe can serve up to 7.4× more requests or 12.6× tighter SLO under various latency constraints. Our contributions are:

- Identify the problems of prefill-decoding interference and resource coupling in existing LLM serving systems and propose to disaggregate the two phases.
- Design a novel placement algorithm to choose the goodput-optimal schema for prefill and decoding instances automatically.
- Conduct a comprehensive evaluation of DistServe with realistic workloads.

2 Background and Motivation

An LLM service follows a client-server architecture: the client submits a sequence of text as a request to the server; the server

[1] The overall request latency equals TTFT plus TPOT times the number of generated tokens in the decoding phase.

[2] https://github.com/LLMServe/DistServe

hosts the LLM on GPUs, runs inference over the request, and responds (or streams) the generation back to the client. As explained in §1, due to the unique prefill-decoding process, LLM service may impose aggressive service-level objectives (SLOs) on both TTFT and TPOT, varying with the application's needs. The serving system must meet both SLOs while minimizing the cost associated with expensive GPUs. In other words, we want the serving system to maximize the requests served per second adhering to the SLO attainment goal for each GPU provisioned – *maximizing per-GPU goodput*. Next, we detail the LLM inference computation (§2.1) and discuss existing optimizations for LLM serving (§2.2).

2.1 LLM Inference

Modern LLMs [37, 51] predict the next token given an input sequence. This prediction involves computing a hidden representation for each token within the sequence. An LLM can take a variable number of input tokens and compute their hidden representations in parallel, and its computation workload increases superlinearly with the number of tokens processed in parallel. Regardless of the input token count, the computation demands substantial I/O to move LLM weights and intermediate states from the GPU's HBM to SRAM. This process is consistent across varying input sizes.

The prefill step deals with a new sequence, often comprising many tokens, and processes these tokens concurrently. Unlike prefill, each decoding step only processes one new token generated by the previous step. This leads to significant computational differences between the two phases. When dealing with user prompts that are not brief, the prefill step tends to be compute-bound. For instance, for a 13B LLM, computing the prefill of a 512-token sequence makes an A100 near compute-bound (see §3.1). In contrast, despite processing only one new token per step, the decoding phase incurs a similar level of I/O to the prefill phase, making it constrained by the GPU's memory bandwidth.

During both phases, intermediate states, known as KV caches [32], are generated at each token position, which are needed again in later decoding steps. To avoid recomputing them, they are saved in GPU memory. Because of the shared use of LLM weights and KV caches in memory, most LLM inference engines opt to colocate the prefill and decoding phases on GPUs, despite their distinct computational characteristics.

2.2 LLM Serving Optimization

In real-time online serving, multiple requests come and must be served within SLOs. Batching and parallelizing their computation is key for achieving low latency, high throughput, and high utilization of GPUs.

Batching. Current serving systems [9, 32, 54] utilize a batching technique known as *continuous batching*. This method batches the prefill of new requests with the decoding of ongoing ones. It boosts the GPU utilization and maximizes the overall system throughput – tokens generated per second across all users and requests. However, as mentioned in §1 and elaborated later in §2.3, this approach leads to trade-offs between TTFT and TPOT. An advanced variant of continuous batching [9] attempts to balance TTFT and TPOT by segmenting long prefill into chunks and attaching decoding jobs with a chunked prefill – but essentially, it trades TTFT for TPOT and cannot eliminate the interference (§2.3). In summary, batching prefill and decoding invariably leads to compromises in either TTFT or TPOT.

Model parallelism. In LLM serving, model parallelism is generally divided as intra- and inter-operator parallelisms [33, 46, 59]. Both can be used to support larger models but may impact serving performance differently. Intra-operator parallelism partitions computationally intensive operators, such as matrix multiplications, across multiple GPUs, accelerating computation but causing substantial communication. It reduces the execution time[3], hence latency, particularly for TTFT of the prefill phase, but requires high bandwidth connectivity between GPUs (e.g., NVLINK). Inter-operator parallelism organizes LLM layers into stages, each running on a GPU to form pipelines. It moderately increases execution time due to inter-stage communication, but linearly scales the system's rate capacity with each added GPU. In this paper, we reveal an additional benefit of model parallelism: reduced queuing delay of both prefill and decoding phases, steaming from shorter execution time. We delve into this further in §3. Besides model parallelism, replicating a model instance, irrespective of its model parallelism configurations, linearly scales the system's rate capacity.

These parallelism strategies create a complex space of optimization that requires careful trade-offs based on the application's latency requirements.

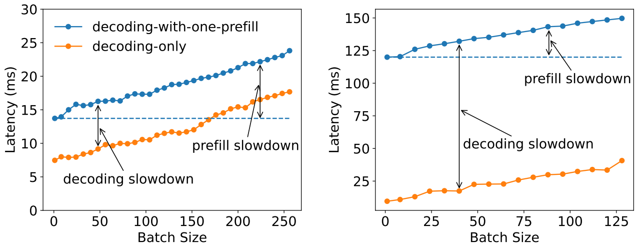
2.3 Problems and Opportunities

Colocating and batching the prefill and decoding computation to maximize the overall system throughput, as in existing systems, is cost-effective for service providers. However, in the presence of SLOs, present approaches struggle to maintain both high service quality and low cost due to the issues discussed below.

Prefill-decoding interference. As Figure 2 shows, adding a single prefill job to a batch of decoding requests significantly slows down both processes, leading to a marked increase in TTFT and TPOT. Specifically, the decoding tasks in the batch must wait for lengthier prefill jobs to complete, thus extending TPOT; the slowdown intensifies with a longer prefill, shown in Figure 2(b). Adding decoding jobs to prefill also increases the time to complete the prefill task, particularly when the GPU is already at capacity (Figure 2 blue curves).

One attempt to mitigate this interference is called *chunked-prefill with piggyback* [3, 9]. It proposes to split the long prefill

[3] we emphasize "execution time" instead of latency here because latency comprises both execution time and queuing delay.



(a) Input length = 128

(b) Input length = 1024

Figure 2: Batch execution time when serving a 13B LLM as batch size increases. Compared between a decoding-only batch and the batch adding one more prefill job.

into chunks and batch a prefill chunk with a few decoding jobs (a.k.a. piggybacking). This technique alleviates the slowdown of the decoding job caused by the long prefill job, but it does not eliminate it. Additionally, it results in an extra overhead for the prefill job which cannot be easily mitigated by adjusting the chunk size. First, if the chunk size is set much lower than the inflection point that can saturate the GPU, then the prefill job will have a longer execution time since it competes with the decoding job in the same batch and cannot solely utilize the GPU resources. Second, if we increase the chunk size to nearly saturate the GPU, the chance of piggybacking will diminish since the remaining slots for decode tokens are limited. Also, chunked-prefill causes significantly more memory access for the prefill jobs. This is because the KV cache of all previous chunks have to be loaded from HBM to SRAM repeatedly to compute each subsequent chunk. Concretely, if a prefill job is split into N equal chunks, we need to load $N+(N-1)+...+1 = O(N^2)$ chunks of KV Cache in total, compared to O(N) in the non-chunked case. This overhead will increase as the context length becomes longer.

Ineffective scheduling. Unbatching prefill and decoding jobs and scheduling them sequentially does not mitigate the interference. Decoding jobs may experience longer queuing delays due to waiting for ongoing prefill jobs on GPUs. Moreover, batches dedicated to decoding often lead to GPU underutilization. Prioritizing tasks in either phase adversely affects the latency of the other, rendering priority scheduling ineffective.

Resource and parallelism coupling. Colocating prefill and decoding phases on the same GPUs unavoidably share their resource and parallelism settings. However, each phase has its unique computational characteristic and latency requirement that calls for more heterogeneous resource allocation. For example, the prefill phase tends to be compute-bound and benefits from more intra-op parallelism to reduce execution time to meet the tight SLO on TTFT. By contrast, the optimal parallelism configuration of the decoding phase depends on the running batch size. In existing systems, due to coupling, resource allocation and parallelism plans are tailored to satisfy the *more demanding* of TTFT and TPOT, which may not be ideal for the other. This often leads to resource over-provisioning to meet both SLOs.

Opportunities. To address these issues, we propose to disaggregate the prefill and decoding phases. We use the term *instance* to denote a unit of resources that manages exactly one complete copy of model weights. One instance can correspond to many GPUs when model parallelism is applied. Note that when we disaggregate the two phases to different GPUs, each phase manages its copy of the model weights, resulting in *prefill instances* and *decoding instances*. A prefill instance, upon receiving a request, performs only the prefill computation for this request to generate the first output token. It then sends the intermediate results (mainly KV caches) to a decoding instance, which is responsible for subsequent decoding steps. Because decoding computation often has low GPU utilization, we may allocate multiple prefill instances per decoding instance. This allows batching more decoding jobs to achieve higher GPU utilization.

Disaggregating prefill and decoding naturally resolves the interference between the two phases and enables each to focus on its optimization target – TTFT or TPOT. Each type of instance can employ different resources and parallelism strategies to meet a variety of latency requirements. By adjusting the number of GPUs and parallelisms provided to the two types of instances, we can maximize the per-device goodput of the overall system, avoiding over-provisioning, eventually translating to reduced cost-per-query adhering to service quality. Next, we develop ways to find out the best resource allocation and parallelism plan for each phase.

3 Tradeoff Analysis

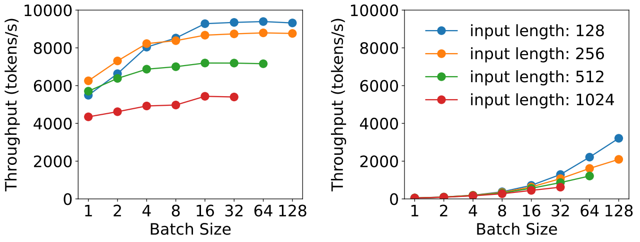
Disaggregation uncouples the two phases and allows a distinct analysis of the characteristics of each phase, providing valuable insights into the algorithm design. It also expands the design space: now each phase needs to be scaled and scheduled independently based on their latency requirements.

In this section, we analyze the computational pattern of prefill (§3.1) and decoding instances (§3.2) *post disaggregation*. We aim to identify key parameters and derive guidelines for batching and parallelism in each phase. We then highlight several practical deployment considerations (§3.3). This section lays the foundation for per-gpu goodput optimization.

3.1 Analysis for Prefill Instance

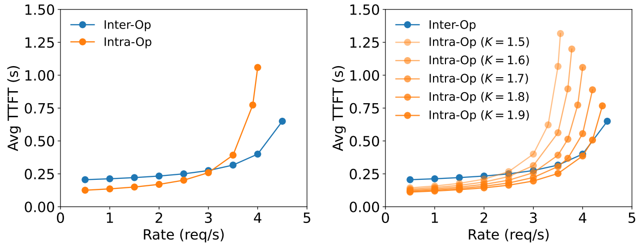
After disaggregation, the prefill phase generates the first token by processing all tokens of the user prompt in parallel. Assuming a given arrival rate, we aim to fulfill the service's latency requirement on TTFT using the least resources.

Batching strategy. The prefill step is typically compute-intensive. Figure 3(a) shows how the throughput of the prefill phase changes with the input length and the batch size. For a 13B parameter LLM, processing a single sequence of 512 tokens can fully engage an A100 GPU. Once the GPU becomes compute-bound, adding more requests to the batch no longer improves GPU efficiency. Instead, it proportionally extends the total processing time for the batch, inadvertently



(a) Prefill phase (b) Decoding phase

Figure 3: Throughput for two phases with different batch sizes and input lengths when serving an LLM with 13B parameters.



(a) Real experiment results (b) Changing intra-op speedup

Figure 4: Average TTFT when serving an LLM with 66B parameters using different parallelism on two A100 GPUs.

delaying all included requests. Hence, for prefill instances, it is necessary to profile the specific LLM and GPUs in advance to identify a critical input length threshold, denoted as L_m, beyond which the prefill phase becomes compute-bound. Batching more requests should only be considered when the input length of the scheduled request is below L_m. In practice, user prompts typically average over hundreds of tokens [8]. Batch sizes for the prefill instance are generally kept small.

Parallelism plan. To study the parallelism preferences for prefill-only instances, we serve a 66B LLM on two A100 GPUs with inter-op or intra-op parallelism strategy. To simplify the problem, we assume uniform requests input lengths of 512 tokens and a Poisson arrival process. We compare the resulting average TTFT at various arrival rates in Figure 4(a): intra-op parallelism is more efficient at lower arrival rates, while inter-op parallelism gains superiority as the rate increases. Disaggregation enables the prefill phase to function analogously to an M/D/1 queue, so we can use queuing theory to verify the observation.

We start by developing notations using the single-device case without parallelism: each request's execution time, denoted as D, remains constant due to uniform prefill length. Since one request saturates the GPU, we schedule requests via First-Come-First-Served (FCFS) without batching. Suppose the Poisson arrival rate is R and the utilization condition of $RD < 1$, the average TTFT (Avg_TTFT) can be modeled by the M/D/1 queue [47] in close form:

$$Avg\_TTFT = D + \frac{RD^2}{2(1-RD)}. \tag{1}$$

where the first term represents the execution time and the second corresponds to the queuing delay. Based on Eq. 1, we incorporate parallelism below.

With 2-way inter-op parallelism, we assume the request-level latency becomes D_s, and the slowest stage takes D_m to finish. We have $D \approx D_s \approx 2 \times D_m$, due to negligible inter-layer activation communication [33, 59]. The average TTFT with 2-way inter-op parallelism is derived as:

$$Avg\_TTFT_{inter} = D_s + \frac{RD_m^2}{2(1-RD_m)} = D + \frac{RD^2}{4(2-RD)}. \tag{2}$$

For intra-op parallelism, we introduce a speedup coefficient K, where $1 < K < 2$, reflecting the imperfect speedup caused by high communication overheads of intra-op parallelism. With the execution time $D_s = \frac{D}{K}$, the average TTFT for 2-degree intra-op parallelism is:

$$Avg\_TTFT_{intra} = \frac{D}{K} + \frac{RD^2}{2K(K-RD)}. \tag{3}$$

Comparing Eq. 2 and Eq. 3: at lower rates, where execution time (first term) is the primary factor, intra-op parallelism's reduction in execution time makes it more efficient. As the rate increases and the queuing delay (second term) becomes more significant, inter-op parallelism becomes advantageous, concurred with Figure 4(a).

The prefill phase's preference for parallelism is also influenced by TTFT SLO and the speedup coefficient K. Seen from Figure 4(a): A more stringent SLO will make intra-op parallelism more advantageous, due to its ability to reduce execution time. The value of K depends on factors such as the input length, model architecture, communication bandwidth, and placement [46, 59]. As shown in Figure 4(b), a decrease in K notably reduces the efficacy of intra-op parallelism. §4 develops algorithms that optimize the resource and parallelism configurations taking into consideration these knobs.

3.2 Analysis for Decoding Instance

Unlike the prefill instance, a decoding instance follows a distinct computational pattern: it receives the KV caches and the first output token from the prefill instance and generates subsequent tokens one at a time. For decoding instances, our optimization goal is to satisfy the application's TPOT requirement using minimal computing resources.

Batching strategy. Since a single decoding job is heavily bandwidth-bound, batching is key to avoiding low GPU utilization (hence high per-gpu goodput), as shown in Figure 3(b). In existing systems where the prefill and decoding phases are colocated, increasing the decoding batch size is difficult because it conflicts with meeting latency goals, particularly in scenarios with high request rates. This is because sharing GPUs cause competition between prefill and decoding jobs, leading to a trade-off between TTFT and TPOT. For

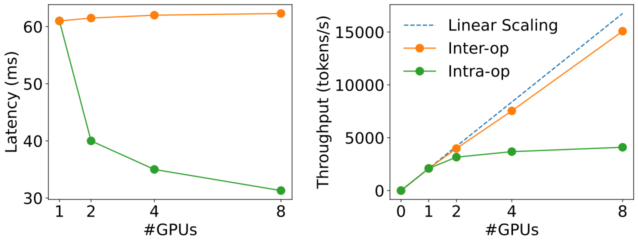


Figure 5: Decoding phase latency and throughput when serving a 13B LLM with batch size = 128 and input length = 256 under different parallel degrees.

example, a higher arrival rate generates more prefill jobs, demanding greater GPU time to meet TTFT requirements if prioritizing prefill jobs, which in turn adversely affects TPOT.

On the contrary, disaggregation offers a solution by enabling the allocation of multiple prefill instances to a single decoding instance. This approach allows for accumulating a larger batch size on dedicated GPUs for the decoding phase without sacrificing TPOT.

Parallelism plan. Post-disaggregation, the batch size for decoding may be constrained by GPU memory capacity, as it is necessary to maintain the KV caches for all active requests. Scaling the decoding instance with model parallelism or leveraging advanced memory management techniques for LLM KV caches, such as Paged-Attention [32] and GQA [10], enable further scaling of the decoding batch size to nearly compute-bound. As the decoding batch size continue to increase to approach the compute-bound, the decoding computation begins to resemble the prefill phase. With this observation, we investigate how the latency and throughput change under different parallelism degrees under large batch conditions in Figure 5: intra-op parallelism reduces latency with diminishing returns, caused by communication and reduced utilization after partitioning. Inter-op parallelism can almost linearly scale the throughput. Hence, when the TPOT SLO is stringent, intra-op parallelism is essential to reduce TPOT to meet latency goals. Beyond this, inter-op parallelism is preferable to enhance throughput linearly.

It is worth noting that when the model can fit into the memory of a single GPU, replication is a competitive option in addition to model parallelism for both prefill and decoding instances, to linearly scale the system's rate capacity. It may also reduce the queuing delay – as indicated by Eq. 1 – by substituting R with R/N assuming requests are equally dispatched to N replicas, at the cost of maintaining additional replicas of the model weights in GPU memory.

3.3 Practical Problems

We have developed foundational principles for selecting batching and parallelisms for each phase. In this section, we discuss and address several challenges encountered during the practical deployment of disaggregated prefill and decoding phases.

Variable prefill length. §3 has assumed uniform prompt length across requests. In real deployments, depending on the LLM application, the lengths of requests are non-uniform. The non-uniformity can cause pipeline bubbles [28, 36] for prefill instances applying inter-op parallelism because the execution time of pipeline stages across requests of different lengths will vary. This results in slight deviations from the conclusions indicated by using the M/D/1 queue model. To address the problem, §4 develops algorithms that search for parallelisms based on workloads, and resort to scheduling to minimize the bubbles (§4.3).

Communication overhead. Transferring KV caches from prefill to decoding instances incurs notable overheads. For example, the KV cache size of a single 512-token request on OPT-66B is approximately 1.13GB. Assuming an average arrival rate of 10 rps, we need to transfer 11.3GB data per second—or equivalently 90Gbps bandwidth to render the overhead invisible. While many modern GPU clusters for LLMs are equipped with InfiniBand (e.g., 800 Gbps), in cases where cross-node bandwidth is limited, DistServe relies on the commonly available intra-node NVLINK, where the peak bandwidth between A100 GPUs is 600 GB/s, again rendering the transmission overhead negligible (see §6.3). However, this requirement imposes additional constraints on the placement of prefill and decoding instances that we take into consideration in the next section.

Through the analysis in this section, we identify the workload pattern, placement constraints, SLO requirements, parallelism strategies, and resource allocation as key parameters that create a web of considerations in designing the disaggregated serving system. How to automatically navigate the search space to find the configuration that achieves optimal per-gpu goodput is challenging, and addressed next.

4 Method

We built DistServe to solve the above challenges. Given the model, workload characteristic, latency requirements, and SLO attainment target, DistServe will determine (a) the parallelism strategies for prefill and decoding instances, (b) the number of each instance type to deploy, as well as (c) how to place them onto the physical cluster. We call the solution a *placement*. Our goal is to find a placement that maximizes the per-gpu goodput.

As explained in §3.3, a key design consideration is to manage communications between disaggregated prefill and decoding phases, given varying cluster setups. In this section, we first present two placement algorithms: one for clusters with high-speed cross-node networks (§4.1) and the other for environments lacking such infrastructure (§4.2); the latter introduces additional constraints. We then develop online scheduling optimizations that adapt to the nuances of real-world workloads (§4.3).

Algorithm 1 High Node-Affinity Placement Algorithm

  for $intra\_op \in \{1, 2, ..., M\}$ do
      for $inter\_op \in \{1, 2, ..., \frac{N \times M}{intra\_op}\}$ do
          if $\frac{G.size}{inter\_op \times intra\_op} < C$ then
              $config \leftarrow (inter\_op, intra\_op)$
              $\hat{G} \leftarrow$ parallel$(G, config)$
              $config.goodput \leftarrow$ simu_prefill$(\hat{G}, W)$
              if $\frac{config_p.goodput}{config_p.num\_gpus} < \frac{config.goodput}{config.num\_gpus}$ then
                  $config_p \leftarrow config$
              $config.goodput \leftarrow$ simu_decode$(\hat{G}, W)$
              if $\frac{config_d.goodput}{config_d.num\_gpus} < \frac{config.goodput}{config.num\_gpus}$ then
                  $config_d \leftarrow config$
  $n, m \leftarrow \lceil \frac{R}{config_p.goodput} \rceil, \lceil \frac{R}{config_d.goodput} \rceil$
  $best\_plm \leftarrow (n, config_p, m, config_d)$
  return $best\_plm$
```

Algorithm 2 Low Node-Affinity Placement Algorithm

```
Input: LLM $G$, #node limit per-instance $N$, #GPU per-node $M$, GPU memory capacity $C$, workload $W$, traffic rate $R$.
Output: the placement $best\_plm$.
  $config^* \leftarrow \emptyset$
  for $inter\_op \in \{1, 2, ..., N\}$ do
      $\mathcal{P} \leftarrow$ get_intra_node_configs$(G, M, C, inter\_op)$
      for $P_p \in \mathcal{P}$ do
          for $P_d \in \mathcal{P}$ do
              if $P_p.num\_gpus + P_d.num\_gpus \leq M$ then
                  $config \leftarrow (inter\_op, P_p, P_d)$
                  $\hat{G}_p, \hat{G}_d \leftarrow$ parallel$(G, config)$
                  $config.goodput \leftarrow$ simulate$(\hat{G}_p, \hat{G}_d, W)$
                  if $\frac{config.^*goodput}{config.^*num\_gpus} < \frac{config.goodput}{config.num\_gpus}$ then
                      $config^* \leftarrow config$
  $n \leftarrow \lceil \frac{R}{config.^*goodput} \rceil$
  $best\_plm \leftarrow (n, config^*)$
  return $best\_plm$
```

4.1 Placement for High Node-Affinity Cluster

On high node-affinity clusters equipped with Infiniband, KV caches transmission overhead across nodes is negligible, DistServe can deploy prefill and decoding instances across any two nodes without constraints. We propose a two-level placement algorithm for such scenarios: we first optimize the parallelism configurations for prefill and decoding instances separately to attain phase-level optimal per-gpu goodput; then, we use replication to match the overall traffic rate.

However, finding the optimal parallel configuration for a single instance type, such as for the prefill instance, is still challenging, due to the lack of a simple analytical formula to calculate the SLO attainment (a.k.a., percentage of requests that meet TTFT requirement), given that the workload has diverse input, output lengths, and irregular arrival patterns. Gauging the SLO via real-testbed profiling is time-prohibitive. We thus resort to building a simulator to estimate the SLO attainment, assuming prior knowledge of the workload's arrival process and input and output length distributions. Although short-term interval is impossible to predict, the workload pattern over longer timescales (e.g., hours or days) is often predictable [33, 55]. DistServe fits a distribution from the history request traces and resamples new traces from the distribution as the input workload to the simulator to compute the SLO attainment. Next, DistServe simply enumerates the placements and finds the maximum rate that meets the SLO attainment target with binary search and simulation trials.

Algorithm 1 outlines the process. We enumerate all feasible parallel configurations, subject to cluster capacity limit, for both prefill and decoding instances. Then, for a specific prefill phase configuration, we use `simu_prefill` to simulate and find its maximum goodput via binary search (similarly for using `simu_decode` for decoding). After determining the optimal parallel configurations for both prefill and decoding instances, we replicate them to achieve the user-required overall traffic rate according to their goodput.

The complexity of Algorithm 1 is $O(NM^2)$, with N as the node limit per instance and M representing the typical number of GPUs per node in modern clusters (e.g., 8). The search space is manageable and the solving time is under 1.3 minutes in our largest setting, as demonstrated in §6.5.

Simulator building. Algorithm 1 relies on a simulator to estimate the goodput under various SLOs and SLO attainment goals given the workload and the parallelism plan. To build an accurate simulator, we analyze the FLOPs and the number of memory accesses for prefill and decoding phases respectively, and use a latency model to approximate the inference execution time. See details in Appendix A. The simulator aligns well with real profiling results, thanks to the high predictability of DNN workloads [23, 33], verified in §6.4.

By far, we have developed Algorithm 1 assuming we can place the prefill and decoding instance between any two nodes (or on the same node) of the cluster, and the KV cache transmission utilizes high bandwidth network. In many real clusters, GPUs inside a node access to high-bandwidth NVLINK while GPUs distributed across nodes have limited bandwidth. We next develop an algorithm to address this constraint.

4.2 Placement for Low Node-Affinity Cluster

A straightforward solution is to always colocate prefill and decoding instances on the same node, utilizing the NVLINK, which is commonly available inside a GPU node. For large models, e.g. with 175B parameters (350GB), we may be unable to even host a single pair of prefill and decoding instances in an 8-GPU node ($80G \times 8 = 640G < 350 \times 2GB$). We incorporate this as additional placement constraints and co-optimize it with model parallelism, presented in Algorithm 2.

The key insight is that KV cache transfer occurs exclusively between corresponding layers of prefill and decoding instances. Leveraging inter-op parallelism, we group layers into stages and divide each instance into segments, termed as *instance segments*, with each segment maintaining one specific inter-op stage. By colocating prefill and decoding segments of the same stage within a single node, we force the transfer of intermediate states to occur only via NVLINK. Inside a node, we set the same parallelism and resource allocation for segments of the same instance. Given the typical limitation of GPUs per node (usually 8), we can enumerate possible configurations inside one node and use the simulator to identify the configurations that yield the best goodput.

As outlined in Algorithm 2, we begin by enumerating inter-op parallelism degrees to get all the possible instance segments. For each segment, we get all possible intra-node parallelism configurations by calling `get_intra_node_configs`. Then we use simulation to find the optimal one and replicate it to satisfy the target traffic rate.

4.3 Online scheduling

The runtime architecture of DistServe is shown in Figure 6. DistServe operates with a simple FCFS scheduling policy. All incoming requests arrive at a centralized controller, then dispatched to the prefill instance with the shortest queue for prefill processing, followed by dispatch to the least loaded decoding instance for decoding steps. This setup, while simple, is optimized with several key enhancements tailored to the nuances of real-world workloads.

Reducing pipeline bubbles. To mitigate the pipeline bubbles caused by non-uniform prompt lengths (§3.3), we schedule the requests in a way that balances the execution time across all batches in the pipeline. This is achieved by noting that, for both prefill and decoding instances, the number of new tokens in the batch is a reliable indicator of the batch's real execution time. For prefill instances, we profile the target model and GPU to figure out the shortest prompt length L_m needed to saturate the GPU. We schedule prefill batches with a total sequence length close to L_m, by either batching multiple requests shorter than L_m or individually scheduling requests longer than L_m. For decoding instances, we set L_m as the largest batch size.

Combat busrtiness. Burstiness in workloads can cause a deluge of KV caches to transfer from prefill to decoding instances, risking memory overload on decoding instances. To circumvent this, DistServe employs a "pull" method for KV cache transmission rather than a "push" approach – decoding instances fetch KV cache from prefill instances *as needed*, using the GPU memory of prefill instances as a queuing buffer. This way, the prefill instance can continue handling other prefill jobs by simply retaining the KV Cache in the GPU memory after processing the prompt. Hence, each type of instance operates at its own pace without complex coordination.

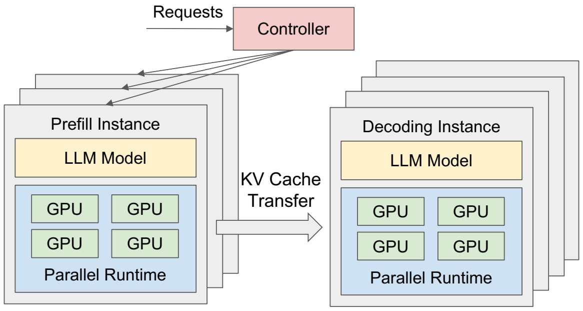

Figure 6: DistServe Runtime System Architecture

Replaning. The resource and parallelism plan in DistServe is optimized for a specific workload pattern, which may become suboptimal if the workload pattern changes over time. DistServe implement periodic replanning. A workload profiler monitors key parameters such as the average input and output length of the requests, the average arrival rate, etc. If a significant pattern shift is detected, DistServe will trigger a rerun of the placement algorithm based on recent historical data. This process is expedient – the proposed algorithm runs in seconds (§6.5) and reloading LLM weights can be completed within minutes – far shorter than the hourly scale at which real-world workload variations tend to occur.

Preemption and fault tolerance. DistServe does not implement advanced runtime policies like preemption [26] and fault tolerance [58], which are complementary to disaggregation. Nevertheless, we discuss how they fit into DistServe. In DistServe, the FCFS policy can lead to a "convoy effect", where longer requests block shorter ones in the prefill stage. Incorporating preemptive strategies, as suggested in existing literature [53], could enhance efficiency and is feasible within our system's architecture. While not a primary focus in the current DistServe, fault tolerance is a critical aspect for consideration. In traditional colocation- and replication-based systems, a fault in one instance typically does not disrupt other replica instances. However, in DistServe, the dependency between prefill and decoding instances introduces the risk of fault propagation. For example, a fault in a single decoding instance mapped to multiple prefill instances could potentially cripple the entire service and cluster. We leave both as future work.

5 Implementation

DistServe is an end-to-end distributed serving system for LLMs with a placement algorithm module, a RESTful API frontend, an orchestration layer, and a parallel execution engine. The algorithm module, frontend, and orchestration layer are implemented with 6.5K lines of Python code. The parallel execution engine is implemented with 8.1K lines of

Application	Model Size	TTFT	TPOT	Dataset
Chatbot OPT-13B	26GB	0.25s	0.1s	ShareGPT [8]
Chatbot OPT-66B	132GB	2.5s	0.15s	ShareGPT [8]
Chatbot OPT-175B	350GB	4.0s	0.2s	ShareGPT [8]
Code Completion OPT-66B	132GB	0.125s	0.2s	HumanEval [14]
Summarization OPT-66B	132GB	15s	0.15s	LongBench [13]

Table 1: Workloads in evaluation and latency requirements.

C++/CUDA code.

The placement algorithm module implements the algorithm and the simulator mentioned in §4 which gives the placement decision for a specific model and cluster setting. The frontend supports an OpenAI API-compatible interface where clients can specify the sampling parameters like maximum output length and temperature. The orchestration layer manages the prefill and decoding instances, responsible for request dispatching, KV cache transmission, and results delivery. It utilizes NCCL [6] for cross-node GPU communication and asynchronous CudaMemcpy for intra-node communication, which avoids blocking the GPU computation during transmission. Each instance is powered by a parallel execution engine, which uses Ray [35] actor to implement GPU workers that execute the LLM inference and manage the KV Cache in a distributed manner. It integrates many recent LLM optimizations like continuous batching [54], FlashAttention [20], PagedAttention [32] and supports popular open-source LLMs such as OPT [56] and LLaMA [51].

6 Evaluation

In this section, we evaluate DistServe under different sizes of LLMs ranging from 13B to 175B and various application datasets including chatbot, code-completion, and summarization. The evaluation shows that DistServe consistently outperforms the current state-of-the-art system across all the settings (§6.2). Specifically, DistServe can handle up to 7.4× higher rates and 12.6× more stringent SLO while meeting the latency requirements for over 90% requests. Additionally, we analyze the latency breakdown in DistServe to show the communication overhead is insubstantial thanks to our bandwidth-aware placement algorithm (§6.3) and do ablation studies of our techniques (§6.4). Finally, we profile the execution time of our placement algorithm (§6.5).

6.1 Experiments Setup

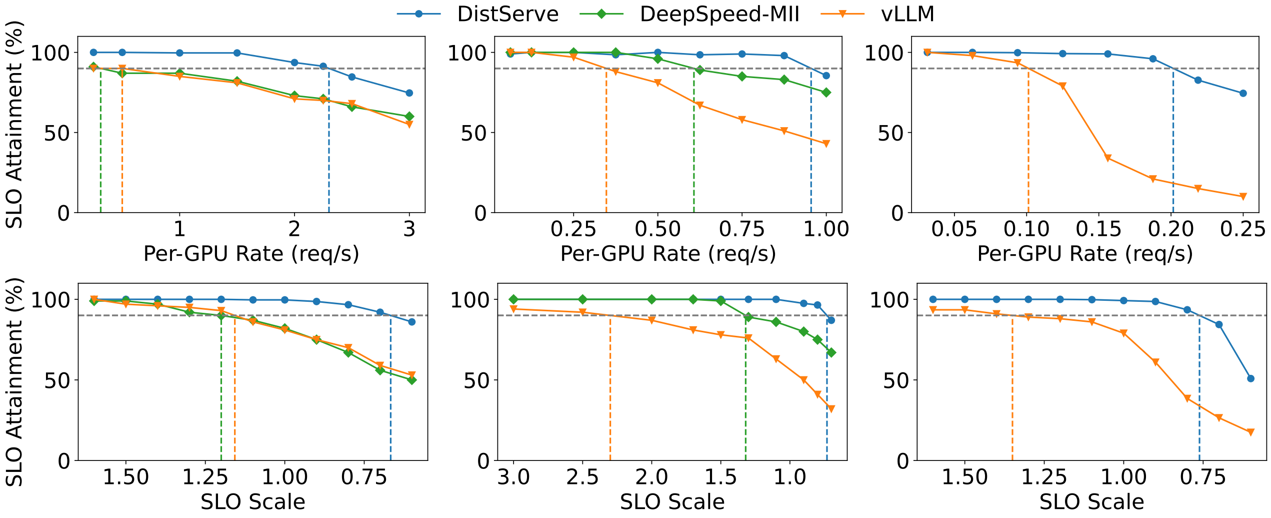
Cluster testbed. We deploy DistServe on a cluster with 4 nodes and 32 GPUs. Each node has 8 NVIDIA SXM A100-80GB GPUs connected with NVLINK. The cross-node bandwidth is 25Gbps. Due to the limited cross-node bandwidth, we use the low node-affinity placement algorithm (§2) for DistServe in most of the experiments except for the ablation study (§6.4) which uses simulation.

Model and workloads setup. Similar to prior work on LLM serving [32], we choose the OPT [56] model series, which is a representative LLM family widely used in academia and industry. Newer GPT model families are adopting memory-efficient attention mechanisms like GQA [10] and MQA [44]. DistServe will show better performance on these models because the transmission overhead is lower due to the decrease in KV cache size. We choose OPT which uses the classic MHA [52] to put enough pressure on the transmission overhead. We use FP16 precision in all experiments. For workloads, as shown in Table 1, We choose three typical LLM applications and set the SLOs empirically based on their service target because there exists no available SLO settings for these applications as far as we know. For each application, we select a suitable dataset and sample requests from it for evaluation. Since all the datasets do not include timestamps, we generate request arrival times using Poisson distribution with different request rates. Due to the space limit, we test the chatbot workload on all three OPT models and the other two workloads on OPT-66B, which matches the largest size in the recent open-source LLM series [51].

- **Chatbot** [1]: We use the ShareGPT dataset [8] for the chatbot application, which is a collection of user-shared conversations with ChatGPT. For OPT-13B, the TTFT SLO is set to 0.25s for responsiveness and the TPOT SLO is set to 0.1s which is higher than the normal human read speed. For OPT-66B and OPT-175B, we slightly relax the two SLOs due to the increase in model execution latency.
- **Code completion** [14]: We use the HumanEval [14] dataset for the code completion task. It includes 164 programming problems with a function signature or docstring which is used to evaluate the performance of code completion models. Since the code completion model is used as a personal real-time coding assistant, we set both SLOs to be stringent.
- **Summarization** [5]: It is a popular LLM task to generate a concise summary for a long article, essay, or even an academic paper. We use LongBench [13] dataset which contains the summarization task[4]. As shown in Figure 7, LongBench has much longer input lengths than the other two datasets. So we set a loose TTFT SLO but require a stringent TPOT.

Metrics. We use *SLO attainment* as the major evaluation metric. Under a specific SLO attainment goal (say, 90%), we are

[4] We capped the input lengths in LongBench because OPT's absolute positional embedding only supports a maximum length of 2048.



(a) OPT-13B (b) OPT-66B (C) OPT-175B

Figure 8: Chatbot application with OPT models on the ShareGPT dataset.

concerned with two things: the maximum per-GPU goodput and the minimal SLO the system can handle. We are particularly interested in an SLO attainment of 90% (indicated by the vertical lines in all curve plots), but will also vary the rate and latency requirements to observe how the SLO attainment changes. We also include the results in the Appendix for an SLO attainment of 99% to show the system performance under a more stringent SLO attainment target.

Baselines. We compare DistServe to two baseline systems:

- **vLLM [32]:** vLLM is a representative LLM serving system widely used in both academia and industry. It supports *continuous batching* [54] to increase throughput and *paged-attention* [32] to reduce memory fragmentation during KV cache allocation. However, it colocates the prefill and decoding computation to maximize the overall system throughput and struggles to meet the latency requirements cost-efficiently. Since vLLM only supports intra-op parallelism, we follow previous work [32] to set intra-op equals 1, 4, and 8 for the three OPT models, respectively.
- **DeepSpeed-MII [3]:** DeepSpeed Model Implementations for Inference (MII) supports *chunked-prefill* by decomposing long prompts into smaller chunks and composing with short prompts to exactly fill a target token budget. It mitigates but cannot eliminate the prefill-decoding interference caused by the long prefill job. We set its intra-op the same as vLLM for OPT-13B and OPT-66B for a fair comparison. However, DeepSpeed-MII cannot serve OPT-175B whose $vocab\_size = 50272$ because its underlying kernel implementation requires $vocab\_size/intra\_op$ is a multiple of 8 where intra-op equals 8 does not satisfy. Setting intra-op equals 4 can satisfy this requirement but will cause the out-of-memory issue.

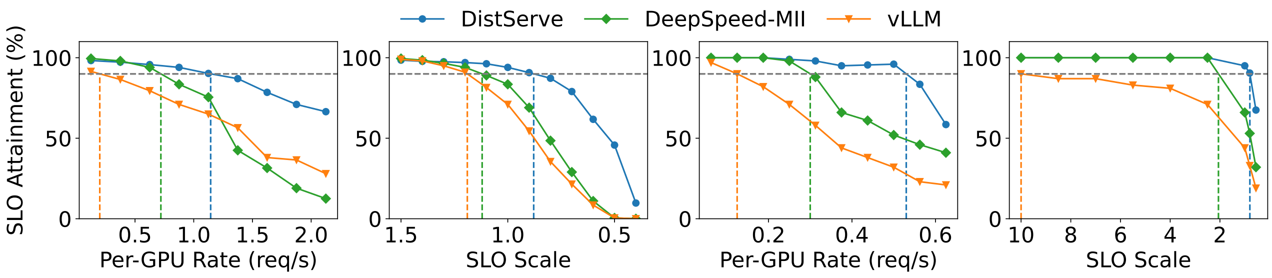
6.2 End-to-end Experiments

In this Section, we compare the end-to-end performance of DistServe against the baselines on real application datasets.

Chatbot. We evaluate the performance of DistServe on the chatbot application for all three OPT models. The first row of Figure 8 illustrates that when we gradually increase the rate, more requests will violate the latency requirements and the SLO attainment decreases. The vertical line shows the maximum per-GPU rate the system can handle to meet latency requirements for over 90% of the requests.

On the ShareGPT dataset, DistServe can sustain 2.0×–4.6× higher request rate compared to vLLM. This is because DistLLM eliminates the prefill-decoding interference through disaggregation. Two phases can optimize their own objectives by allocating different resources and employing tailored parallelism strategies. Specifically, by analyzing the chosen placement strategy[5] for 175B, we find the prefill instance has inter-op = 3, intra-op = 3; and the decoding instance has inter-op = 3, intra-op = 4. Under this placement, DistServe can effectively balance the load between the two instances on ShareGPT, meeting latency requirements at the lowest cost. This non-trivial placement strategy is challenging to manually find, proving the effectiveness of the algorithm. In the case of vLLM, collocating prefill and decoding greatly slows down the decoding phase, thereby significantly increasing TPOT. Due to the stringent TPOT requirements of chatbot applications, although vLLM meets the TTFT SLO for most requests, the overall SLO attainment is dragged down by a large number of requests that violate the TPOT SLO. Compared to DeepSpeed-MII, DistServe can sustain 1.6×–7.4× higher request rate. DeepSpeed-MII shows better performance

[5] All the placements chosen by DistServe can be found in Appendix B.



(a) Code Completion

(b) Summarization

Figure 9: Code completion and summarization tasks with OPT-66B on HumanEval and LongBench datasets, respectively.

on larger models because the prefill job is larger and chunked-prefill mitigates the interference to some extent. However, due to the reasons discussed in §2.3, chunked prefill is slower than full prefill, so it struggles to meet the TTFT SLO as a sacrifice for better TPOT.

The second row of Figure 8 indicates the robustness to the changing latency requirements of the two systems. We fix the rate and then linearly scale the two latency requirements in Table 1 simultaneously using a parameter called *SLO Scale*. As SLO Scale decreases, the latency requirement is more stringent. We aim to observe the most stringent SLO Scale that the system can withstand while still achieving the attainment target. Figure 8 shows that DistServe can achieve 1.8×–3.2× more stringent SLO than vLLM and 1.7×–1.8× more stringent SLO than DeepSpeed-MII, thus providing more engaging service quality to the users.

Code completion. Figure 9(a) shows the performance of DistServe on the code completion task when serving OPT-66B. DistServe can sustain 5.7× higher request rate and 1.4× more stringent SLO than vLLM. Compared to DeepSpeed-MII, DistServe can sustain 1.6× higher request rate and 1.4× more stringent SLO. As a real-time coding assistant, the code completion task demands lower TTFT than chatbot, this leads to both systems ultimately being constrained by the TTFT requirement. However, in comparison, by eliminating the interference of the decoding jobs and automatically increasing intra-operation parallelism in prefill instances through the searching algorithm, DistServe reduces the average latency of the prefill jobs, thereby meeting the TTFT requirements of more requests.

Summarization. Figure 9(b) shows the performance of DistServe on the summarization task when serving OPT-66B. DistServe achieves 4.3× higher request rate and 12.6× more stringent SLO than vLLM. Compared to DeepSpeed-MII, DistServe achieves 1.8× higher request rate and 2.6× more stringent SLO. The requests sampled from LongBench dataset have long input lengths, which brings significant pressure to the prefill computation. However, due to the loose requirement of TTFT for the summarization task, the TPOT service quality becomes particularly important. Since vLLM collocates prefill and decoding phases, it experiences a greater slowdown in the decoding phase with long prefill jobs and fails to meet the TPOT requirement.

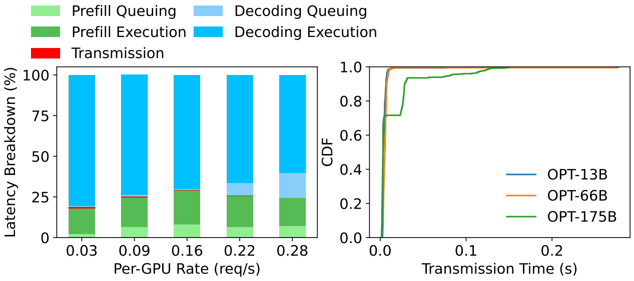


Figure 10: *Left:* Latency breakdown when serving OPT-175B on ShareGPT dataset with DistServe. *Right:* The CDF function of KV Cache transmission time for three OPT models.

The results above are all under the 90% SLO attainment target. We observe that DistServe can have better performance under a more stringent attainment target (say, 99%) and present the results in Appendix C.

6.3 Latency Breakdown

To understand DistServe's performance in detail, we make a latency breakdown of the requests in DistServe. We divide the processing lifecycle of a request in DistServe into five stages: *prefill queuing*, *prefill execution*, *transmission*, *decoding queuing*, and *decoding execution*. The total time consumed by all requests in each stage is then summed up to determine their respective proportions in the system's total execution time.

Figure 10(a) shows the latency breakdown for the OPT-175B models on the ShareGPT dataset. We chose OPT-175B because the KV Cache transmission is more demanding for larger models. In fact, even for OPT-175B, the KV Cache transmission only accounts for less than 0.1% of the total latency. Even by examining the CDF of the absolute transmission time shown in Figure 10(b), we observe that over 95% of requests experience a delay of less than 30ms, despite our testbed having only limited cross-node bandwidth. This is due to the algorithm described in §4.2, where we require the prefill and decoding instance to maintain the same stage on one machine, enabling the use of intra-node NVLINK bandwidth for transmission, thus significantly reducing transmission delay.

Rate	vLLM		DistServe-Low	
(req/s)	Real System	Simulator	Real System	Simulator
1.0	97.0%	96.8%	100.0%	100.0%
1.5	65.5%	65.1%	100.0%	100.0%
2.0	52.8%	51.0%	99.3%	99.3%
2.5	44.9%	46.1%	87.3%	88.3%
3.0	36.7%	38.3%	83.0%	84.1%
3.5	27.8%	28.0%	77.3%	77.0%
4.0	23.6%	24.1%	70.0%	68.9%

Table 2: Comparison of the SLO attainment reported by the simulator and the real system under different rates.

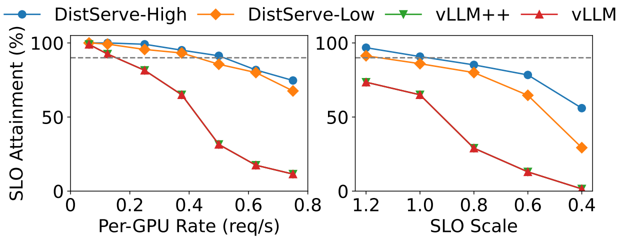

Figure 11: Ablation experiments.

6.4 Ablation Studies

We study the effectiveness of the two key innovations in DistServe: disaggregation and the placement searching algorithm. In §6.2, we choose the default parallelism setting for vLLM following its original paper [32]. So we implement "vLLM++" which enumerates different parallelism strategies and chooses the best. For DistServe, We also compare the placement found by Alg. 2 (DistServe-Low) with the one found by Alg. 1 (DistServe-High) which has fewer searching constraints and assumes high cross-node bandwidth. Since vLLM does not support inter-op parallelism and our physical testbed does not have high cross-node bandwidth, we use simulation for this experiment.

Simulator accuracy. Noticing that DNN model execution [24] has high predictability, even under parallel settings [33, 59]. We study the accuracy of the simulator in Tab. 2. For "vLLM" and "DistServe-Low", we compare the SLO attainment reported by the simulator and by real runs on our testbed under different rates. The error is less than 2% in all cases, verifying the accuracy of our simulator.

Results. Figure 11 shows the performance of the four systems when serving OPT-66B on the ShareGPT dataset. "vLLM++" has the same performance as "vLLM" because we find the default parallelism setting (intra-op=4) has the best per-GPU goodput. This further demonstrates the importance of disaggregation. The interference between the prefill and decoding phases significantly reduces the potential performance improvement through adjusting parallelism. In contrast, "DistLLM-High" can achieve further improvements over "DistLLM-Low" because it is not constrained by the deployment constraint that the prefill and decoding instance on one node should share the same model stage. Through disaggregation, we can use tailored parallelism strategies for prefill and decoding instances and optimize their targets without the coupling effects.

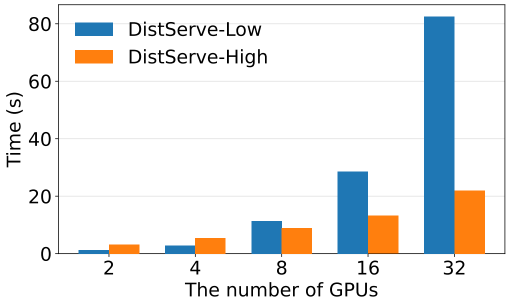

Figure 12: Algorithm Running Time

6.5 Algorithm Running Time

Figure 12 shows the running time for Alg. 1 (DistServe-Low) and Alg. 2 (DistServe-High) on an AWS m5d.metal instance with 96 cores as the number of GPUs ($N \times M$) provided to a single instance increases. According to the results, DistServe scales well with the number of GPUs and is independent of the model size. This is because the simulator only simulates discrete events and the running time is the same no matter how big the model is. On the other hand, both algorithms are highly parallelizable, as the searches for different parallelism strategies are independent of each other, allowing the execution time of the algorithms to accelerate almost linearly with more CPU cores.

As the number of GPUs increases, the execution time of "Dist-Low" becomes higher than that of "Dist-High". This is because the search for parallelism strategies for prefill and decoding instances in "Dist-High" is independent and can be parallelized. But for "Dist-Low", due to additional restrictions on deployment, we need to enumerate all the possible intra-node parallelism combinations for prefill and decoding instances. Even so, the execution time of the algorithm is in minutes, and since it only needs to be executed once before each redeployment, this overhead is acceptable.

7 Discussion

In this paper, we focus on the goodput-optimized setting and propose DistServe under the large-scale LLM serving scenario. As LLMs are widely used and deployed across various service scenarios with different optimization targets and resource limits, it becomes almost impossible to find a one-size-fits-all solution that effectively addresses all aspects of LLM serving. In this section, we discuss the pros and cons of DistServe and potentially better solutions in other scenarios.

Throughput-optimized scenarios. In offline applications that are not latency-sensitive, users typically have lower requirements for response time [45]. This allows serving systems to shift focus towards maximizing overall throughput instead of goodput and the effectiveness of DistServe may be compromised. In this case, techniques such as chunked-prefill with piggyback [3, 9] may be preferred since it can fill each batch to the compute-bound threshold, thereby maintaining higher GPU utilization in every iteration.

Resource-constrained scenarios. Small-scale enterprises and individual researchers often lack the resources to deploy LLMs on large-scale clusters [45, 48]. In resource-constrained scenarios, such as environments with only a few or even a single GPU, the design space for DistServe is significantly limited. It struggles or even fails to adjust the parallel strategies and resource allocation to effectively enhance serving performance. In this case, simpler architectural choices like non-disaggregated systems [3, 32] may reduce deployment complexity and optimize operational efficiency.

Long-context scenarios. Nowadays, more and more GPT models support extremely long contexts, such as Claude-3 [11], Gemini-1.5 [22], and Large World Model (LWM) [34], which all have a 1M context window. In such scenarios, the transmission overhead will increase as the size of the KV cache grows linearly with the prompt length. However, the prefill computation grows quadratically, so the relative duration of transmission and prefill job decreases. Meanwhile, a longer context further exacerbates the disparity in computational demands between prefill and decoding jobs, leading to increased interference between them. Therefore, the disaggregation approach proposed in DistServe remains promising in long-context serving.

8 Related Work

Inference serving. There has been plenty of work on inference serving recently. They range from general-purpose production-grade systems like TorchServe [7] and NVIDIA Triton [19] to systems optimized specifically for Transformer-based LLMs [9, 18, 21, 33, 50, 53, 54, 60]. Among them, Orca [54] introduces continuous batching to increase throughput. vLLM [32] proposes paged-attention for fine-grained KV cache management. SARATHI [9] suggests a chunked-prefill approach, splitting a prefill request into chunks and piggybacking decoding requests to improve hardware utilization. FastServe [53] implements iteration-level preemptive scheduling to mitigate the queuing delay caused by long jobs. However, they all employ a colocation approach for prefill and decoding processing, thus leading to severe interference. There are also concurrent works such as Splitwise [38], TetriInfer [27] and DéjàVu [49] which adopt similar disaggregation idea to optimize LLM inference, further confirming the effectiveness of this method. Differently, DistServe emphasizes the goodput optimization scenario more and takes a closer look at the aspect of network bandwidth.

Goodput-optimized systems. Optimizing goodput is a hot topic in DL applications. Pollux [39] improves scheduling performance in DL clusters by dynamically adjusting resources for jobs to increase cluster-wide goodput. Sia [29] introduces a heterogeneous-aware scheduling approach that can efficiently match cluster resources to elastic resource-adaptive jobs. Clockwork [23] and Shepherd [55] provide latency-aware scheduling and preemption to improve the serving goodput, but they only target traditional small models. AlpaServe [33] focuses on LLMs, employing model parallelism to statistically multiplex the GPU execution thus improving the resource utilization. However, it only targets the non-autoregressive generation. DistServe is the first work to optimize the goodput for autoregressive LLM inference.

Resource disaggregation. Resource disaggregated systems [17, 25, 43] decouple the hardware resources from the traditional monolithic server infrastructure and separate them into resource pools to manage independently. It allows for more flexible, efficient, and scalable deployment and increases resource utilization. Many applications benefit from a truly disaggregated data center with high-speed network bandwidth and heterogenous hardware support [12, 30, 57]. DistServe shares the concept by disaggregating its system components, allowing for independent resource scaling and management.

Model parallelism for training. DistServe is orthogonal to the large body of work on model parallelism in training [28, 36, 40, 46, 59]. As described in §3.3, inference-serving workloads have unique characteristics not found in training settings. Where these systems do intersect with DistServe, is in their methods for implementing model parallelism along various dimensions. DistServe can integrate new parallelism optimizations into its placement searching algorithm.

9 Conclusion

We present DistServe, a new LLM serving architecture that disaggregates the prefill and decoding computation. DistServe maximizes the per-gpu goodput – the maximum request rate that can be served adhering to the SLO attainment goal for each GPU provisioned, hence resulting in up to 7.4× lower cost per LLM query with guaranteed satisfaction of SLOs. Our findings affirm that as latency becomes an increasingly important metric for LLM services, prefill and decoding disaggregation is a vital strategy in promising improved performance and service quality guarantees.

A Latency Model for LLM Inference

To accurately simulate the goodput of different placement strategies, we use an analytical model to predict the execution time of the prefill and decoding phases in LLM inference.

In modern LLM serving systems [18, 32, 53], memory-bound operations like Softmax and LayerNorm are usually fused with matrix multiplication kernels for efficiency. Thus the GEMMs dominate the overall latency and our analysis primarily focuses on them.

A.1 Symbol Definition

Here are symbols related to the architecture of the model:

- h: hidden size
- n: number of heads
- s: head size ($h = n \cdot s$)
- m: FFN intermediate size

Note: If tensor parallelism is used, h, n, and m should be divided by the tensor parallelism size.

Below are symbols that characterize the batch to be executed:

- B: batch size
- $l_0, l_1, \dots, l_{B-1}$: input length of each request within the batch
- t: number of tokens in the batch, ($t = \sum_{i=0}^{B-1} l_i$)
- t_2: squared sum of the input lengths ($t_2 = \sum_{i=0}^{B-1} l_i^2$)
- b: block size in the attention kernel. This parameter is used in FlashAttention [20], a common kernel optimization technique adopted by current LLM serving systems.

A.2 Prefill Phase Latency Modeling

Since the attention operation uses specially optimized kernels, we first discuss the other four matrix multiplications in the prefill phase:

GEMM Name	Shape of M	Shape of N
QKV Linear	(t,h)	$(h,3h)$
Attn Output	(t,h)	(h,h)
FFN Input	(t,h)	(h,m)
FFN Output	(t,m)	(m,h)

The arithmetic intensity (AI) of these operations is $O(t)$. On NVIDIA A100-80GB GPU, it is compute-bound when AI is over 156. Since t usually can reach several hundred in real cases, all of these operations are compute-bound. Therefore, we can model the latency of these operations according to the total FLOPs:

$$T_1 = C_1 \cdot (4th^2 + 2thm)$$

Next, we discuss the prefill attention operation with FlashAttention [20] optimization. Since the attention only operates among the tokens in the same request, current implementations launch attention kernels for each request in the same batch. For one attention head and a request with l tokens, the attention kernel needs to perform a total of $2sl + 3sl \cdot (l/b) \approx 3sl \cdot (l/b)$ memory reads and writes, alongside $2sl^2 + sl(l/b) \approx 2sl^2$ FLOPs. So the AI is $2b/3 = 10.677$ (when $b = 16$) or 21.333 (when $b = 32$), indicating that it is a memory-bound operation on A100 GPU. Therefore, the whole attention layer latency (including all requests and all heads) can be modeled as:

$$T_2 = C_2 \cdot n \cdot \sum_{i=0}^{B-1} \frac{3sl_i^2}{b} = C_2 \cdot \frac{3nst_2}{b} = C_2 \cdot \frac{3ht_2}{b}$$

Overall, the latency of the prefill phase can be modeled as:

$$T_{Prefill} = C_1 \cdot (4th^2 + 2thm) + C_2 \cdot \frac{3ht_2}{b} + C_3$$

We use C_3 to quantify other overheads like Python Runtime, system noise, and so on. Then we use profiling and interpolation to figure out the values of C_1, C_2, and C_3.

A.3 Decoding Phase Latency Modeling

Similarly, we first focus on the following GEMMs in the decoding phase:

GEMM Name	Shape of M	Shape of N
QKV Linear	(B,h)	$(h,3h)$
Attn Output	(B,h)	(h,h)
FFN Input	(B,h)	(h,m)
FFN Output	(B,m)	(m,h)

The AI of these operations is $O(B)$. B is limited by the GPU memory size and stringent latency requirements, so in existing serving scenarios, these operations are memory-bound. The total memory reads and writes is $8Bh + 4h^2 + 2hm + 2Bm$, and since h and m are usually significantly larger than B, we can model the latency as:

$$T_3 = C_4 \cdot (4h^2 + 2hm)$$

As for the decoding attention operation, for one attention head and a request with l generated tokens, it needs to perform $3sl$ memory reads and writes, alongside $2sl$ FLOPs. It is memory-bound, so we can model the latency of decoding attention as:

$$T_4 = C_5 \cdot n \cdot 3s \sum_{i=0}^{B-1} l_i = C_5 \cdot 3ht$$

Summing up, the latency of the decoding phase is:

$$T_{Decoding} = C_4 \cdot (4h^2 + 2hm) + C_5 \cdot 3ht$$

Here we do not introduce the overhead term (like C_3 in the profiling stage) because $4h^2 + 2hm$ is already a constant, and the overhead can be put into C_4. Similarly, we use profiling and interpolation to figure out the values of C_4 and C_5.

B DistServe Placements in End-to-end Experiments

Table 3 shows the tensor parallelism (TP) and pipeline parallelism (PP) configurations for prefill and decoding instances chosen by DistServe in the end-to-end experiments §6.2.

Model	Dataset	Prefill		Decoding	
		TP	PP	TP	PP
OPT-13B	ShareGPT	2	1	1	1
OPT-66B	ShareGPT	4	1	2	2
OPT-66B	LongBench	4	1	2	2
OPT-66B	HumanEval	4	1	2	2
OPT-175B	ShareGPT	3	3	4	3

Table 3: The parallelism strategies chosen by DistServe in the end-to-end experiments.

C End-to-end Results under 99% SLO attainment

Figure 13 and Figure 14 show the end-to-end performance between DistServe and baselines with the same setup in §6.2 except that the SLO attainment goal is changed to 99%. We can see that under a more stringent SLO attainment goal, compared to vLLM, DistServe can still sustain 3×–8× higher rate and 1.24×–6.67× more stringent SLO. When compared to DeepSpeed-MII, DistServe can achieve 1.32×–8× higher rate and 1.20×–1.58× more stringent SLO.

ACCL+: an FPGA-Based Collective Engine for Distributed Applications

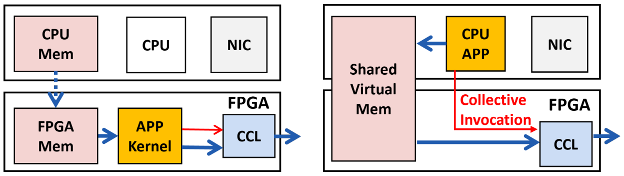
Abstract

FPGAs are increasingly prevalent in cloud deployments, serving as Smart-NICs or network-attached accelerators. To facilitate the development of distributed applications with FPGAs, in this paper we propose ACCL+, an open-source, FPGA-based collective communication library. Portable across different platforms and supporting UDP, TCP, as well as RDMA, ACCL+ empowers FPGA applications to initiate direct FPGA-to-FPGA collective communication. Additionally, it can serve as a collective offload engine for CPU applications, freeing the CPU from networking tasks. It is user-extensible, allowing new collectives to be implemented and deployed without having to re-synthesize the entire design. We evaluated ACCL+ on an FPGA cluster with 100 Gb/s networking, comparing its performance against software MPI over RDMA. The results demonstrate ACCL+'s significant advantages for FPGA-based distributed applications and its competitive performance for CPU applications. We showcase ACCL+'s dual role with two use cases: as a collective offload engine to distribute CPU-based vector-matrix multiplication, and as a component in designing fully FPGA-based distributed deep-learning recommendation inference.

1 Introduction

FPGAs are increasingly being deployed in data centers [16, 81] as Smart-NICs [29, 35, 64, 67, 103], streaming processors [31, 32, 55, 68], and disaggregated accelerators [15, 41, 61, 65, 86, 93, 115]. In scenarios where FPGAs are directly connected to the network, efficient distributed systems can be built using direct FPGA-to-FPGA communication. However, designing distributed applications with FPGAs is difficult. It requires both a network stack on the FPGA compatible with the data center infrastructure, and a higher level abstraction, e.g., *collective communication*, for more complex interaction patterns. Unlike in the software ecosystem where many such libraries exist [38, 76], there is a lack of similar resources for FPGAs. While new development platforms [53, 59] are improving FPGA programmability, and other recent efforts [10, 18, 60, 70, 72, 100] focus on virtualizing FPGA resources for abstracting data movement, they lack support for networking. This forces distributed applications on FPGAs to rely on the CPU for communication [22, 92, 116], thereby increasing the latency of data transfers between FPGAs. It has not been until recently that native networking support [14, 45, 56, 87, 95] has become available for FPGAs. But these systems lack collective communication, limiting their applicability in larger distributed use cases.



(a) For distributed accelerator

(b) For Smart-NIC

Figure 1: Collective communication library (CCL) in different FPGA-accelerated systems, where the blue line indicates application data flow and the red line indicates collective invocation commands.

Implementing high-performance and versatile collective abstractions for FPGAs poses several challenges:

Challenge 1: Support of Diverse Transport Protocols. This requirement stems from the need for application-specific solutions and to ensure interoperability in mixed environments where FPGAs coexist with CPUs and accelerators. The ability to adapt to various communication protocols is crucial for integrating FPGA-based components seamlessly with other parts of a system. Existing work [25, 26, 36, 44, 73, 84, 85, 101, 104, 112] is often tailored to scenarios where FPGAs are directly connected to each other rather than connected through a data center packet-switched network. In these approaches, communication is through low-level link-layer protocols, leading to scalability and integration challenges at a data-center scale.

[*] Work done during internship at AMD Research

Challenge 2: Flexibility for Collective Implementation. A key challenge is to provide a flexible design in hardware allowing the selection of different collectives and algorithms at runtime. Current solutions [26,45] often integrate all possible collective modules directly into FPGA hardware, resulting in static primitives that necessitate hours-long recompilations for any changes. Alternative approaches, e.g., collectives using embedded micro-controllers (uC) [89] on FPGAs, offer more flexibility at the expense of performance.

Challenge 3: Portability Across Applications and Platforms. Portability stands out as a key challenge, as FPGAs are used in a wide variety of configurations. Figure 1a shows the FPGA collective communication library (CCL) as enabler for direct networking between FPGAs accelerators. It also demonstrates a *partitioned memory model* [54, 59, 60] for FPGA-centric applications, where an explicit memory copy is required if the data originates from CPU memory (dashed line). Figure 1b illustrates CCL's role as an collective offload engine for a CPU application with *shared virtual memory* [62,70,75,106]. This portability also raises questions about which *communication models* should be provided to the application. Should interfaces support message passing, i.e., MPI, where communication occurs between memory buffers, or streaming, where communication flows through continuous data streams?

In summary, the key question to address is *how to effectively design a portable, flexible, high-level collective abstraction on FPGAs that can support various memory models (e.g., partitioned and shared virtual memory model), communication models (e.g., message passing and streaming), and transport protocols (e.g., TCP and RDMA), while accommodating a broad spectrum of applications*. Achieving this objective is complex, given the significant impact of these configurations on runtime, interfaces, and data movement. Moreover, given FPGAs' extended compilation times and lengthy hardware debugging cycles, we need a parameterized approach that allows a FPGA-resident CCL to be modified without recompilation, in order for the CCL to be practical in real-world use. Table 1 summarizes existing FPGA-based solutions, and all existing solutions have their own limitations.

Our Contributions. To address these challenges, we introduce ACCL+, an **A**daptive **C**ollective **C**ommunication **L**ibrary on FPGAs. ACCL+ can be used to enable direct communication between FPGAs and can function as a collective offload engine for the CPU. ACCL+ provides MPI-like collective APIs with explicit buffer allocation and streaming collective APIs with direct channels to the communication layer. To achieve portability, we employ a modular system architecture which decouples platform-specific IO management and runtime from the collective implementation, incorporating platform and network protocol-specific adapters and drivers. For flexibility, we have developed a platform and protocol-independent collective offload engine that supports modifying the collective implementation without hardware recompilation. We test ACCL+ on two platforms, a commodity, partitioned memory platform (AMD Vitis [59]) and a shared virtual memory platform (Coyote [62]). We choose AMD Vitis for its recent integration of high-performance 100 Gb/s UDP [107] and TCP [45] hardware stacks, aligning with our goal of leveraging cutting-edge networking capabilities for optimal communication performance. Coyote is used due to its unique provisioning of unified and virtualized memory across CPU-FPGA boundaries [62], coupled with comprehensive network services, including RDMA. ACCL+ is also designed to minimize control overheads, improve scalability, and facilitate simulation.

Table 1: Comparison of ACCL+ with FPGA-based solutions in terms of bandwidth, flexibility in implementing different collectives, target application scenarios, and supported transport protocols.

Solution	BW (Gb)	Flex.	Application	Protocol
Easynet [45]	100	Low	FPGA	TCP
SMI [26]	40	Low	FPGA	Serial Link
Galapagos [97]	10	Low	FPGA	TCP
ZRLMPI [85]	10	Low	FPGA	UDP
TMD-MPI [89]	<10	High	FPGA	Serial Link
ACCL+ (Ours)	100	High	CPU/FPGA	UDP/TCP/RDMA

Key Results. We first evaluate ACCL+ using micro benchmarks. ACCL+ achieves a peak send/recv throughput of 95 Gbps, almost saturating the 100 Gb/s network bandwidth. We evaluate collective operations under two scenarios: FPGA-to-FPGA distributed applications with FPGA kernels directly interacting with ACCL+ (F2F), and CPU-to-CPU distributed applications with ACCL+ as a collective offload engine (H2H). ACCL+ exhibits significantly lower latency in F2F scenarios compared to software RDMA MPI for FPGA-generated data. In H2H scenarios, ACCL+ has comparable performance to software RDMA MPI for CPU-generated data while freeing up CPU cycles and reducing pressure on CPU caches. Then, we examine ACCL+ with two use-case scenarios. First, distributed vector-matrix multiplication with CPU computation and ACCL+-based reduction, where ACCL+ improves performance compared to software MPI. Secondly, we show that ACCL+ enables the distribution of an industrial recommendation model across a cluster of 10 FPGAs, achieving more than two orders of magnitude lower inference latency and more than an order of magnitude higher throughput than CPU solutions. The use case study not only highlights ACCL+'s effectiveness in different scenarios but also paves the way for future research opportunities in investigating hybrid CPU-FPGA co-design for distributed applications.

2 Background

FPGA Programming. In the past, hardware description language (HDL - Verilog, VHDL) was the sole method to program FPGAs. With High-Level-Synthesis (HLS) [21], the programmability of FPGAs is enhanced by allowing the developers to program in C-like code with hints (pragmas) to infer parallel hardware blocks. Unfortunately, existing HLS-based libraries lack networking and collective abstractions.

Communication Models. Message passing, e.g., MPI, is a communication model for distributed programming on CPUs, whereby communicating agents exchange messages, i.e., user buffers, typically resulting from previous computation. This model can be applied to FPGAs [46, 84, 85], but a more common communication model for FPGAs is the streaming model. FPGA kernels support direct streaming interfaces, into which data can be pushed in a pipelined fashion during processing. Kernels executing on the same FPGA can stream data to each-other through low-level latency-insensitive channels, such as AXI-Stream [9]. The streaming model can be applied for communication across FPGAs, however, existing streaming communication framework [26, 33, 34] often do not have transport protocols or collective abstractions.

FPGA Development Platforms. Modern FPGA platforms adopt various virtualization methodologies [13, 83, 99] for FPGA resources. Most simplify development with a static *shell* for resource management and data movement, with some offering additional *services* like transport layer networking, and the host-device interaction relies on *runtime* libraries. This approach allows developers to concentrate on designing the application kernel. Many commodity platforms [54, 59] implement a partitioned memory model, which permits data movement from FPGA applications to FPGA memory while restricting direct access to host CPU memory. In contrast, shared virtual memory platforms, such as Coyote [62] and Optimus [70], offer a virtualized and unified memory space between CPU and FPGA.

Network-Attached FPGAs. FPGAs today feature 100 Gb/s transceivers, enabling direct processing of network data [81, 105]. FPGA-based Smart-NICs [2, 14, 28, 35, 66, 67, 98, 103, 119] perform programmable packet filtering but often leave the network stack to the CPU software, limiting their applicability to FPGA applications. Distributed machine learning [3, 12, 19, 77, 118], and data processing [24, 61, 65] applications capitalize on network-attached FPGAs. Following this trend, there is an increasing effort to develop hardware network stacks on FPGAs, such as UDP [47, 107], TCP [4, 27, 56, 87, 94], and RDMA [65, 69, 91, 95]. With the growing demands and the increasingly distributed nature of these applications, their communication patterns have become more complex, motivating the need for high-level collective abstractions on FPGAs. Therefore, simply offloading the network stack is often insufficient for complex applications in distributed settings.

3 Related Work

Collective for Accelerators. MPI implementation of collective communication are becoming more accelerator-aware, e.g., GPU-aware MPI [80, 102, 111] or FPGA-aware MPI [22]. In GPU-Direct RDMA collective libraries, e.g., NCCL [74] and RCCL [5], the network data can be directly forwarded to the GPU memory from the commodity RNIC via the shared PCIe switch, bypassing the CPU memory. However, FPGAs can connect directly to the network, and as such, the RDMA stack in ACCL+ resides completely in FPGA, eliminating the need for an external NIC. ACCL+ can provide streaming interfaces directly to FPGA kernels, in addition to the standard READs/WRITEs to memory used by commodity RNICs, therefore reducing latency by bypassing the memory hierarchy. Finally, the commodity RNICs typically lack offload capabilities, with collectives implemented on GPU cores, leading to computation and communication contention on the GPU which affects performance [51, 79]. Thus, ACCL+ could serve as a collective offload engine for GPUs in the future.

FPGA-based Collectives. Projects such as Galapagos [30, 97] and EasyNet [45] provide in-FPGA communication stacks for data exchange within a cluster, serving as a foundation for collectives without an external NIC. TMD-MPI [88, 89] orchestrates in-FPGA collectives using embedded processors, yet its bottleneck lies in control due to sequential execution in low-frequency FPGA microprocessors. Collective offload with NetFPGA [6–8] has been explored, but static collective offload engines limit flexibility and often rely on software-defined network switches for orchestration. SMI [26] proposes a streaming message-passing model, exposing streaming collective interfaces to FPGA kernels. While SMI enables kernels to initiate collectives directly, it employs dedicated FPGA logic for collective control, limiting flexibility for post-synthesis reconfiguration. In an earlier prototype, ACCL [46], we focused primarily on message-passing collectives for FPGA applications. However, the coordination of collectives required CPU involvement, it lacked significant streaming support, and was not tested at scale.

Collective Offload for CPUs. BluesMPI [11, 96] offloads collective operations to a BlueField DPU, demonstrating comparable communication latency to host-based collectives, but it does not target accelerator applications. The latency of ACCL+ targeting host data matches BluesMPI, even with BluesMPI ARM cores working at ten times the frequency.

Multi-FPGA Frameworks. Frameworks like ViTAL and its successors [112–114] propose FPGA resource virtualization and compilation flows for mapping large designs onto multiple FPGAs through latency-insensitive channels. OmpSs@cloudFPGA [25] introduces a multi-FPGA programming framework that partitions large OpenMP programs with domain-specific programs into smaller distributed parts for execution on FPGA clusters, providing communication through static, compile-time-defined send/recv and collective opera-

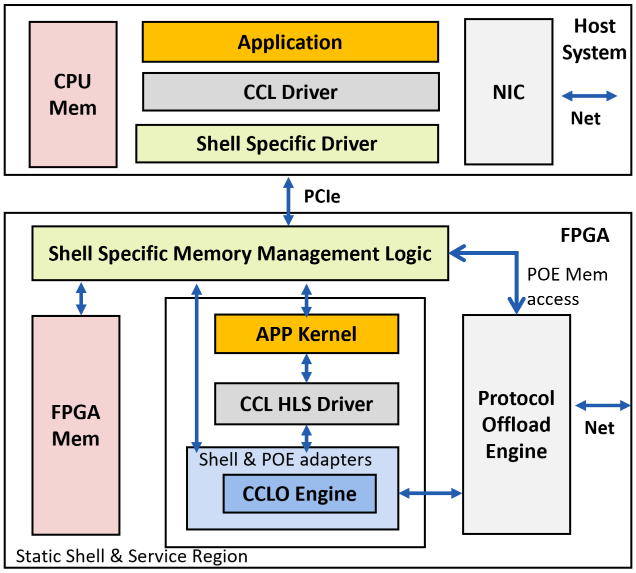


Figure 2: System overview of the FPGA-based collective communication library.

tions supporting only the unreliable UDP protocol. ElasticDF [3] and FCsN [40] present domain-specific frameworks for automatically distributing large neural network model inference across FPGAs with hardware UDP/TCP send/recv for FPGA-to-FPGA data movement. These projects are complementary to our work, and integrating ACCL+ will enhance their flexibility and performance.

4 ACCL+: An FPGA Collective Engine

ACCL+ is an FPGA-based collective abstraction designed for both FPGA and CPU applications, focusing on versatility and adaptability. Its primary goals include:

G1: Offering a standard collective API that abstracts different platforms and protocols from the application layer.

G2: Providing flexibility to dynamically select collectives and their algorithms at runtime, and to modify them without major architectural changes.

G3: Ensuring portability across various FPGA platforms and communication models for a wide range of applications.

G4: Supporting multiple transport protocols under a high-level collective abstraction.

G5: Providing high-throughput and low-latency performance for various collectives.

To achieve these goals, ACCL+ features a modular design that separates platform-specific and transport layer components from the core collective design. Its architecture includes layers of abstraction in both software and hardware, as shown in Figure 2, enabling a central CCL offload engine (CCLO) to adapt to diverse platforms and communication protocols. In this section we will describe each layer.

4.1 Application Interface

To satisfy **G1**, ACCL+ provides standard APIs for both CPU and FPGA applications. ACCL+ implements two drivers that offer similar, platform- and protocol-agnostic collective APIs for these scenarios. The ACCL+ drivers expose an MPI-like API, catering to the message-passing paradigm and facilitating the porting of existing MPI-based applications to ACCL+ collectives, and a streaming collectives API to overlap communication and computation in hardware.

ACCL+ Drivers. The host-side CCL driver allows initialization and runtime management of platform and ACCL+ data structures and hardware, as well as protocol offload engine (POE) initialization, i.e., setting up sessions for TCP or queue-pairs for RDMA. The CCL HLS driver is not capable of such initialization, and therefore the application must perform host-side initialization before any FPGA application kernels are started. We provide a more detailed description of ACCL+ initialization in Appendix A.

Listing 1: Reduce collective API in C++.

```
CCLRequest *reduce(BaseBuffer &buf, unsigned int
      count, unsigned int root, reduceFunction func,
      communicatorId comm_id, flagType flags);
```

MPI-like Collective API. This API require the application to store data in memory before invoking collectives. Listing 1 shows the MPI-like collective API, including arguments like datatype, buffer pointer, and element count, along with flags indicating buffer location (host or FPGA memory) and the option for synchronous calls. To facilitate portability, message passing collectives operate on an ACCL+ specific buffer class which can wrap normal C++ arrays with additional platform-specific information. Common collectives, such as reduce, broadcast, and barrier, are supported. Each MPI-like collective call in the host CCL driver has a corresponding HLS API call with a similar syntax for direct invocation from FPGA kernels.

Streaming Collective API. This API allows data to originate and terminate at the stream interfaces between the FPGA application kernels and the ACCL+ hardware, instead of in memory buffers.

Listing 2: Example kernel using streaming send in HLS.

```
// set up command and data interfaces
cclo_hls::Command cclo(cmd, sts, communicator);
cclo_hls::Data data(data_to_cclo, data_from_cclo);
// issue streaming send command without buffer argument
cclo.send(type, count, dst_rank);
// push data in streams to network without buffering
for (int i = 0; i < N; i++) {
    data.push(/* generate data */); }
cclo.finalize(); // wait for send completion
```

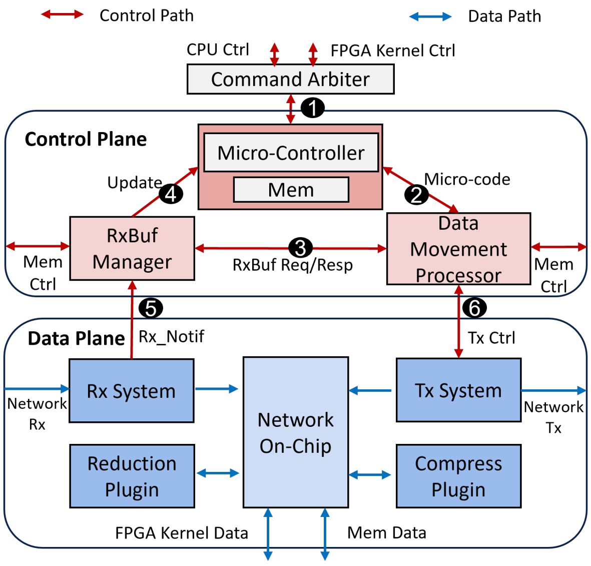

Figure 3: Hardware architecture of CCLO engine.

Listing 2 demonstrates an example FPGA kernel issuing a streaming send command to the CCLO engine (line 5) and subsequent pushes to the CCLO streaming data interface, 64B per cycle (line 8), followed by a wait for CCLO completion. The HLS-based streaming APIs are tailored for FPGA applications running in a streaming fashion and this code is synthesizable with HLS tools. HDL-based FPGA kernels can interact with the collective engine directly, through the same interfaces. Additionally, the host can also call streaming collectives via the host-side CCL driver.

4.2 CCLO Engine

Our approach to satisfying **G2**, i.e., achieving flexible collective implementation in hardware, differs from related work. One method deploys all collective modules in FPGA fabric simultaneously [26, 45], consuming extensive resources and not allowing modifications to the collective algorithms without recompiling the entire design. Another method pursues flexibility by implementing the collectives in embedded micro-controllers (uC) on FPGAs [89], which are often limited by a low clocking frequency, e.g., 200 MHz, and the sequential execution nature, thus sacrificing performance.

Our Approach. We utilize a hybrid approach that leverages the strengths of both methods. To ensure flexibility, low latency, and high throughput, the key design principle is to *decouple the CCLO logic into the flexible control plane and the parallel data processing plane*. The CCLO control plane is flexible, centered around an embedded uC [108], which enables the implementation of different collective algorithms through firmware updates without needing to refactorize the entire design and re-synthesize. The CCLO data plane contains independent latency-optimized hardware modules with wide data path for concurrent execution. Moreover, to further reduce the load on the uC, *we minimize its code footprint by offloading tasks* such as packet assembling and tag matching to hardware. Additionally, interactions with memory controllers are offloaded to dedicated hardware, preventing the uC from stalling during memory accesses. As a result, the uC handles a set of high-level data movement primitives that facilitate the implementation of the actual collective algorithms.

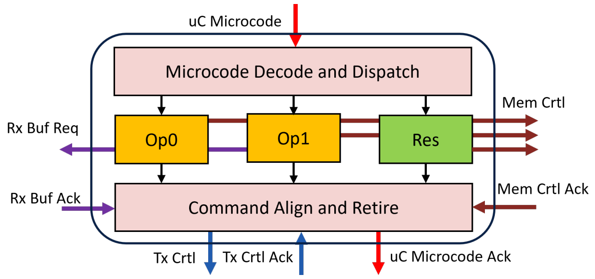

Figure 4: Architecture of the Data Movement Processor.

Figure 3 shows the overall architecture of the CCLO engine, which orchestrates the collective data movement through a set of standardized CCLO interfaces to interact with the application, the memory and the network. The CCLO accepts communication requests from the host or application kernels, communicates with the protocol offload engine, manages buffers in FPGA memory (HBM, DDR, BRAM), and manage data streams from other kernels.

4.2.1 Flexible Control Plane

The CCLO control plane contains a uC that issues high-level data movement commands to a hardware-accelerated data movement processor (DMP). The CCLO control plane also contains a RxBuf Manager (RBM), which manages temporary Rx buffers. The uC, DMP, and RBM store states in a small configuration memory implemented as FPGA BRAM. The configuration memory is also accessible by the CPU through MMIO and includes information about the communicator, e.g., session or queue pair IDs, pool of allocated Rx buffers. Besides, FIFO queues are incorporated into all command paths, allowing multiple in-flight instructions. Currently, these FIFO queues are set to a depth of 32, which can be further increased at compile time.

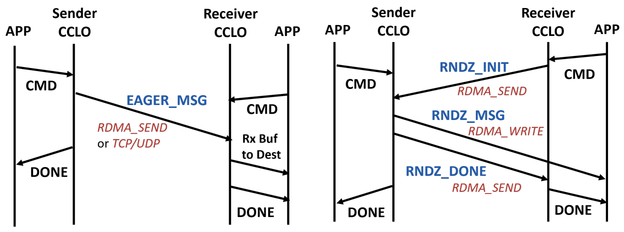
Collective Programming with Primitives in uC. The uC firmware implements various collective algorithms and synchronization protocols, such as eager and rendezvous, using high-level primitives. Each primitive instruction consists of three slots: two for operands (data entering CCLO) and one for the result (data exiting CCLO). This design aligns with common collective operations, e.g., reduce, which processes two inputs to produce one output. Unary operations like send can disregard one operand slot. Operand slots include opcodes and flags that define the data movement specifics, dictating *when* and *where* data should move. For instance, data can be moved immediately or upon arrival, sourced from a memory buffer when using the MPI-like API, or from the data interface of the FPGA kernel when using the streaming API. Additionally, the data can either be sent to a remote node through the network or remain local as intermediate results. These elements can be combined to cover nearly all data movement needs in collective operations.

Data Movement Processor. The primary purpose of the DMP is to conceal memory access latency from the uC, ensuring that the uC does not stall for memory accesses or wait for data streams, as shown in Figure 4. Upon the receipt of the microcode generated by the uC ❷, the DMP first decodes the microcode and dispatch the code to different compute units (CUs). The DMP primarily consists of three CUs, aligning with the structure of the primitive, each responsible for controlling one or more components in the datapath. If the microcode indicates to fetch data from memory and forward it to the network, the CU issues memory requests to the target address and then issues the Tx control ❻ to the data plane, ensuring the data plane waits for incoming memory streams to forward to the network. If the operand is expected to come over network and buffered in temporary buffers, the DMP also sends out requests periodically to the RBM to check if the message has arrived ❸. The DMP operates in a pipelined fashion, and each operand slot independently interprets its instruction fields, emitting commands for corresponding datapath blocks. Upon receiving acknowledgements from datapath blocks, the DMP signals instruction completion to the uC.

RxBuf Manager. The RBM alleviates uC load by autonomously managing temporary Rx buffers and reassembling messages from network packets, especially under the eager protocol. It uses a state table in FPGA on-chip memory and a set of finite-state machines (FSMs) to handle Rx buffers. Upon notification of incoming messages ❺, RBM checks the state table using the message ID. If the message is new, it identifies a free Rx buffer from the configuration memory and issues requests to store the message there. Since messages are often split into packets that may arrive interleaved, RBM uses the state table to piece together packets into complete messages in the appropriate Rx buffer. When a full message is assembled, RBM updates the exchange memory's buffer list ❹, marking it ready for retrieval, and stores essential metadata (source ID, tag, Rx buffer address) for tag matching, facilitating buffer identification by the DMP.

4.2.2 Parallel Data Plane

Rx and Tx System. In ACCL+, we implement a message protocol that includes a signature for each message. This signature contains metadata such as message type, destination rank, length, tag, and a sequence number to track the order of messages. The Tx and Rx systems feature a 512-bit wide data path and are responsible for packetizing and depacketizing the signature along with the user payload. They also issue commands to interact with the POEs. The processes of issuing commands, inserting signatures, and parsing can vary across different synchronization protocols. Both the Rx and Tx systems incorporate a finite state machine to manage these variations appropriately.



(a) Eager protocol (b) Rendezvous protocol

Figure 5: CCLO eager and rendezvous with send/recv.

Network On Chip. All the data streams internal to the CCLO can be routed in the granularity of packets based on the dest field that comes along with the data.

Streaming Plugins. The plug-ins are utilized for applying unary and binary operations to in-flight data and can be enabled at compile time. Binary operations are typically utilized to implement reductions - sum, max, etc. Unary operators may implement compression or encryption. Each of the plug-ins is a streaming kernel and may implement more than one function, in which case the control plane will specify the desired function by setting its dest field of the plugin input stream.

4.2.3 Message Synchronization Protocol

The CCLO supports two distinct message synchronization protocols: eager and rendezvous. Thanks to its flexible design, both protocols can be tuned dynamically at runtime.

The eager protocol allows the sender CCLO to immediately send data upon receiving a command, and the receiver buffers the data in the CCLO Rx buffer before moving it to its destination (either in memory or in FPGA kernel streams depends on runtime configuration), as shown in Figure 5a. This protocol is preferred for small messages to minimize latency since there is no handshake phase and small message sizes incur little overhead. We implement the eager protocol using UDP/TCP or two-sided RDMA verb.

In contrast, the rendezvous protocol requires resolving the result buffer address before transmission, as shown in Figure 5b. Once resolved, data is directly placed into the destination, eliminating the need for temporary buffering. We use two-sided RDMA `SEND` for rendezvous handshake messages, and we use one-sided RDMA `WRITE` for actual message transmission bypassing the intervention from the receiver uC. Given that one-sided RDMA operations are transparent to the receiver uC, a key design decision is how the uC should detect message arrival. One approach is to make the uC pe-

Table 2: Algorithms used for example collectives.

Collective	Eager	Rendezvous
Bcast	One-to-all	One-to-all;Recursive doubling
Reduce	Ring	All-to-one;Binary tree
Gather	Ring	All-to-one;Binary tree
All-to-all	Linear	Linear

riodically poll the destination buffers in memory. However, this approach increases uC overhead and latency, especially since buffers may be located in various memory systems like CPU or FPGA memory. Additionally, if the destination is a streaming interface rather than a buffer, polling is not feasible. Therefore, we choose an alternative method: the sender uC dispatches a small control message using two-sided RDMA `SEND` immediately after the one-sided RDMA `WRITE`. This control message is processed by the receiver uC to confirm the completion of the data transfer. Though not depicted in Figure 3, the uC contains specific ports that directly interact with the data plane for rendezvous handshake and control messages, bypassing the RBM and DMP. These command paths also incorporate FIFO queues.

4.2.4 Collective Algorithms

We provide different implementations for various collectives, and users can define their own. Collectives are realized by specifying a communication pattern as a C function in uC firmware, and then executing this pattern through instructions in DMP and Tx/Rx System on each FPGA in the communicator. Table 2 summarizes the algorithms and communication patterns used to implement collectives. For eager protocols with unreliable transmission (e.g., UDP), we currently use simple algorithms like ring and one-to-all to minimize the chances of packet loss. Future firmware improvements can enhance POE awareness for finer-grained algorithm selection. In contrast, when using RDMA, the rendezvous protocol employs more advanced algorithms like tree or recursive doubling. The token-based flow control in RDMA makes it well-suited for these sophisticated algorithms in the rendezvous protocol. For broadcast, we implement a simple one-to-all algorithm with small rank size, while with large rank size, we adopt more advanced recursive doubling such that the data transmission is not bottlenecked at the root rank. For gather and reduce, we apply a similar strategy. With small message size, we adopt an all-to-one approach to reduce the number of intermediate hops needed. On the other hand, with larger message sizes, to avoid a potential in-cast problem with the all-to-one approach, we adopt a tree-based algorithm. Tuning of the algorithms for specific collectives can be done at runtime through configuration parameters to the CCLO engine.

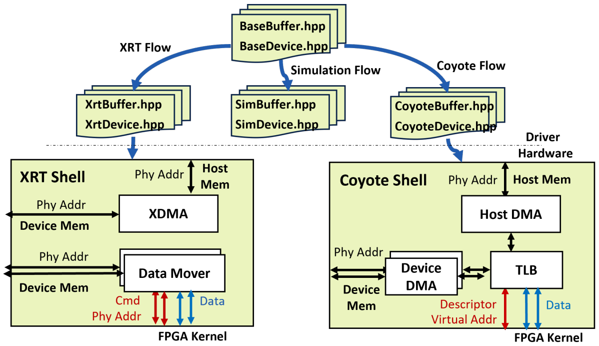


Figure 6: CCL driver for different memory managements.

4.3 ACCL+ Platform Support

A platform is defined by a software interface specification, defining how FPGA memory is allocated and manipulated, and how FPGA kernels are called, and a hardware interface specification, i.e., how FPGA kernels, including the CCLO, plug into hardware services in the FPGA. To facilitate portability between platforms and to satisfy **G3**, the ACCL+ host CCL driver layers the APIs on top of generic class types, such as BaseBuffer for memory allocation and data movement between host and FPGA, and BaseDevice for CCLO invocation. These are specialized to individual platforms through class inheritance, as illustrated in Figure 6. Each specific CCL class interfaces with platform-native drivers and employs distinct processes for handling data movement. ACCL+ supports both the commercial AMD Vitis platforms and the open-source Coyote platform [62], as well as a virtual simulation platform. New platforms can be added easily.

Integration with Coyote. Coyote utilizes a shared-memory model with a central memory management logic governed by a software-populated translation lookaside buffer (TLB). This TLB records allocated pages and facilitates virtual-physical address translation. The FPGA kernel issues memory requests through a descriptor interface, using virtual addresses directed to either host or device memory. The TLB interprets these requests, interacting with host DMA or device DMA based on the physical location of the memory page, forwarding the data to FPGA applications in a streaming manner. If a memory page is not registered during TLB lookup, it triggers an interruption to the CPU, resulting in a page fault and introducing a performance penalty. Therefore, the CCL driver, specifically the CoyoteBuffer class, eagerly maps pages to the Coyote TLBs when instantiating buffers. We modified Coyote, during integration, to increase the associativity of the TLB cache and expand the number of streaming interfaces Coyote provided to a single application region, from a single interface to three interfaces which is required by the CCLO engine. We also implemented a Coyote-specific adapter to convert from CCLO (R)DMA request syntax to Coyote-specific syntax, as indicated in Figure 7.

Integration with Vitis. Vitis platforms implement a partitioned memory model and the Xilinx Runtime (XRT) [59] is utilized by the CCL driver for low-level interaction with the platform. A XRT-controlled XDMA IP core [110] moves data between host and FPGA memory, while FPGA memory is accessed by FPGA kernels through Data Movers [109]. The CCLO memory interfaces align with the Data Mover interfaces, eliminating the need for dedicated memory interface adapters for the Vitis platform. As a result of the partitioned memory, the CCL driver explicitly migrates buffers between host and FPGA memory prior to or after the collective execution if the data originally resides in host memory - a process denoted staging. Staging creates performance penalty when ACCL+ collectives target host memory, as observed by related work on collective offload on DPUs [96]. Therefore, Vitis platforms favor distributed FPGA applications where data is streamed or resides in FPGA memory.

Simulation Platform We implemented an additional simulation platform for debugging and performance optimization. This simulation platform roughly models a Vitis platform, whereby FPGA chip interfaces (XDMA, Ethernet) are replaced by ZMQ [48] interfaces. A stand-alone simulated FPGA node is compiled to include memory and one ACCL+ CCLO Engine. The ACCL+ host driver includes dedicated buffer and device abstractions capable of connecting to the simulated node via ZMQ. ACCL+ provides convenient launch scripts to set up a simulated cluster of such simulation nodes.

The simulated nodes connect to each other through ZMQ rather than real Ethernet. While the simulated ZMQ network may lack realistic features like packet loss and reordering, it serves as a valuable functional simulation.

ACCL+ provides two simulation levels of the CCLO engine: functional simulation using compiled ACCL+ HLS source code and C firmware, and cycle-accurate (but slow) simulation using Verilog HDL generated from compiling the CCLO HLS code and firmware. For FPGA applications requiring streaming data exchange between FPGA kernels and the CCLO, we provide a bus functional model of the CCLO that connects via ZMQ to the simulated node.

4.4 Protocol Offload Engine

To satisfy **G4**, ACCL+ supports several 100 Gb/s protocol offload engines (POE) in hardware: UDP [107] and TCP [45] on Vitis platforms, and all the network services provided by Coyote. Notably, ACCL+ supports collectives with RDMA by leveraging the unified and virtualized memory space across the FPGA and the CPU provided by Coyote. All the POEs expose streaming control and data interfaces to other modules and some POEs (e.g., TCP) require direct memory access for packet buffering for re-transmission. For portability, the CCLO Engine has a set of POE-independent internal interfaces - two pairs of meta and data streaming interfaces (one for Tx and one for Rx). The meta interfaces contains various sub fields to indicate the op code, data length, communication session IDs, etc. The meta interfaces are then adapted to the POE interfaces with dedicated FPGA components as exemplified in Figure 7. The selection of the POE and its adapters is a compile time parameter of the CCLO Engine.

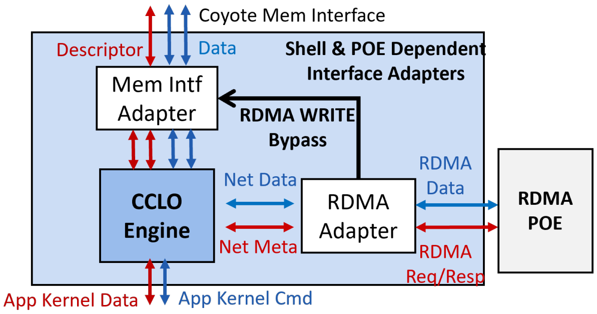

Figure 7: ACCL+ with Coyote-RDMA data path with corresponding POE and memory adapters.

Coyote RDMA POE. It supports standard RDMA verbs, including one-sided operations like `WRITE` and two-sided operations like `SEND`. The RDMA POE incorporates various streaming interfaces for RDMA commands, memory commands, and data. *Default Configuration:* On the initiating side of a `WRITE` operation, the RDMA POE issues memory requests directly to the Coyote memory management logic, fetching data from either host or device memory and streaming it through the network. On the passive side of `WRITE`, the data is directly written to virtualized memory. *ACCL+ Integration:* In the ACCL+-enabled configuration, the CCLO engine acts as a "bump-in-the-wire" engine between the memory management unit and the RDMA POE, as shown in Figure 7. On the initiating side of a `WRITE`, the CCLO engine issues RDMA commands and is responsible for data preparation, either fetching from memory or obtaining it from the application kernel in the form of streams. On the passive side, data bypasses the CCLO and is directly forwarded to the memory management unit. For single-sided `WRITE`, streaming into the application kernel is also possible by configuring the datapath at compile time. The CCLO engine consistently manages data and metadata streams from two-sided `SEND`. For CCL driver with RDMA, a queue pair needs to be exchanged between each node and needs to be registered to the RDMA POE.

TCP POE. The TCP POE supports up to 1,000 connections and can be configured to support window scaling and out-of-order packet processing. As a reliable transmission protocol, the TCP POE also needs to access protocol-internal buffers for re-transmission. The CCLO engine prepares and accepts all the data streams with the TCP POE. For CCL driver with TCP POE, a TCP session needs to be established between each node to construct the communicator.

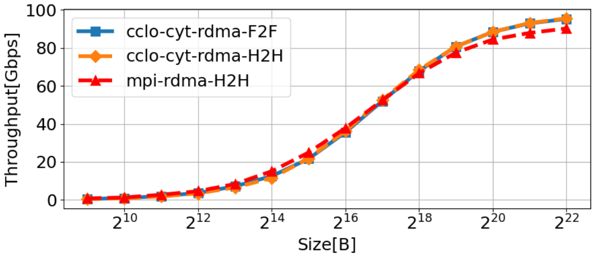

Figure 8: Send/Recv throughput comparison.

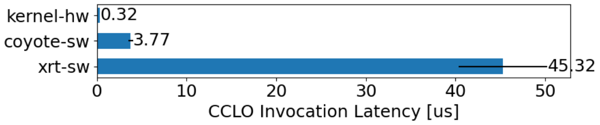

Figure 9: CCLO invocation latency from different parts.

5 Microbenchmark Evaluation

We evaluate ACCL+ on a heterogeneous cluster with 10 AMD EPYC CPUs and 10 attached FPGA cards (Alveo-U55C). Each CPU is equipped with a 100 Gb/s Mellanox NIC, while each FPGA features a 100 Gb/s Ethernet interface. All devices are connected to Cisco Nexus 9336C-FX2 switches. Evaluation scenarios consider data residing on the FPGA for distributed FPGA application (suffix *F2F*) and on the CPU for distributed CPU applications (suffix *H2H*). For F2F, the FPGA application data traverses the network directly through ACCL+. As a baseline, the FPGA data initially is moved to the CPU memory and then is transmitted via a commodity NIC. In H2H, the CPU application data is transferred to the FPGA and then transmitted with ACCL+. This is compared to transmitting the CPU data directly with a commodity NIC. We use the notion of *cclo* with different suffixes to indicate different configurations of ACCL+. The focus of these experiments is evaluating RDMA running with Coyote (suffix *cyt*) due to space limitations. We nevertheless present some results with ACCL+ running TCP on top of the Vitis XRT (suffix *xrt*) platform to compare it to ACCL [16], which utilizes an embedded micro-controller to orchestrate collective operations. Experiments configure both MPI-like collectives with memory pointers and streaming collectives. For the H2H experiments, MPI-like collectives are mandatory, while the F2F experiments are configured to run with streaming collectives. ACCL+ operates at 250 MHz in micro-benchmarks, with varying frequency in the use-case study due to the design complexity. The comparisons involve MPICH 4.0.2 with TCP and OpenMPI 4.1.3 compiled with RDMA using OpenUCX 1.13.1 on the cluster CPUs and Mellanox 100 Gb/s NICs. MPI libraries self-configure for collective algorithms and synchronization protocols. Each micro benchmark experiment is averaged over 250 runs.

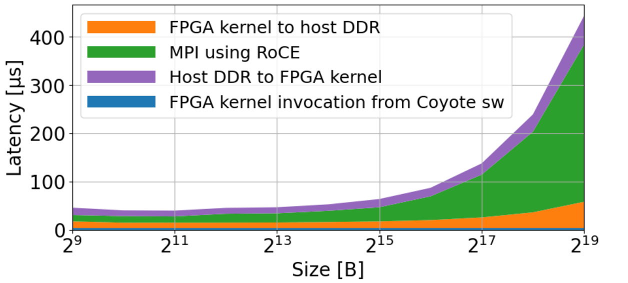

Figure 10: Latency breakdown of broadcasting FPGA produced data using software MPI with eight ranks with Coyote.

Send/Recv Throughput. We first evaluate pure throughput using send/recv. Figure 8 shows the throughput comparison of ACCL+ with Coyote RDMA and software MPI with RoCE backend. Notably, ACCL+ with RDMA achieves a peak throughput of 95 Gb/s, nearly saturating the network bandwidth. Compared to software MPI variants, ACCL+ exhibits comparable and slightly higher peak throughput. This is attributed to the FPGA network stack's ability to process network packets at line-rate in a pipelined fashion. Moreover, there is minimal distinction between F2F and H2H for ACCL+, thanks to the unified memory space provided by Coyote and both host memory access through PCIe and FPGA memory access offer higher bandwidth than the network.

Invocation Latency. Figure 9 shows the invocation latency of the CCLO engine to execute a dummy NOP operation, which includes the time from receiving request untill the acknowledgement. For FPGA kernels that can directly interact with the CCLO engine, the invocation latency is minimal compared to software invocation from the host, showing a clear benefit of bypassing host control with FPGA-based applications. Coyote software driver contains a thin and optimized layer for invocation and scheduling and the resulting CCLO invocation time mainly consists of a PCIe write and a PCIe read latency. In contrast, the XRT invocation latency is significantly higher as it is not intended for fine-grained data movement.

FPGA-to-FPGA with Software MPI. To enable a more direct ACCL+ vs. software MPI comparison for executing collectives between kernels on FPGA, we model the execution time for MPICH- and OpenMPI-based device-to-device data movement, which includes: (1) moving data from FPGA HBM/kernel to host DDR through the PCIe, (2) executing the collective using software MPI, (3) moving data from host DDR to FPGA HBM/kernel, and (4) invoking the next computation kernel. We use the CCLO host invocation time as an approximation of the invocation time of other computation kernels. We measure the duration of each of the above steps and present a break-down of execution time of the collective with Coyote platform in Figure 10. We could observe that the PCIe transfer time is dominant for small messages while the collective time is dominant for large messages. Such

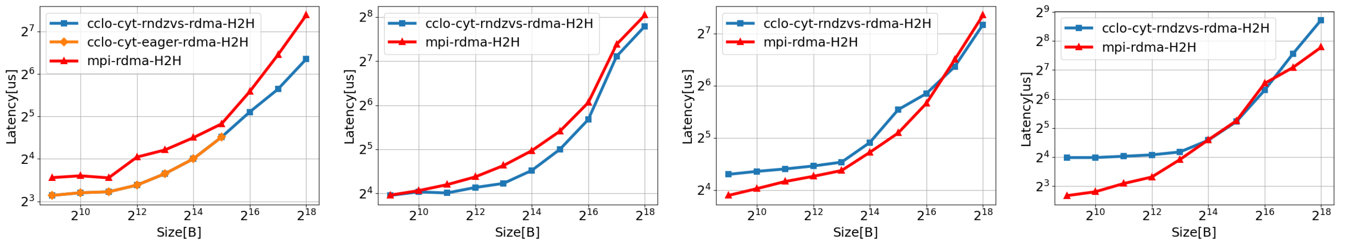
Figure 11: Collective latency comparison between ACCL+ RDMA and software MPI RDMA with eight ranks and device data



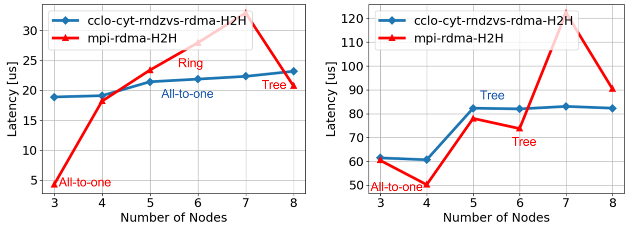
(a) Broadcast (b) Gather (c) Reduce (d) All-to-all

Figure 12: Collective latency comparison between ACCL+ RDMA and software MPI RDMA with eight ranks and host data

breakdown for XRT platform can be derived by changing the Coyote invocation latency to XRT invocation latency.

F2F Collective Latency RDMA. Figure 11 illustrates the latency of ACCL+ RDMA collectives with various message sizes on eight Alveo-U55C boards. This is compared to FPGA-to-FPGA data movement with software MPI over RDMA. For clarity, we present experiments showcasing better performance between eager and rendezvous collectives. The algorithms for each collective in ACCL+ are detailed in Table 2. Notably, ACCL+ exhibits significant performance benefits compared to its software counterpart. This advantage stems from the hardware's efficient execution of collectives and the direct network access within the FPGA device, eliminating the need for data copying to CPU memory.

H2H Collective Latency RDMA. Figure 12 illustrates a latency comparison between ACCL+ and software MPI targeting host data. The performance gains with ACCL+ vary across different collectives. Notably, for operations like broadcast and gather, ACCL+ consistently outperforms software MPI across a range of message sizes. However, for other collectives such as reduce and all-to-all, ACCL+ shows only marginal benefits and, in some cases, falls short of software MPI performance. One reason is that software MPI adapts its algorithms more finely to different configurations, whereas ACCL+ currently supports only a limited set of options. However, by offloading collective to hardware, CPU cycles could be freed for other computation tasks. Besides, by comparing ACCL+ F2F and H2H performance, we could observe that the ACCL+ collective latency has minimal difference because Coyote with unified memory allows direct memory access to both host and FPGA memory.

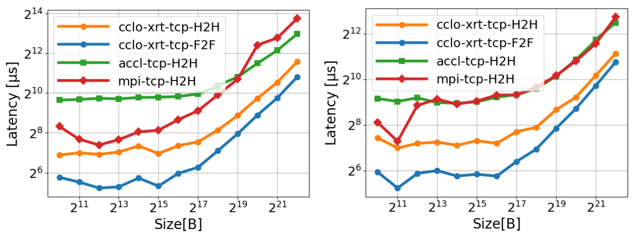


(a) 8KB message size. (b) 128KB message size.

Figure 13: Latency vs. rank sizes (Reduce).

Effect of Synchronization Protocol. Despite the simpler algorithms used by most eager collectives, such as one-to-all or ring, we observe that eager collectives can sometimes outperform rendezvous collectives with small message sizes, as seen in broadcast. This is because eager collectives do not require a handshake to resolve addresses.

Collective Algorithm and Scalability. Figure 13 illustrates the impact of algorithm selection and scalability on both ACCL+ and software MPI during collective executions. For an 8 KB message size, ACCL+'s reduce operation adopts an all-to-one algorithm, resulting in minimal latency increase across nodes. However, recognizing potential bottlenecks at the root node with this approach, ACCL+ switches to a binary tree algorithm for larger message sizes, such as 128 KB. In this case, an increase in latency is observed after



(a) Gather.

(b) Reduce.

Figure 14: Comparison of collective performance between ACCL+ TCP with XRT, software MPI TCP and ACCL TCP.

four nodes, stabilizing until eight nodes due to a consistent tree depth. On the other hand, software MPI exhibits a more fine-grained approach to algorithm selection based on the scale of the message size and the number of nodes. For instance, it deploys three distinct algorithms within the 8 KB range: an all-to-one algorithm for fewer than four nodes, a ring protocol for four to eight nodes, and an optimized binomial algorithm for 8 nodes. Additionally, for larger messages, software MPI switches between an all-to-one algorithm below three nodes and a binomial tree algorithm between four and eight nodes. This fine-grained algorithmic tuning contributes to its superior performance in certain H2H scenarios. While software MPI's approach involves detailed algorithmic tuning, ACCL+'s flexible design allows for potential future enhancements through additional fine-grained tuning to further optimize performance.

XRT Platform and TCP. In Figure 14, we evaluate ACCL+ TCP with the XRT platform and compare it against software MPI with TCP. We also include a comparison with ACCL [46] collectives, which employs a similar embedded processor to orchestrate collectives and supports TCP on the XRT platform. Notably, ACCL+ TCP consistently outperforms its software counterpart across all configurations, benefiting from the line-rate processing capabilities of a hardware TCP POE. Furthermore, ACCL+ demonstrates superior performance compared to ACCL. While both ACCL+ and ACCL utilize embedded microprocessors for collective orchestration in hardware, ACCL+ distinguishes itself by offloading more tasks to the hardware data plane, such as utilizing the RxBuf Manager for packet assembling. In contrast, ACCL relies more on the microprocessor, leading to lower performance. When comparing ACCL+ TCP for serving host applications and device applications, a significant overhead is observed for host applications. This is attributed to the limitation of XRT platform, which prohibits direct data movement from the FPGA kernel to host buffers, resulting in a memory-copy overhead. Additionally, the XRT software invocation latency is notably higher, as indicated in Figure 9.

6 Case Study: Deep Learning Recommendation Model

Deep Learning Recommendation Models (DLRM) are widely used in personalized recommendation systems for various scenarios [23, 37, 117]. The structure of a DLRM includes two major components: memory-bound embedding layers and computation-bound fully-connected (FC) layers. These models handle both dense and sparse features, with the latter stored as embedding vectors in tables. In inference, these vectors are accessed via indexes, resulting in multiple random memory accesses. The retrieved embedding vectors are then concatenated with dense features and passed through several FC layers to predict the click-through rate, incurring heavy computational loads due to vector-matrix multiplication.

DLRM has been a focal point for acceleration on GPUs and FPGAs, given that CPU solutions are generally constrained by both random memory access and computation [43, 49, 63]. GPU-based solutions [42, 49, 52, 58] mostly accelerate the computation-bound FC layers to gain high throughput. However, the large batch sizes required for efficient GPU computation, coupled with random memory access, often lead to increased latency (tens of milliseconds). FPGA-based techniques [57, 71] overcome the embedding lookup bottleneck by distributing tables across memory banks and enabling parallel accesses, leveraging high-bandwidth-memory (HBM) and on-chip memory (BRAM/URAM). However, this approach is constrained by the requirement for embedding tables to fit within a single FPGA's memory (e.g., 16 GB HBM on AMD Alveo-U55C), limiting the size of embedding layer. Additionally, the finite computational resources on a single node pose restrictions on overall throughput for all FC layers.

6.1 Distributed DLRM Inference

We aim to demonstrate that ACCL+ can facilitate distributing DLRM inference across FPGAs to accommodate larger embedding layers, as in many large-scale industrial settings, while at the same time achieving low latency and high throughput. Table 3 shows the detailed configuration of such an industrial-level recommendation model [58]. In such a use

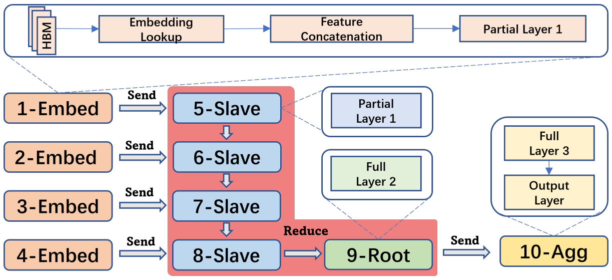

Figure 16: Conceptual design of partitioned DLRM, with $FC1$ decomposed and $FC2$, $FC3$ pipelined across nodes.

case, the embedding table does not fit into a single FPGA HBM and therefore both the embedding lookup and the computation are distributed across the network. This poses significant challenges for performance, scalability, and networking.

Vector-Matrix Multiplications Decomposition for DLRM. The computation pattern in DLRM inference involves a chain of three vector-matrix multiplications, with the inference output vector computed as a sequence of operations involving three matrices of FC layers ($FC1$, $FC2$, $FC3$) and a concatenated embedding vector. The concept of distributed vector-matrix multiplication has been extensively studied in literature [90] across CPUs and the same principle can be applied to an FPGA cluster. One common approach is *checkerboard block decomposition of matrix*, as shown in Figure 15. This method involves partitioning the matrix in terms of both rows and columns, while partitioning the vector ensures that processes associated with the same matrix row partition share the same sub-embedding vector. Each process can then perform partial computations, and the results belonging to the same row partition are concatenated and subsequently aggregated.

Decomposed and Pipelined Distributed DLRM. The partitioning strategy for the DLRM considers the need for balanced resource utilization, ensuring that the overall throughput is not limited by any process among all nodes. Typically, the computation load of the $FC1$ is significantly larger than subsequent layers like $FC2$ and $FC3$. To accommodate this, resource distribution should reflect the varying computation requirements. Additionally, for modern FPGAs with HBM, the capacity requires a minimum number of FPGAs to effectively store the embedding layer. A conceptual partitioned DLRM is illustrated in Figure 16. In this scenario, $FC1$ is decomposed and distributed across multiple FPGAs using the checkerboard block decomposition, and $FC2$ and $FC3$ are assigned to one FPGA each. The embedding tables are evenly distributed across nodes 1-4, with partial vectors transmitted to nodes 5-8, leveraging the network's low latency. Similarly, partial results computed on nodes 1-4 are forwarded to corresponding nodes 5-8, where an overall reduction of all partial $FC1$ results is conducted. The aggregated $FC1$ results are then forwarded to node 9 for $FC2$ computation, followed by node 10 for $FC3$ computation and final processing. Scaling resources according to the computation distribution requirements of each layer could lead to improved performance. For example, increasing the allocation of FPGAs for different layers based on their computational load. Such partitioning method requires diverse communication patterns by each node, such as send-only, send/recv, and reduction and ACCL+ provides a unified design supporting all the communication requirements of the DLRM through a standard interface. Additionally, for nodes that do not require reduction, the streaming reduction plugins of ACCL+ can be removed with a compilation flag, reducing resource consumption and improving routing and timing. Furthermore, the cross-node simulation provided by ACCL+ can facilitate the development process, reducing hardware debugging cycles.

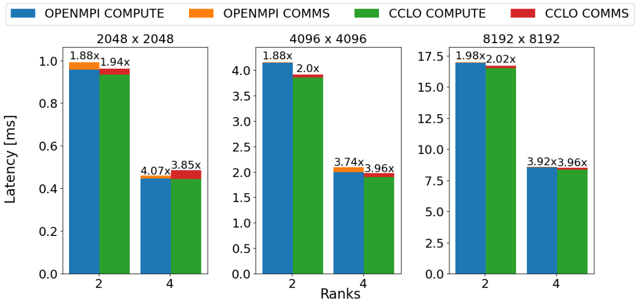

Figure 17: Speedup comparison and latency breakdown of distributed vector-matrix multiplication.

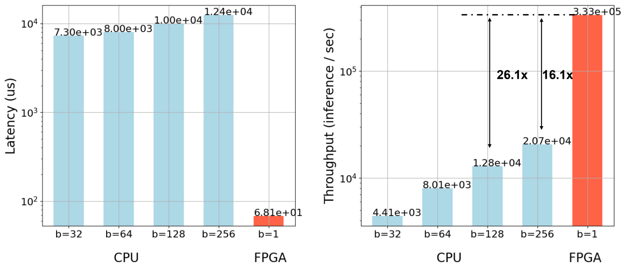
6.2 Use Case Evaluation

Distributed FC Layer Execution on CPU. We use an illustrative example to demonstrate how ACCL+ can be utilized to improve the efficiency of distributed work executing on CPU. In this use case, we distribute an FC layer workload (matrix-vector multiplication) by partitioning the weight matrix column-wise, with each rank receiving part of the input vector and a subset of the weight matrix columns. The matrix-vector product is obtained by summing the partial rank products using the reduce collective. For the implementation, we use the highly optimized Eigen library [39], distributing it with both ACCL+ RDMA and MPI RDMA. In this experiment we do not overlap computation and communication.

The overall execution time of the distributed FC layer is compared to its single-node execution, as depicted in Figure 17, where top-of-bar numbers indicate the speed-up compared to single-node execution. We observe that utilizing ACCL+ instead of MPI for the reduction generally results in lower matrix-vector computation time. This performance increase is most likely due to reduced pressure on the CPU cache, as ACCL+ utilizes FPGA memory for all intermediate reduction data structures. The figure indicates two instances of super-linear scaling, attributed to the weight matrix partitions fitting into either L2 (8 MB) or L3 (128 MB) caches



(a) DLRM latency.

(b) DLRM Throughput.

Figure 18: ACCL+ DLRM performance comparison.

on the CPU after partitioning, whereas the entire matrix did not fit in caches during single-node execution. The reduction time itself is higher in most cases due to an additional copy required to move data between Eigen result buffers and ACCL+ buffers, which can be eliminated with further optimization. Overall, distributing work with ACCL+ achieves lower latency, especially for specific configurations of FC size and number of ranks.

Distributed FPGA-based DLRM. We distribute an industrial DLRM model, as in Table 3, with ACCL+ on 10 U55C FPGAs following the same design principle as shown in Figure 16. The communication between the embedding node and the reduce slave node during each inference requires the transmission of a 3.2 KB partial embedding vector and a 4 KB partial result. Additionally, the reduction process spanning nodes 5 to 9 operates with a message size of 8 KB per inference. The achieved operating frequency is 115 MHz. We utilize 32-bit fixed-point precision for computation. All the application kernels utilize streaming collective APIs to interact with ACCL+. ACCL+ DLRM is configured with the TCP backend from XRT. Though the communication latency could be further optimized with ACCL+ RDMA, it is not on the critical path of overall latency as it is overlapped with computation. We also compare with CPU implementation [58], where the DLRM inference is run on an Intel Xeon Platinum 8259CL CPU @ 2.50 GHz (32 vCPU, Cascade Lake, SIMD supported) and 256 GB DRAM with TensorFlow Serving enabled. Figure 18(a) shows the latency comparison between ACCL+ and the CPU baseline. We evaluate various batch sizes on the CPU. On the other hand, ACCL+ works with streaming data without batching. The hardware implementation demonstrates two orders of magnitude lower latency compared to the CPU. This substantial latency reduction in the hardware implementation is attributed to the parallel arithmetic units in hardware and the significant latency introduced by random memory accesses. Figure 18(b) shows the throughput comparison. ACCL+ shows more than an order of magnitude higher throughput compared to CPU baseline.

Table 4: Resource utilization.

Component	CLB kLUT	DSP	BRAM	URAM
U55C(100%)	1303	9024	2016	960
CCLO	12.1%	1.6%	5.7%	0
TCP POE	19.8%	0	10.6%	0
RDMA POE	13.0%	0	5.3%	0
DLRM FC1	278.1%	580.1%	186.3%	798.3%
DLRM FC2	29.6%	85.1%	34.2%	97.9%
DLRM FC3	6.2%	16.1%	2.2%	20.8%

6.3 Resource Consumption

The resource utilization of ACCL+ components and the overall utilization of DLRM across nodes are summarized in Table 4. In the ACCL+ subsystem, the majority of resources are allocated to POEs, with the TCP POE being the most resource-intensive, while the CCLO engine utilizes comparatively fewer LUT and memory resources. DLRM utilization is categorized by different layers, and the presented utilization values represent the sum across multiple FPGAs after decomposition. Note that DLRM $FC1$ utilization exceeds 100%, reflecting the decomposition across 8 FPGAs (max 800%). The primary resource bottlenecks for DLRM are URAM, serving as fast on-chip memory for storing small embedding tables, and DSP, essential for matrix computations.

7 Discussion

In this paper we have explored the design of ACCL+ targeting efficient and high-speed offload of MPI-like collective operations. However, due to its flexible and portable design, ACCL+ can be utilized in various applications and scenarios beyond the demonstrated use cases. This section explores how ACCL+ can be extended for a broader range of users applications.

Integrating ACCL+ with Machine Learning Frameworks. While in HPC it is commonplace to develop distributed applications utilizing MPI collectives explicitly, in the field of Machine Learning, codes are often written by Data Scientists who reason about distributed execution in high-level terms such as data, model, or expert parallelism [20]. Integrating ACCL+ into popular machine learning frameworks like TensorFlow [1] and PyTorch [78] is therefore essential to enable its use in ML. Our ongoing work focuses on integrating ACCL+ into PyTorch's Distributed Data Parallel (DDP) [82] module. DDP supports various communication backends for collective operations, which are invoked automatically by the PyTorch execution orchestrator to distribute work to a cluster. We aim to add ACCL+ as a new communication backend to PyTorch DDP, enabling the use of FPGA-based smartNICs to enhance collective operations in AI training and inference.

Additionally, we plan to extend ACCL+ support to other machine learning frameworks.

ACCL+ for Streaming Applications. ACCL+ can also be used for distributed applications that do not require bulk synchronous parallel collective communications, such as streaming applications. In such a scenario, one could use ACCL+ as a transport layer for model-parallel, multi-FPGA streaming accelerators, e.g., Elastic-DF [3]. ACCL+ has existing streaming primitives and collectives which could be utilized for this purpose, as demonstrated in the implementation of the DLRM in Section 6. A more flexible transport based on ACCL+ would, for example, enable higher flexibility in partitioning DNNs to multiple FPGAs.

Implementing Other Distributed Programming Models with ACCL+. The shared memory (SHMEM) programming model [17] is gaining in popularity as it becomes evident that it enables finer-grained overlap between compute and communication on GPU-accelerated systems [50]. SHMEM libraries include MPI-like collectives but add asynchronous one-sided operations (put/get) and signals. These additional operations could be implemented easily into ACCL+ with minimal firmware modifications and no hardware recompilation. Utilizing ACCL+ could reduce the latency of one-sided SHMEM operations, especially where these are used to implement complex communication sequences such as halo exchanges in stencil computations.

8 Conclusion

In this paper, we introduce ACCL+, an open-source FPGA-based collective library designed for portability across diverse platforms and communication protocols. ACCL+ offers flexibility in implementing collectives without the need for FPGA re-synthesis and demonstrates high performance as collective abstractions for FPGA-distributed applications and as a collective offload engine for CPU applications. With ACCL+, there is potential for exploring new possibilities by extending collectives across CPU and FPGA boundaries and orchestrating them for a unified application.

Appendices

A ACCL+ Initialization

ACCL+ is specifically designed to deliver a high-speed collective communication solution tailored for FPGAs, or to function as a specialized NIC for CPUs. To simplify the initialization process, we choose not to generalize the network stack in the hardware for general-purpose communication. Instead, we utilize the conventional NIC in the CPU system for launching ACCL+ applications in a distributed environment, such as through *mpirun*, or for establishing RDMA queue pairs for ACCL+ communicators. This NIC only involves a lower-speed connection to other ranks.

Other than the *collective API*, the CCL driver also exposes a *housekeeping API* which enables CCLO configuration and monitoring, and a *primitive API* consisting of simple data movement operations (send, receive, copy). Listing 3 illustrates the three APIs - the code initializes ACCL+, invokes the ACCL+ send/receive primitives to exchange data between ranks 0 and 1, and executes an reduce collective on all ranks.

In this example, we utilize the MPI library to determine the local rank ID (lines 6-8) when the application has been launched with mpirun. Then ACCL+ is initialized by calling the constructor function and passing the Coyote device object (line 11). Similar approach is applied for Vitis device object. Within the constructor, it also allocates and configures a set of CCLO-managed Rx buffers for collective operations in the FPGA memory, e.g., for the eager protocol. The code then constructs the communicator according to rank information and protocol type (line 15). If the protocol is TCP, the code will issue commands to open connections between each rank in the communicator via the protocol offload engine. If the protocol is RDMA, the code utilizes the commodity NIC to change queue pair information. The TCP connections and the RDMA queue pairs are generalized to session IDs in the communicator. All configuration information is offloaded to the FPGA so that the CCLO can rapidly access them. Just like MPI, ACCL+ can be configured with multiple communicators of different sizes. While not pictured here for brevity, each ACCL+ collective can specify the communicator it operates on, with COMM_WORLD being the default.

Lines 21-25 implement data movement from the buffer of rank 1 to the buffer of rank 0 utilizing the primitives API. Lines 27 execute collectives on the entire communicator using the collectives API.

```
1   #include "accl.hpp"
2   #include <mpi.h>
3   using namespace ACCL;

5   int main(int argc, char **argv) {
6       int mpi_rank;
7       MPI_Init(&argc, &argv);
8       MPI_Comm_rank(MPI_COMM_WORLD, &mpi_rank);

10      CoyoteDevice* device = new CoyoteDevice();
11      ACCL* accl = new ACCL(device);

13      std::map<int, std::string> ranks_dict = /*
            Populate rank vector*/;
14      Protocol protocol = TCP; // or RDMA
15      accl->configure_communicator(ranks_dict, mpi_rank,
            protocol);

17      const int bufsize = 64;
18      auto opbuf = accl->create_buffer<int>(bufsize);
19      auto resbuf = accl->create_buffer<int>(bufsize);

21      if (mpi_rank == 0) {
22          accl->send(opbuf, bufsize, 1); // Send to rank 1
23      } else if (mpi_rank == 1) {
24          accl->receive(opbuf, bufsize, 0); // Receive
                from rank 0
25      }

27      accl->reduce(opbuf, resbuf, bufsize, 0); // Root
            rank 0

29      opbuf->free_buffer();
30      resbuf->free_buffer();
31      delete accl;
32      delete device;
33      MPI_Finalize();
34  }
```

Listing 3: Initialization and invocation of collectives from CPU.

Beaver: Practical Partial Snapshots for Distributed Cloud Services

Liangcheng Yu[♡] Xiao Zhang[♠] Haoran Zhang[♡] John Sonchack[♣] Dan Ports[♢] Vincent Liu[♡]
[♡]*University of Pennsylvania* [♠]*Shanghai Jiao Tong University* [♣]*Princeton University* [♢]*Microsoft / University of Washington*

Abstract

Distributed snapshots are a classic class of protocols used for capturing a causally consistent view of states across machines. Although effective, existing protocols presume an isolated universe of processes to snapshot and require instrumentation and coordination of all. This assumption does not match today's cloud services—it is not always practical to instrument all involved processes nor realistic to assume zero interaction of the machines of interest with the external world.

To bridge this gap, this paper presents Beaver, the first practical partial snapshot protocol that ensures causal consistency under external traffic interference. Beaver presents a unique design point that tightly couples its protocol with the regularities of the underlying data center environment. By exploiting the placement of software load balancers in public clouds and their associated communication pattern, Beaver not only requires minimal changes to today's data center operations but also eliminates any form of blocking to existing communication, thus incurring near-zero overhead to user traffic. We demonstrate the Beaver's effectiveness through extensive testbed experiments and novel use cases.

1 Introduction

The ability to capture a consistent, global view of a system is a powerful tool. For many tasks—deadlock detection, checkpoints and failure recovery, network telemetry, debugging of distributed software, and many others [3–5, 8, 9, 17, 33, 37, 39, 52, 54, 55, 58, 60]—a global view, and particularly a consistent one, is essential for correct operation. Without consistency, results are unreliable, and the value of associated tools is questionable.

The classic method for capturing consistent global states is the Chandy-Lamport snapshot algorithm that was proposed almost four decades ago and its subsequent variants [11, 26, 33–35, 41, 57, 60]. At a high level, these protocols flood snapshot initiation messages throughout the system, triggering local captures of state at every node they pass in a manner that guarantees causal consistency of the recorded values. Some versions (including the original) also include support of capturing messages that are in-flight at the time of the snapshot, i.e., channel state.

While these protocols have been simple, effective, and widely used for decades, they all rely on the fundamental assumption that the set of participants in the protocol is closed under causal propagation. In other words, if any node can both send and receive messages from participants in the protocol, it can propagate Lamport's 'happened-before' relation [35] and must also be a participant in the snapshot. For systems operating in isolation, ensuring full participation is trivial; however, modern cloud deployments are not so utopian.

Today's cloud services are often modular, e.g., structured as microservices, each of which might be developed and maintained by a different user, team, or organization or hosted on otherwise inaccessible infrastructure. Take, for instance, a managed pub/sub messaging layer like Amazon's Simple Notification Service (SNS). As a proprietary and black-box service, users cannot directly propagate snapshot initiation markers through the service. Further, while they might be able to add markers to the application-level content manually, with concurrency, replication, and reordering (e.g., due to prioritization), content-based markers are unlikely to track causal relationships accurately. Even when developers fully control all relevant servers, the clients of the service can also introduce hidden causal relationships, for example, when the user of a generative AI chatbot sends a follow-up message based on the response to the previous prompt. Ultimately, the nature of causal consistency means that a single non-participant can render all snapshots useless.

Observing this gap between classical assumptions and the practicalities of real-world deployments, we ask the question: Can we make distributed snapshots practical in modern cloud data centers, i.e., is it possible to capture a causally consistent snapshot when only a subset of the broader system participates? At first glance, this goal seems far-fetched: With partial participation, we cannot control the messaging behaviors nor instrument any coordination logic for machines external to those of interest. Complicating the issue is the fact that, to be practical, the protocol cannot block, e.g., by buffering or delaying user packets during a snapshot. In essence, this means that hidden causal relationships between participants and external communication partners are unavoidable.

This work presents Beaver[1], the first 'partial' snapshot protocol that extends the capability of distributed snapshots to cloud services with external interactions. Beaver provides the same basic abstraction as other snapshot protocols—for any event whose effects are observed in the snapshot, all other

[1] The animal species known for their engineering expertise in constructing dams using locally available materials such as rocks and tree branches.

events that ‘happened-before’ are also included. It achieves this even when the target service communicates with an arbitrary number of external, black-box entities, regardless of their scale, semantics, or placement, and despite potential multi-hop propagation of causal dependencies. Beaver does all of this without blocking or delaying user requests. Beaver tackles this seemingly impossible problem by:

1. Relying on two features found in all of today’s largest cloud data centers: (a) Layer-4 Software Load Balancers (SLBs) that interpose on a subset of inbound traffic [15, 28, 49, 50] and (b) servers with low time strata or otherwise stable clocks [13, 25, 29, 36, 38, 42, 44, 45].
2. Eschewing the enforcement of causal consistency in favor of simply *detecting* when violations may have occurred, a mechanism we call Optimistic Gateway Marking (OGM).

Note that for (1b), Beaver does not rely on the traditional notion of clock synchronization that other recent systems [13, 38, 42] are founded upon, which requires that the clocks of distinct machines have bounded drift. Instead, it uses a much weaker property [25, 40] over the frequency drift of a single machine[2]. Also note that (2) implies a tradeoff: snapshots are not always successful, but users can be assured of their correctness when they are and retry when they are not.

At a high level, Beaver’s approach is based on the observation that when examining the causal consistency of a snapshot, only inbound traffic is relevant and only a small subset therein. More specifically, we can divide inbound traffic into messages that are ‘causally irrelevant’ (e.g., triggered asynchronously and, thus, are not a part of any transitive causal relationships) and messages that are ‘causally relevant’ (e.g., triggered by post-snapshot outbound traffic but may not carry any markers of that fact). Beaver’s OGM mechanism is an approximate but full-recall detector of causally relevant traffic.

Our prototype[3] of Beaver demonstrates that not only is it possible to build an OGM mechanism, but by leveraging the aforementioned features of today’s cloud data centers, we can render the possibility of rejected snapshots minimal (near-zero in many cases). To summarize, this paper makes the following contributions:

- To the best of our knowledge, we are the first to detail the gap between classical assumptions of distributed snapshots and the practicalities of real-world clouds.
- We propose Beaver, the first partial distributed snapshot primitive for modern cloud services. Beaver presents a unique design point by tightly coupling the protocol with the regularities of the underlying data center environment.
- We evaluate Beaver through end-to-end implementation on a real-world testbed aligned with the production data center settings. We also show that the causally consistent view provided by Beaver enables a spectrum of use cases.

[2] Bounded clock drift to a low-stratum reference server is sufficient to guarantee bounded local frequency drift, but not necessary.

[3] The prototype is available at https://github.com/eniac/Beaver.

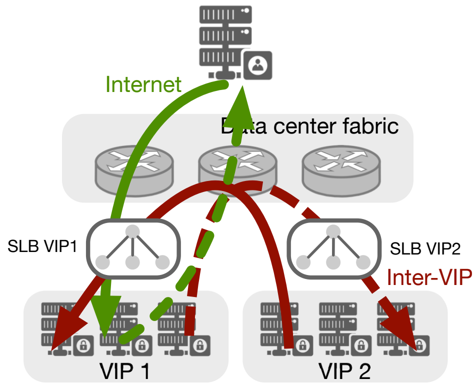

Figure 1: Today’s public cloud services place SLBs to handle the external traffic to its VIP in the inbound direction (solid lines to VIP 1). The response to inbound messages (dotted lines from VIP 1) typically bypasses its SLB to minimize the SLB traffic load.

2 Background and Motivation

We begin by describing the structure of today’s cloud services and the data centers in which they reside before we discuss the application of distributed snapshots to these services.

2.1 Communication in Public Cloud Data Centers

Today’s cloud data centers are massive collections of servers connected by a network fabric that host user services of diverse sizes and scopes. In this context, we can abstract user services as a set of virtual or bare metal machines managed as a single logical entity. Each service is typically assigned a public Virtual IP (VIP) address, and each physical machine a private Direct IP (DIP) address [15, 50].

Software Load Balancers (SLBs). A set of dedicated servers or programmable devices is responsible for translating between VIPs and DIPs. We refer interested readers to prior work [15, 50] for full details, but at a high level, these layer-4 devices act similarly to traditional Network Address Translators (NATs), allocating a new mapping for every new connection and rewriting the headers of every passing packet according to the mapping. In cloud systems, these devices are distributed, replicated, and serve an additional purpose as software load balancers that spread requests over available backend servers. A single service/VIP typically has a dedicated set of SLBs based on its scale (e.g., ∼7–20, including replication).

The path of packets in public clouds. In the presence of SLBs, packets can take different paths depending on the relationship between their source and destination (Figure 1):

Internet traffic: Incoming packets from the Internet are always routed through an SLB to translate from the service’s publicly visible VIP to a relevant internal DIP [15, 21, 22, 43, 50, 63]. Unlike most other NAT-like mechanisms, response packets are usually sent back directly, bypassing the SLB using techniques like Direct Server Return (DSR) [15, 50].

Inter-service traffic: Inbound traffic from other services within the same provider also passes through SLBs [15, 21, 22, 43, 50, 63], which still need to perform the same VIP-to-DIP translation. This is true even if the two service's servers are physically adjacent. Note that, like with Internet traffic, outbound traffic can bypass the responder's SLB; however, even in this case, the packet will still need to pass through the SLB responsible for the destination VIP(s), as shown in Figure 1. Note that while cached DIPs have been suggested to bypass inbound SLBs on the fast path [50], this optimization is currently disabled for major classes of production traffic due to load imbalance and cache management issues. The implication is that, at least for public clouds, this need to interpose on all inbound traffic is ubiquitous [10, 15, 63].

Intra-service traffic: Finally, messages between sources and destinations belonging to the same VIP are sent directly, bypassing the SLBs entirely.

Typical service communication patterns. In parallel to the above, we note that modern cloud services rarely operate in isolation. Frontend services typically rely on a wide array of backend services, e.g., to handle storage, analytics, and learning, thus triggering inter-service traffic. The rise of managed cloud service offerings and microservice design patterns have further encouraged modularity and the associated growth in the number of distinct services involved in processing a single user request. At a more basic level, most cloud services take requests from and return responses to external clients, each with its own internal, causality-carrying logic.

2.2 Revisiting the Chandy-Lamport Snapshot

The ability to capture a consistent snapshot of a cloud service's global state is a powerful tool. Indeed, many problems in distributed systems boil down to determining the global state across machines, including distributed logging and debugging, network telemetry, checkpointing and recovery, and deadlock detection [3, 11, 17, 33, 56, 60].

Intuitively, a snapshot is a collection of local states captured from the processes of a system. For simplicity, we omit channel states in our definitions, but the analysis is similar. The snapshot is deemed consistent if the captured states at each process 'cut' the timeline of events in a way that respects the following definition:

Definition 1. *(Consistent Snapshot [11, 56]). For a snapshot, let C be the set of events on every process that occurs before the 'cut'. C is causally consistent iff $\forall e \in C$, if $e' \rightarrow e$, then $e' \in C$, where $x \rightarrow y$ denotes that x 'happened before' y.*

The seminal Chandy-Lamport algorithm was the first to present a solution for this problem. We refer the interested readers to the original paper [11] or a distributed systems textbook [33, 56] for complete details, but we give a simplified description of the model and the protocol below:

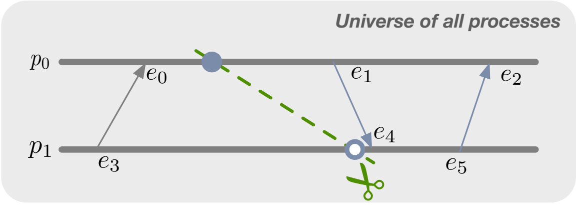

Figure 2: A minimal example of a consistent cut for 2 processes p_0, p_1 and 6 events $e_{0,1,...,5}$. The global snapshot formed from the collection of ○ and ● is a 'causal cut' of the event timelines for all processes, where ● and ○ indicate snapshot initiations triggered out-of-band or by receiving marker messages, respectively.

- *Model:* A system involves a set of asynchronous processes $P = \{p_0, p_1, \ldots, p_{N-1}\}$ that interconnect with each other through FIFO message channels. Each process p_i holds state of interest, s_i, that may change in response to local events (e.g., local computation, message sends or receives, etc.). A global snapshot involves a union of states $\{s_i\}$ recorded at different times for all processes.
- *Protocol state machine:* The protocol requires coordination in *all* processes $p \in P$. An initiator process first records its local state and then sends a marker message to all others. The captured state is application-dependent and can range from a single bit representing the state of a lock to all of local memory. When any other process p_i receives a marker message for the first time, it records its state s_i and, to ensure consistency, sends marker messages immediately through all other channels.

Later variants refine the basic algorithm to generalize channel assumptions, allow for concurrent initiation, or reduce message complexity [26, 33, 34, 41, 57, 60]. In particular, the Lai-Yang algorithm permits non-FIFO and lossy channels by having processes piggyback a single marker bit in every sending message [34] rather than sending separate marker messages as in the original protocol. Upon receiving a message with a marker bit set, the receiving process *first* records the local state, processes the payload, and sets the bit for future sending messages. Additional bits can be used to support concurrent snapshots. Figure 2 shows a consistent cut with the Lai-Yang algorithm.

2.3 A Case for Partial Snapshots

The above snapshot algorithm makes a fundamental and implicit assumption that *all* processes that can communicate with processes in P are themselves in P. Unfortunately, as previously mentioned, today's cloud services are frequently interconnected, with efforts toward modular design and managed solutions promoting increasing complexity in the dependency graph over time. As a rough indication of severity,

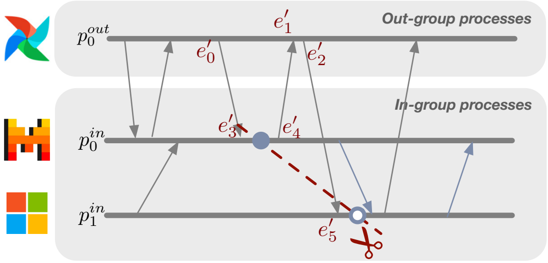

Figure 3: An application where a distributed serving system is accessed by an external user (e.g., an Apache Airflow workflow). The out-group process p_0^{out} imposes a hidden causal relationship $e'_4 \rightarrow e'_5$ between events e'_4 and e'_5, rendering a traditional snapshot of only the serving system inconsistent.

previous studies have shown that inter-service traffic comprises 10–50% of total traffic in the data center, and Internet traffic accounts for 5–25% [21, 22, 50].

Consider, for instance, a HuggingFace-like ML inference service [2] that hosts a collection of models that can be accessed from external clients. As they are externally visible, the models are frequently used in larger jobs, e.g., as part of an interactive chatbot (where clients submit requests based on prior responses) or more complex Apache Airflow workflows.

The inference service might want to capture a service-wide statistic (e.g., tracking the maximum number of in-flight requests) to decide on the number of servers to provision. Any analysis of the developer's application that does not consider the potential dependencies introduced by external services or clients will miss important causal dependencies.

Figure 3 shows a simple example of this, where a single external Airflow job makes requests to multiple models hosted by the inference service such that only one request is outstanding at any given time. Occasional internal messages are for monitoring and coordination. Although there is at most one outstanding request at any given time, a traditional distributed snapshot that only considers the inference service will not respect that bound.

For example, in Figure 3, the depicted cut 'observes' two inflight messages because it fails to capture the external interactions ($e'_5 \in C$, yet $e'_4 \notin C$). In fact, for a single client that issues a single request at a time, an n-server snapshot can 'observe' any number of in-flight requests [0, n]. These arbitrary results can cause the developer to waste money and resources on redundant provisioning. More broadly, while the frequency and consequences of consistency violations are application-dependent, there is often a meaningful difference between 'correct' and 'incorrect'.

Although converting all cloud services into participants of the snapshot protocol might be possible given either (a) a well-resourced developer who can implement and manage everything (even if machines are geo-distributed or on the broader Internet) in-house or (b) support from the cloud provider to propagate snapshot markers on all packets, these approaches are not always feasible. For (a), the popularity of managed services demonstrates their importance to low-cost and agile development. For (b), forced instrumentation can lead to overhead and fragmentation for users not involved in the snapshot. Even worse, if the external source of dependencies is a human (e.g., accessing your service through a browser), incorporating her into the snapshot is impractical.

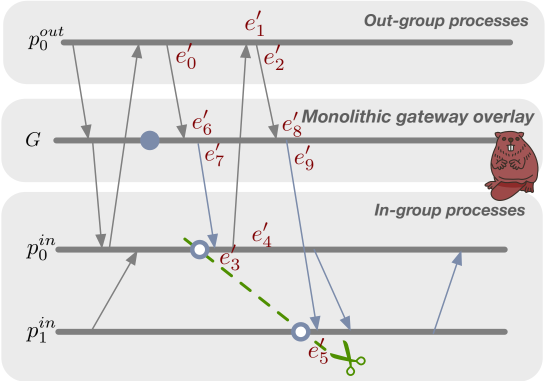

Figure 4: With the gateway indirection, Beaver's MGM results in a new frontier at the in-group process p_1^{in} that precedes rather than succeeds the event e'_5 (as in the scenario of Figure 3), converging to a consistent partial snapshot.

A formal definition of partial snapshots. We seek the design and implementation of a partial snapshot. In a partial snapshot, processes are divided into two groups. The first, *in-group processes* P^{in}, are the machines of the VIP(s) of interest. The second, *out-group processes* P^{out}, includes all other machines, whether in the same data center or the broader Internet.

Given these sets, we refine Definition 1 to obtain a definition of consistent partial snapshots:

Definition 2. *(Consistent Partial Snapshot). Consider a universe of processes* $P = P^{in} \cup P^{out}$, $P^{in} \cap P^{out} = \emptyset$. *Let* C_{part} *be the set of pre-snapshot events for* P^{in}. C_{part} *is causally consistent iff* $\forall e \in C_{part}$, *if* $e'.p \in P^{in} \wedge e' \rightarrow e$, *then* $e' \in C_{part}$.

Similar to traditional snapshots, for a set of in-group processes P^{in}, if a consistent partial snapshot includes the effect of an event e, it must include any event e' at $p \in P^{in}$ that leads to it. Like traditional snapshots, the 'happened before' relation, → is transitive and defined over events in the universe of processes. Unlike traditional snapshots, however, the included events only account for in-group events.

3 Gateway Marking

This paper introduces Beaver, a partial snapshot primitive that captures a causally consistent collection of state for cloud services sitting behind one or more operator-specified VIPs.

Fundamentally, the nodes in P^{out} are uncontrollable and, as a result, can introduce arbitrary hidden causal relationships, disrupting the consistency of traditional snapshots. At

Symbol	Description
P	Set of all processes.
P^{in}	Set of in-group processes with states of interest.
P^{out}	Set of out-group processes without any control.
G	Set of gateways handling inbound traffic for P^{in}.
C	Set of pre-snapshot events for a snapshot 'cut'.
e	Event tuple $e = (p, m, t)$.
$e.p$	The process at which an event e occurs.
$e.m$	The message involved in an event e, if any.
$e.t$	Global wall clock time, for ease of discussion.
e^{ss}_{gmax}	The event when the last gateway is in a new snapshot.
e^{ss}_{gmin}	The event when the first gateway is in a new snapshot.
e^{ss}_{g}	The event when $g \in G$ enters a new snapshot.
e^{ss}_{p}	The event triggering $p \in P^{in}$ to enter a new snapshot.
$d(p,q;V)$	One way delay from p to q with intermediate nodes $v \in V$ $(p, q \in (P \cup G), V \subseteq (P \cup G))$ in sequence.
τ_{min}	Min time for an external causal chain to occur.

Table 1: Summary of notations in Beaver.

the core of Beaver is a primitive called Optimistic Gateway Marking (OGM), which allows Beaver to detect when such causality violations may have occurred. As we show later in §5, by combining this primitive with common-case features of today's cloud data centers, Beaver can provide:

- Partial deployability where *only* the in-group machines for the target VIP(s) participate while ensuring high-rate, consistent partial snapshots for the target service(s).
- Minimal cost for data center infrastructure, for example, without switch reconfiguration or additional SLB replicas.
- Near-zero impact on existing data center service traffic.

In this section, we first introduce a strawman version of the primitive before discussing practicalities and how Beaver addresses them with OGM in §4.

Strawman: Monolithic Gateway Marking (MGM). Beaver starts with a simple idea: for all packets originating from out-group nodes and destined for in-group nodes, route them through a gateway. The gateway is responsible for two tasks:

1. Tagging incoming packets to in-group nodes with snapshot markers.
2. Initiating snapshots by tagging all subsequent inbound messages accordingly.

After the gateway initiates a snapshot, the protocol proceeds as a traditional snapshot among the in-group nodes. For the strawman, assume that the gateway is implemented by a single monolithic node. Figure 4 shows an example execution using the above protocol and the same application-level communication pattern as Figure 3. In contrast to Figure 3, indirection and marking via a gateway cause p^{in}_1 to take the snapshot at the correct time. In a way, the gateway node in this protocol can be seen as a stand-in for all nodes in P^{out}. We can prove that MGM produces a consistent partial snapshot.

THEOREM 1. *With MGM, a partial snapshot C_{part} for $P^{in} \subseteq P$ is causally consistent, that is, $\forall e \in C_{part}$, if $e'.p \in P^{in} \wedge e' \to e$, then $e' \in C_{part}$.*

PROOF. *Let $e.p = p^{in}_i$ and $e'.p = p^{in}_j$. There are 3 cases:*

1. *Both events occur in the same process, i.e., $i = j$.*
2. *$i \neq j$ and the causality relationship $e' \to e$ is imposed purely by in-group messages.*
3. *Otherwise, the causality relationship $e' \to e$ involves* at least *one* $p \in P^{out}$.

In cases (1) and (2), the theorem is trivially true using identical logic to proofs of traditional distributed snapshot protocols. We prove (3) by contradiction.

Assume $(e \in C_{part}) \wedge (\exists e' \to e)$ but $(e' \notin C_{part})$. With (3), $e' \to e$ means that there must exist some e^{out} (at an out-group process) satisfying $e' \to e^{out} \to e$. Now, because $e' \notin C_{part}$, we know $e^{ss}_{p^{in}_j} \to e'$ or $e^{ss}_{p^{in}_j} = e'$, that is, p^{in}_j's local snapshot happened before or during e'. Combined with the fact that the gateway is the original initiator of the snapshot protocol, we know that $e^{ss}_g \to e' \to e^{out} \to e$.

We can focus on a subset of the above causality chain: $e^{ss}_g \to e$. From the properties of the in-group snapshot protocol, $e^{ss}_g \to e$ implies $e \notin C_{part}$.

This contradicts our original assumption that $e \in C_{part}$! □

Theorem 1 implications: Beyond correctness, the strawman exhibits several valuable properties:

1. *Obliviousness to out-group semantics:* The proof treats the internals of the out-group processes as a black box. In fact, the protocol remains correct, even if the causal dependency results from multiple network hops through distinct out-group nodes or if an element of the out-group chain is a human.
2. *Obliviousness to outbound messages:* The gateway only needs to observe messages inbound to in-group processes without requiring any visibility or tagging of outbound messages. MGMs achieve this by initiating the snapshot at the gateway, which—as a stand-in for P^{out}—obviates the need to track dependencies carried to the out-group.

SLBs as a candidate for gateway marking. The SLBs described in §2.1 are a convenient candidate for implementing gateway marking as VIPs are a natural granularity for service-specific partial snapshots, and SLBs already interpose on all incoming traffic to a VIP—regardless of whether it is from the Internet or a different service. MGM's obliviousness to outbound messages helps here as well, making the system amenable to DSR.

Of course, assuming that a single server can handle all incoming traffic to a service is not feasible. The scale of modern SLBs serves as proof that even for simple gateway processing incoming requests for a single service, multiple servers are necessary to handle typical data volumes, load balance among SLBs, and provide fault tolerance.

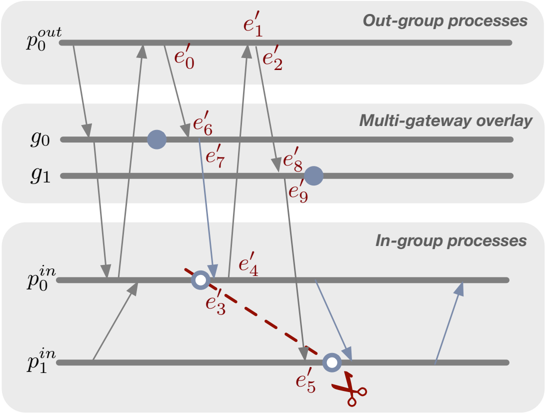

Figure 5: An inconsistent partial snapshot using two asynchronous SLBs g_0, g_1. When $e'_8.m$ arrives at g_1, g_1 has not initiated the new snapshot mode to mark the message, thus triggering the violation.

4 Optimistic Gateway Marking (OGM)

Beaver extends gateway marking to practical, distributed environments using OGM. First, to see why asynchronous SLBs could break the consistency guarantee, consider a simple scenario in Figure 5 where two SLBs, signaled by an out-of-band controller, initiate a new snapshot. When g_0 initiates snapshot mode and marks $e'_6.m$, it triggers a snapshot at p_0^{in}. However, a new message $e'_2.m$ from p_0^{out} is routed to a different gateway g_1[4], which has not yet entered snapshot mode. This leads to inconsistency: while $e'_5 \in C$ and $e'_4 \to e'_5$, $e'_4 \notin C$.

To block or not to block? An obvious solution would be to block inbound packets at SLBs during a snapshot and only resume forwarding them after all SLBs have 'committed' to the new snapshot. Unfortunately, this method introduces large overheads—not only to the applications, whose response times will spike while the SLB is blocking requests but also to the cloud providers, where the SLB would require large buffers and overprovisioned capacity to drain said buffers after a snapshot.

Rather than trying to enforce consistency, Beaver seeks a method to (a) detect *in*consistency, (b) reject snapshots when they are potentially inconsistent, and (c) minimize the rejection rate. It seeks to do this with near-zero overhead for applications and cloud infrastructure.

4.1 Causal Relevance and Irrelevance

A key idea in Beaver is that, even among the incoming traffic to the in-group, only a subset of that traffic is causally relevant. Using Figure 5 to illustrate, an incoming message, m, is **causally relevant** only when (1) an initiated SLB (g_0) sends a marked message to an in-group node (e.g., p_0^{in}), (2) that node interacts directly or indirectly with an out-group node (e.g., p_0^{out}), and (3) that out-group node sends m back to a different in-group node via an uninitiated SLB (e.g., g_1). Other communication patterns, e.g., an m triggered by an uninitiated process, are **causally irrelevant**.

In essence, causally relevant messages are only produced if the message loop: $GW_A \to IN_A \to OUT \to GW_B$ all occurs within the window of time in which the gateways are propagating snapshot initiation. More formally:

THEOREM 2. *In a system with multiple asynchronous gateways, let the wall-clock time of the first and last gateway initiating snapshots be $e^{ss}_{gmin}.t = \min_{e^{ss}_g}(e^{ss}_g.t)$ and $e^{ss}_{gmax}.t = \max_{e^{ss}_g}(e^{ss}_g.t)$, $\forall g \in G$, respectively. Also let $\tau_{min} = min(d(g,g';\{p,q\}))$, $\forall g,g' \in G$, $p \in P^{in}$, and $q \in P^{out}$. If $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t < \tau_{min}$, then the partial snapshot is causally consistent.*

PROOF. *We extend the proof of Theorem 1 to a distributed setting. Similar to Theorem 1, there are three cases, with (3) being the one that differs. We again prove it by contradiction.*

Assume $(e \in C_{part}) \wedge (\exists e' \to e)$ but $(e' \notin C_{part})$. As before, there must be some chain $e' \to e^{out} \to e^g \to e$. Because $e' \notin C_{part}$, we have $e^{ss}_{p_j^{in}} \to e'$ or $e^{ss}_{p_j^{in}} = e'$, that is, p_j^{in} must have been triggered directly or indirectly by an inbound message. Denote the arrival of this inbound message at its marking gateway as $e^{g'}$. By the definition of τ_{min}, we have $e^g.t - e^{g'}.t \geq \tau_{min} > e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$. Thus, at event e^g, the gateway must have already initiated the snapshot and will mark $e^g.m$ before forwarding. This results in $e \notin C_{part}$, a contradiction! □

Theorem 2 implications: Informally, this theorem suggests that if the time gap between the first and last SLB snapshot initiations ($e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$) is sufficiently small, or the minimum time for a message to revisit a gateway (τ_{min}) is long enough, causally relevant messages are impossible and the concerned partial snapshot is provably consistent[5].

Causally relevant messages are rare in the real world. Intuitively and with anecdotal evidence, the inequality $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t < \tau_{min}$ can be satisfied with an exceedingly high probability in real-world contexts:

For the LHS ($e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$): This time gap is essentially the difference in one-way delays between the controller and each of the SLBs. As SLBs share a region with the target service, a well-placed initiator (e.g., equidistant from all target SLBs or one whose messages are forced to travel to the root of the data center fabric) can simultaneously ensure reactive snapshot initiation and $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$ of near zero.

For the RHS (τ_{min}): This value includes multiple network hops, extending from an SLB to in-group nodes, then to out-group nodes, and back to an SLB. Particularly when out-group nodes are in other data centers or are end-host clients,

[4] This is typical in ECMP routing, where connections even from the same source may reach different SLBs.

[5] In principle, another sufficient condition is when the in-group snapshot completes quickly enough. We do not rely on this because it has worse scaling properties than SLB convergence, but it can be added as an optimization.

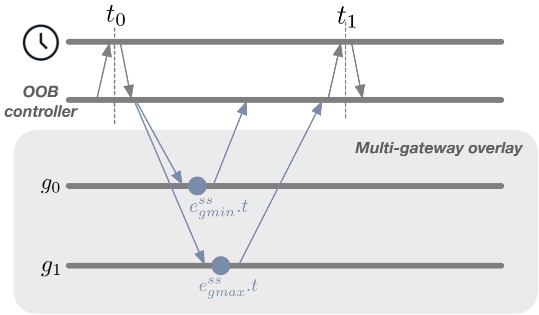

Figure 6: The time difference $t_1 - t_0$ as a safe upper bound for $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$ by querying a single hardware clock source with bounded frequency drift.

this value can be orders of magnitude higher than typical values for the LHS—on the order of milliseconds or tens of milliseconds. However, even when the out-group nodes are in the same region or data center as the in-group, we can still expect that this value is higher than any observed delta between initiator-to-SLB one-way delays as it includes *at least three trips* through the data center fabric in addition to processing time at the in/out-group network stacks[6].

4.2 Efficiently Verifying Causal Irrelevance

The primary technical challenge of OGM is minimizing the LHS of the above inequality and efficiently/confidently verifying that the resulting inequality held for a given snapshot, even in the presence of message drops, delays, and other sources of unexpected latency. The cloud provider can compute the two sides of the inequality separately.

4.2.1 Computing a Lower Bound for the RHS

For the RHS, the value can be determined statically, as dynamic network conditions like failures and congestion can only add to the latency of the message sequence. The latency is then equivalent to the sum of each hop's minimum propagation, transmission, and processing delays. These values depend on the relative placements of the in-group nodes, SLBs, and out-group communication partners, but all of those are known at runtime. To ensure a conservative lower bound, operators can and should assume that application-level processing and transmission delays are zero (Figure 13).

4.2.2 Determining an Upper Bound for the LHS

The LHS is harder to compute statically as failures and congestion mean a true upper bound may not exist[7]. Instead, we need to measure an upper bound online for the observed difference between gateway timestamps ($e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$) for the snapshot in question.

	Rubidium	JILA Sr	Quartz	Quartz (calibrated)
Δf	±0.05 ppb	$\pm 2.1 \times 10^{-18}$	±100 ppm	±100 ppb

Table 2: Frequency drift (Δf) uncertainty range of today's clocks, ppb (parts per billion) $= 10^{-9}$, ppm (parts per million) $= 10^{-6}$.

The typical method of measuring time gaps on different machines is via clock synchronization. Although today's clock synchronization techniques can achieve microsecond or sub-microsecond precision, fundamentally, they rely on frequent cross-machine messaging to correct the offset, which is sensitive to congestion and failures, thus impacting the bound on clock drift in the worst case [23, 62]. Data center services like TrueTime provide a reliable interface to query time points and calculate their differences. However, a general timing service incurs higher overhead and a typical clock uncertainty range of 1–7 ms [13], much greater than the timescales relevant for Beaver detection.

Synchronization-free approach. Beaver adopts an alternative, customized approach using a single hardware clock to calculate the elapsed time. As depicted in Figure 6, the controller queries the start time at t_0 from this clock source with a read t^r_0 before initiating a new snapshot. Once the final ACK from the SLBs arrives, it reads the end time t^r_1 at t_1 from the source, where t_0, t_1 represents the global wall clock time, and t^r_0, t^r_1 the actual clock reads. This hardware clock can be a local hardware clock from either a COTS PCIe NIC [46] or from one equipped with an atomic clock, which are increasingly deployed in production data centers [42, 48].

Note that $t_1 - t_0$ is an upper bound on the LHS as $t_1 > e^{ss}_{gmax}.t$ and $t_0 < e^{ss}_{gmin}.t$. Thus, if $t_1 - t_0 < \tau_{min}$, the partial snapshot under examination is consistent. In practice, the time difference $t^r_1 - t^r_0$ is adjusted to account for the maximum frequency drift Δf according to the clock data sheet, to determine an upper bound estimate for the corresponding elapsed time $t_1 - t_0$, thus the detection criteria $(t^r_1 - t^r_0) \times (1 + \Delta f) < \tau_{min}$. This method, which relies solely on a single hardware clock to calculate time differences, eliminates issues common in traditional clock synchronization approaches, such as cross-machine message congestion and errors stemming from delays in clock readings due to software interrupts. The frequency drift of a single clock is relatively low and is mainly deterministically affected by temperature, which has low variance in modern data centers [38, 44, 59]. Standard quartz crystal oscillators in production data centers typically drift by ±100 ppm, or 0.01% error [13, 25, 36, 38, 44]; recent studies are able to reduce this drift of quartz clocks in commodity data center servers to ±100 ppb (10^{-7} error) by calibrating the offset due to temperature variations. More advanced oscillators (e.g., atomic clocks) can reduce this frequency drift by further orders of magnitude [29, 45] (Table 2).

Snapshot invalidation. While ensuring correctness (i.e., no

[6] Even with the detection criteria later described in §4.2, LHS entails only 2 trips and encompasses a simpler data path with SLB stacks that are heavily optimized for minimal processing latency and jittering [15, 18, 22, 63].

[7] Beyond the heat death of the universe or at least the life of a data center.

false negatives), our proposed upper bound adds an additional margin to the original time gap. This margin comprises the clock query latency and the RTT between the controller and the SLBs, which may lead to false positives. In practice, however, we note that many devices support precise hardware timestamping along with the packet data path (i.e., when sending the first notification and when receiving the last notification). Our evaluations on a cloud data center in §7 reveal that the resulting snapshot invalidation rate is $< 5\%$ for typical SLB scales today, even in worst-case scenarios when the out-group nodes are in the same data center and under stressed snapshot operation frequencies.

In the end, false positives—while leading to the invalidation of potentially consistent snapshots—are of little concern due to our system's efficient snapshot operations and its ability to achieve a high snapshot rate.

5 Beaver's Partial Snapshot Protocol

As mentioned previously, Beaver's snapshot 'quantum' is a single VIP—Beaver can provide snapshots for one or more such VIPs within a single region.

Operation. At a high level, Beaver's partial snapshot protocol distinguishes itself from traditional snapshots in two aspects: (1) its lightweight SLB marking logic for inbound traffic and (2) the snapshot verification process at the controller.

In-group processes: Among in-group processes, Beaver inherits its coordination logic (and the omitted, optional recording of in-flight messages) from prior snapshot algorithms [34, 60] that piggyback 'marker' information per message to handle non-FIFO and lossy channels[8]. Figure 7 depicts the core logic: upon receiving a packet, either from an SLB or another in-group process, the current in-group process evaluates if $pkt.sid > csid$. If true, it signals a new snapshot operation: it records the relevant state, updates the local $csid$, and asynchronously notifies the controller of completion. For outgoing packets, if the destination address falls within the scope of in-group processes, the process updates $pkt.sid$ to its current $csid$.

SLBs: As discussed in §4, Beaver instantiates the gateway overlay with the SLBs. For the set of SLBs handling the target in-group process traffic, Beaver embeds logic for marking inbound messages. On receiving an inbound packet, an SLB first checks if the destination VIP is for the in-group [line 16]—since operators may multiplex a single SLB server for multiple VIPs—and modifies the snapshot ID field accordingly. On the control path, the SLB initializes a new snapshot upon receiving an 'INIT' notification from the controller and subsequently sends the acknowledgment to the controller. This process happens out-of-band to avoid biases in the snapshot verification process. Combined, Beaver's gateway logic requires minimal processing and can be incorporated into existing SLB data planes at line rate, including hardware-accelerated ones.

```
• $csid$: Current snapshot ID state for $p \in P^{in}$ or $g \in G$.
– $pkt.sid$: Snapshot ID ($N$b) in SLB encapsulation header.
– $pkt.dst$: Destination address of a user packet.
– $pkt.src$: Source address of a user packet.

1  function IN-OnReceive (pkt):
2      /* Signaled a new snapshot */
3      if $pkt.sid > csid$ then
4          Record the state of interest;
5          Send FIN for $csid + 1, \ldots, pkt.sid$ to the controller;
6          $csid \leftarrow pkt.sid$;

7  function IN-OnSend (pkt):
8      if $pkt.dst \in P^{in}$ then
9          $pkt.sid \leftarrow csid$;

10 function SLB-OnReceive (INIT):
11     if $INIT.sid > csid$ then
12         $csid \leftarrow INIT.sid$;
13         ACK for $csid + 1, \ldots, pkt.sid$ to the controller;

14 function SLB-OnReceive (pkt):
15     /* Mark inbound packet from out-group */
16     if $(pkt.dst \in P^{in}) \wedge (pkt.src \notin P^{in})$ then
17         $pkt.sid \leftarrow csid$;
18     Forward packet to $pkt.dst$;
```

Figure 7: Logic for partial snapshots at in-group processes and SLBs. All control plane operations are asynchronous.

Controller: With Beaver, operators can designate any server with direct or indirect access to a stable clock source, preferably located near the pertinent SLBs, as the controller. The core logic to initiate snapshots, shown in Figure 8, involves continuously sending INIT commands to SLBs to initiate new snapshots. The protocol maintains the number of snapshots in flight and controls the snapshot frequency. The detection of invalid snapshots follows the methodology outlined in §4.2: The controller queries the clock read for t_0 before sending notifications [line 5] and uses the clock reads upon receiving the last ACK to determine the snapshot's validity [line 20]. It the local NIC supports hardware time-stamping capabilities, `queryClock()` can occur along the data path during the send of the first INIT notification and the receive of the last ACK response.

Handling packet loss, delay, and reordering. Beaver is robust to faults in data- and control-plane communications.

Data plane: Unlike the original Chandy-Lamport protocol, which relies on separate marker messages, Beaver draws inspiration from subsequent variants [34, 60] to incorporate marker information by piggybacking it into existing traffic. This piggybacking makes Beaver inherently resilient to 'marker' losses and reordering on the data path, whether these occur within the network core or the host networking stacks.

Control plane: Although timely and reliable delivery of control messages can be beneficial (e.g., through an alternate port that is dedicated to control tasks) Beaver does not de-

[8] Optional broadcast of marker messages from SLBs to in-group processes may accelerate the snapshot convergence when service traffic is infrequent.

```
• $csid$: The next snapshot ID to initiate at the controller.
• $receivedFIN[sid][p]$: If received FIN from $p \in P^{in}$ for $sid$.
• $receivedACK[sid][g]$: If received FIN from $g \in G$ for $sid$.
• $t_0[sid]$: Timestamp $t_0$ for $sid$.
– $FIN.p$: The source process sending the FIN.
– $FIN.sids$: The associated $sid$(s) of the FIN.
– $ACK.g$: The source SLB sending the FIN.
– $ACK.sids$: The associated $sid$(s) of the ACK.

```

Figure 8: Main controller logic for continuous snapshots.

pend on it for its core functionality. It operates effectively even with unreliable transport protocols such as UDP and it requires only a negligible number of control messages: $|P^{in}|$ FIN messages (or less as members of the in-group, P^{in}, can batch updates in a single ACK on the increments in prior snapshots), $|G|$ INIT commands, and $|G|$ ACK responses for each snapshot.

While delays or losses of the above messages might slow down the snapshot rate—a minimal impact as observed in our evaluation—they do not compromise the correctness of Beaver. The controller, in response to any delays or losses, simply invalidates the affected snapshot.

Handling failures. One important problem is how to handle failures of the SLBs and backend servers. Fortunately, most public clouds today already apply central management mechanisms that ensure fault tolerance and state consistency during changes in membership of machines for each VIP[9] [10, 15, 22, 50]. Operating on top of the abstraction, Beaver's controller coordinates with the SLBs and backend servers belonging to the requested VIP (as indicated by the current central state), incurring minimal additional costs and deployment complexity. To handle failure events during a snapshot, Beaver incorporates a single ACK mechanism (Figure 8): if the controller does not receive the ACK from an SLB or an in-group process, Beaver simply invalidates the snapshot or drops affected states while guaranteeing correctness.

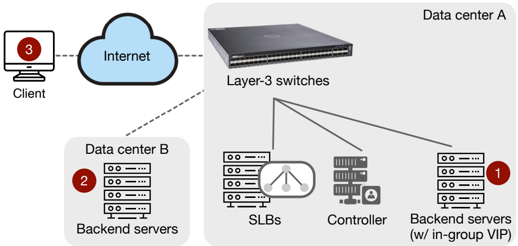

Figure 9: Evaluation setup considering three different out-group locations: within the same data center, data center of a different region, or on the Internet (from a local laptop).

Supporting parallel snapshots. Many cases, such as event-driven or telemetry tasks, require higher-frequency state capture [60, 61]. Rather than waiting for the completion of one snapshot before initiating another, limiting the snapshot rate to the slowest component in the snapshot convergence process, Beaver can initiate snapshots concurrently. The controller ensures that the number of packets in flight remains within $2^N - 1$ [line 3 in Figure 8], the maximum concurrent snapshots supported by the header field sid. The extra $^{-1}$ in the exponent is to eliminate ambiguities in comparator operations at in-group processes [line 3 in Figure 7] under worst-case wrap-around conditions.

Beaver also supports parallel snapshots for distinct groups of VIPs without needing extra metadata. This is facilitated by the SLBs' ability to naturally segregate operations based on VIP information. Consequently, the same sid header space can be utilized for simultaneous snapshots across groups with non-overlapping VIPs.

6 Implementation

We implement a Beaver prototype on a cloud data center [14] (Figure 9) that aligns with a production setup [15, 28, 50].

Supporting SLB-associated functionalities. We implement an end-to-end workflow to mirror the behaviors associated with SLBs in production data centers [15, 28, 50]. Additionally, our system facilitates automated service discovery operations through an out-of-band controller server.

SLB implementation: Our setup configures DELL EMC PowerSwitch S4048-ON [1] for layer-3 ECMP forwarding based on service VIPs to SLBs. Emulating prior work [15, 28], we implement the core SLB functions with DPDK [19], involving around 1860 lines of C/C++ code. Each SLB maintains an in-memory connection flow state, employs consistent hashing on the 5-tuple of each packet to determine the appropriate backend server, and caches the decision for future

[9] Unlike the DIP caching feature in §2.1, the consistency mechanism was originally absent in [50], but later incorporated as an essential component.

decisions. Then, the SLBs encapsulate the inbound packet's header and forward it to the backend server with the destination DIP. To maximize utilization of SLB servers, we perform load balancing across different CPU cores using RSS.

Backend servers: To maintain transparency for the upper-layer applications, we implement the re-computation of checksums, NAT caching in a shared eBPF map, and the de-encapsulation of incoming packets from the SLB via XDP [27]. For outbound packets, we instrument the Linux `tc` to look up the NAT entries and perform the header transformations to replicate Direct Server Return (DSR). In total, they involve 1040 lines of C/C++ code.

Topology. Our testbed supports typical communication patterns, encompassing a variety of out-group positions, including other VIPs within the same data center, VIPs in other data centers, and Internet clients—all through the layer-3 switches and SLBs, along with DSR on the return path. We scale up to 16 SLB servers, each capable of supporting 64 in-group processes, due to limits in resource availability. Our current testbed servers are equipped with Intel(R) Xeon(R) CPU E5-2640 v4 @ 2.40GHz and dual-port ConnectX-4 Lx NICs.

Integrating the Beaver protocol. We implement Beaver's partial snapshot protocol from §5. The SLBs append a snapshot ID to inbound packet headers that encapsulate the destination DIP and the source SLB IP. The in-group processes and SLBs embed Beaver's snapshot logic from Figure 7 through XDP and DPDK. The additional logic involves 68 lines of C++ for SLB data-path logic and 102 lines of C codes for eBPF at in-group processes. The controller server, following Figure 8, automates the initiation, control, collection, and verification of snapshots. We use UDP for bi-directional control messages with SLBs and unidirectional messages from in-group servers. The controller currently exploits local NIC hardware timestamping (`SOF_TIMESTAMPING_RAW_HARDWARE`) for precise timing of INIT and ACK messages on their data path [47].

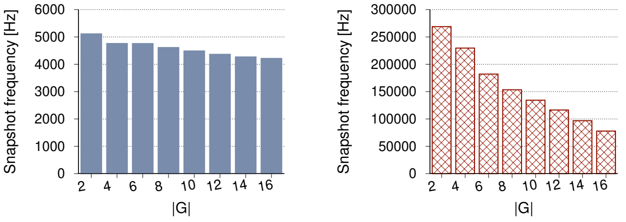
7 Evaluation

Our evaluation focuses on exploring the following questions.

- Can Beaver sustain fast snapshot rates? How does the scale of the in-group nodes and SLBs affect? (§7.1)
- What about effective snapshot rates? How often do Beaver invalidate snapshots in cloud data centers? (§7.2)
- Does Beaver's distributed coordination affect the existing service traffic? (§7.3)
- How does Beaver help real-world services? (§7.4)

7.1 Beaver Supports Fast Snapshot Rates

To stress-test Beaver, unless otherwise specified, our evaluation runs Beaver at very high snapshot frequencies. To further ensure that our performance/overhead results are conservative, state capture in the snapshots are NOPs. Real local record operations (which are application-dependent and orthogonal to the study of distributed snapshot protocols) will only result in less contention and overhead.



(a) w/o parallelism (b) w/ parallelism

Figure 10: Beaver's sustained snapshot frequency versus a strawman approach with blocking operations at varying scales of SLBs and backend processes.

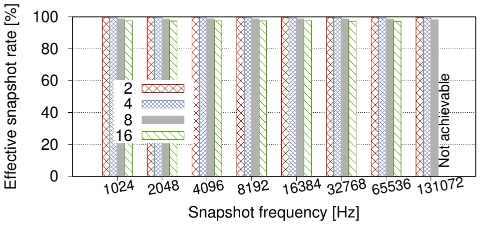


Figure 11: Beaver's effective snapshot rates under varying snapshot frequencies and in-group process scale.

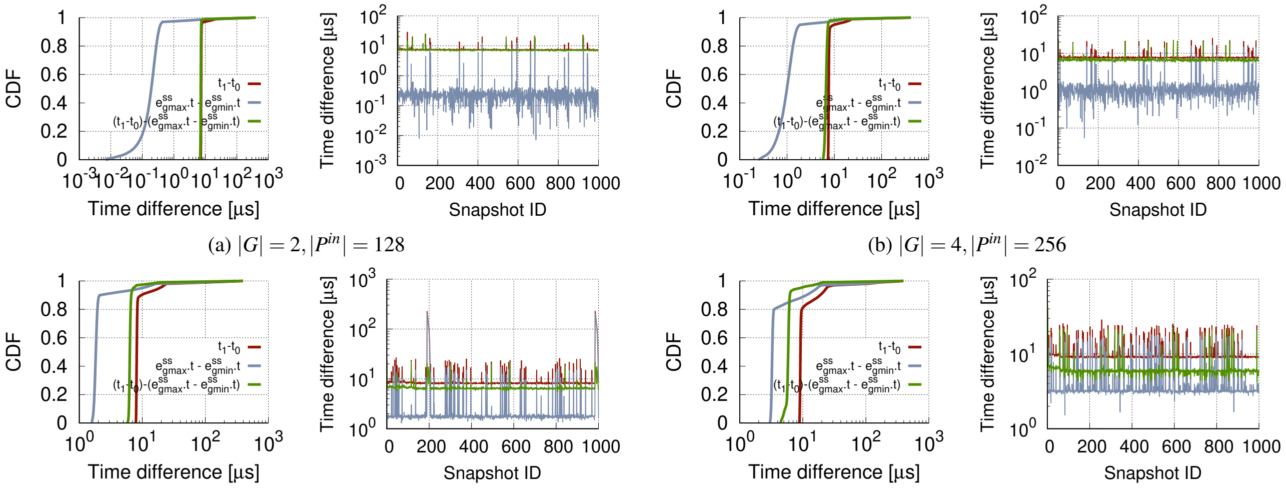
As a measure of Beaver's efficiency and scalability, even at these high rates, Beaver exhibits good performance. Figure 10 shows the maximum snapshot rate compared to a strawman approach, which waits for completion before initiating another. The maximum rate is determined by increasing the snapshot frequency until we observe backlogs in the ACK and INIT message notification queue. We vary the number of gateways ($|G|$) up to 16, aligning with typical values for SLBs assigned to a VIP.

The baseline is limited by the snapshot convergence time, which depends on factors such as scale, traffic pattern, and topology. In contrast, Beaver's parallel snapshot capability significantly enhances the rate and shifts the bottlenecks to the processing power of the controller's CPU. Even at the maximum scale, Beaver reaches a snapshot rate of $>$ 77000 Hz, $>$ 18× that of the strawman. In practical applications, leveraging a more powerful processor or scaling the controller server could further improve its speed.

7.2 Beaver Invalidates Snapshots Infrequently

With a high snapshot frequency, how does Beaver perform in terms of effective snapshot rates? Recall in §4.2, Beaver uses an upper bound $t_1 - t_0$ for the time gap between SLB initiations ($e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$) to eliminate the need for time synchronization, it invalidates a snapshot if the bound is greater than τ_{min}, the minimum time to for an external causal chain to occur. While this upper bound ensures correctness, it may reject snapshots and reduces the effective snapshot rate.



(a) $|G| = 2, |P^{in}| = 128$

(b) $|G| = 4, |P^{in}| = 256$

(c) $|G| = 8, |P^{in}| = 514$

(d) $|G| = 16, |P^{in}| = 1024$

Figure 12: CDF of Beaver's upper bound $t_1 - t_0$ with the ground truth ($e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$) for $>$ 10M snapshots and a zoom in to its snapshot series, under stressed scenario with 65536 Hz snapshot frequency and varying number of SLBs/processes.

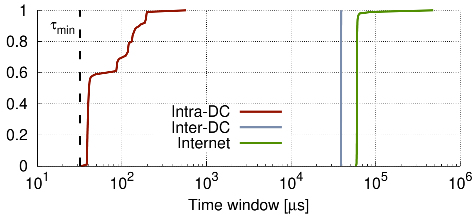


Figure 13: Measurement of the minimum time window for a external causal chain to occur under worst case conditions.

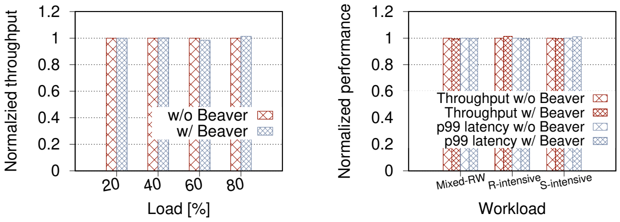
To measure the time for an external causal chain to occur, we consider three distinct scenarios for out-group process locations in Figure 9. In each scenario, we set up a worst-case condition where, immediately following an SLB's snapshot initiation, the SLB forwards an inbound packet to the closest in-group node. The in-group node then loopbacks an immediate message to out-group node with the shortest path, which bounces the packet back to any SLB. Figure 13 shows that the intra-DC scenario results in the shortest time window, resulting in τ_{min} as $33\mu s$. This value is robust because, even though varying cloud conditions often cause latency spikes, they primarily affect the tail rather than the minimum.

To stress test Beaver's performance, we focus on the worst-case scenarios with out-group processs located within the same data center. For other scenarios, τ_{min} is significantly greater, leading to 100% effective snapshot rates across 10M snapshot operations. We execute Beaver in various experimental settings, including scale and snapshot frequencies. For each configuration, we calculate the effective rate based on more than 10 million snapshots. The results, as in Figure 11, reveal that the proportion of snapshots invalidated by Beaver is remarkably low even under the maximum operating frequencies and scales of our testbed.

To better understand the results, we compare the recorded upper bound estimation of $t_1 - t_0$ with the true ground truth $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$. As the two events e^{ss}_{gmax} and e^{ss}_{gmin} occur on separate SLB machines, we synchronize the clocks of all SLBs to controller's PTP master clock over symmetric paths without contending traffic, which reports maximum 50 ns offsets during the ground truth measurement. This step, meant solely to understand the behavior, should not be confused with Beaver's clock-synchronization-free approach. Figure 12 shows the comparison over $>$ 10M snapshots when Beaver operates at a frequency of 65536 Hz. Overlapping tails of $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$ and the heads of $t_1 - t_0$ are expected—the cdf of the pairwise calculation of $(t_1 - t_0) - (e^{ss}_{gmax}.t - e^{ss}_{gmin}.t)$ for each snapshot clearly demonstrates that the upper bound is strictly higher than the ground truth SLB initiation time gap. The observed outliers in $t_1 - t_0$ are typically due to queueing in our manager's processing queue at high rates or asynchrony in SLB initiations. Furthermore, the margin introduced by $t_1 - t_0$ over $e^{ss}_{gmax}.t - e^{ss}_{gmin}.t$ is due to the RTT between the controller and the SLBs, which is used to ensure the theoretical upper bound without clock synchronization.

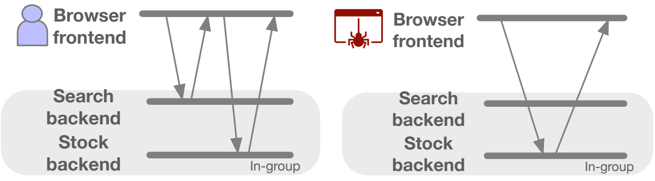
7.3 Beaver Incurs Near-zero Impact

We also stress test the overhead of Beaver on user traffic. Figure 14a compares throughput with and without Beaver under the 65536 Hz snapshot frequency and the max scale of our testbed. `iperf` clients send traffic with varying degree of the total consumed bandwidth capacity of the 16 SLBs. We also run YCSB benchmark workloads [12] with varying mix of read, update, and scan operations, as shown in Figure 14 for backend servers running CassandraDB [6]. The requests follow zipfian distributions, and the scan length adheres to the uniform distribution.



(a) Stressed workloads (b) YCSB benchmarks

Figure 14: Performances with and without Beaver's overhead, normalized to the value without Beaver.



(a) Benign (b) Bot access

Figure 15: Example benign and bot access patterns.

The results of various performance metrics are almost identical, confirming that Beaver has a near-zero effect on service traffic. This is because Beaver, by design, eliminates any delay or blocking operations on the data path for distributed coordination, and the lightweight control path messages are orthogonal.

7.4 Use Cases

We also examine several use cases of Beaver. These examples are intended as instruments through which we can understand its potential utility, differences versus traditional snapshots, and the semantics of its causal consistency guarantee under partial deployments that were previously impossible.

7.4.1 Detecting Anomalous Access

Web applications often feature a JavaScript browser frontend for user interaction and a backend providing service APIs. Consider a legitimate user access in an e-commerce application (Figure 15a). The frontend calls a Search API `fetch("example.com/api/v1/search")`, followed by a Stock API `fetch("example.com/api/v1/get_stock")` for product details. However, malicious traffic, such as web scrapers, might bypass the initial search stage and directly query the stock backend, potentially overwhelming the server. This type of traffic can be challenging to detect as it differs from legitimate traffic in intent rather than content [16, 31].

Beaver can help detect such anomaly patterns, as its partial snapshot can capture the external dependency of these requests, even though it occurs through communication with the Internet. To illustrate, we run a varying mixture of benign and illegal bot clients on our testbed. The backend servers maintain per-client request count in a BPF map through double buffering, so as to 'freeze' the current state through a single switch of the pointer and minimize the impact of blocking local record calls. Table 3 shows detection results calculated against the ground truth. We find that Beaver can accurately recognize the interdependence between the accesses. For example, when all clients are benign, Beaver consistently results in true negatives, aligning with the ground truth. However, a polling-based approach and traditional snapshots (L-Y) can result in false positives due to interpretations of erroneous capture of higher counts at the Search backend than at the Stock backend.

Method	Bot ratio = 0% TP, FP, TN, FN	Bot ratio = 5% TP, FP, TN, FN	Bot ratio = 10% TP, FP, TN, FN
Polling	0, 0.005, 0.995, 0	0.005, 0.062, 0.874, 0.059	0.069, 0.136, 0.666, 0.129
L-Y	0, 0.005, 0.995, 0	0.001, 0.058, 0.886, 0.055	0.011, 0.105, 0.783, 0.101
Beaver	0, 0, 1, 0	0.053, 0, 0.947, 0	0.113, 0, 0.887, 0.001

Table 3: Beaver's detection accuracy versus (1) polling-based approach using time synchronization, and (2) Lai-Yang algorithm, a state-of-the-art global snapshot protocol.

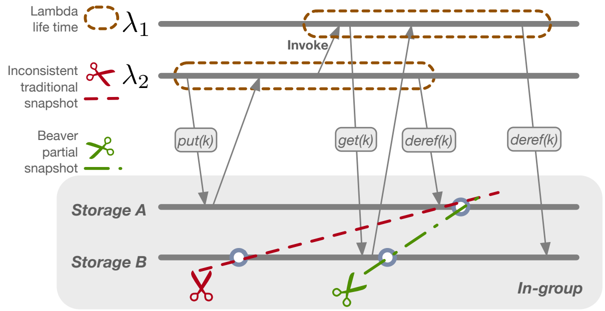


Figure 16: Garbage collection for the ephemeral storage for serverless analytics.

7.4.2 Serverless Garbage Collection

Backend services that support serverless applications are also a natural fit, as requests to serverless functions rely on schedulers and logic that are not visible to the backend services or the serverless functions themselves. Consider an application that provides storage for a serverless analytics job and uses reference counting for garbage collection [32]. The storage service deploys multiple servers for scalability and supports three primary APIs: `get()`/`put()`, which fetch/upload the object and increment the reference counter, and `deref()`, which indicates that the previously fetched object is no longer in use and decrements the reference counter.

Beaver's consistent partial snapshots can support safe garbage collection decisions. To illustrate, we instantiate two serverless functions through [30] that follow the workflow of Figure 16 on our testbed. The backend storage maintains an in-memory state of reference counters for each KV object. When a reference counter reaches 0 in a snapshot, the controller informs the backends to recycle the correspond-

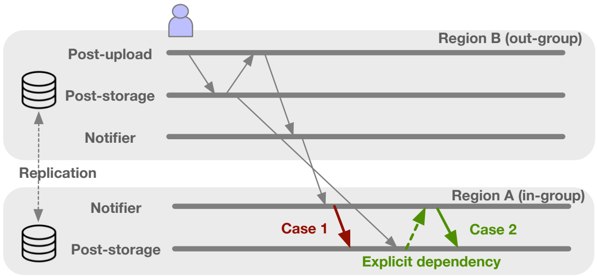

Figure 17: A simplified example of geo-distributed social media application [17] which includes distinct services such as post-upload, post-storage, and notifier.

ing object. During invocations, we also record the incident counts of invalid `get()` access or `deref()` calls. We find that, across invocations, the Lai-Yang algorithm may produce inconsistent snapshots (shown in Figure 16) that indicate *no* open references to the object—however, λ_1 is still keeping a reference to it. This leads to unsafe decisions to recycle the object associated with the key and results in an observed invalid call percentage of 23–29%. In contrast, Beaver's partial snapshots guarantee causal consistency even in the presence of external communication that ensures safe reclamation of the object and consistently results in 0 invalid calls.

7.4.3 Integration Testing

Integration testing, commonly used in CI/CD pipelines [24], extends the coverage of testing to inter-service logic. Unfortunately, applying it to distributed applications can be challenging. Consider the example shown in Figure 17, a violation of the application specification occurs when followers in a region receive a notification and request the storage DB (case 1) before the cross-region protocol actually replicates the post data. Recent solutions [17, 53] address the inconsistencies by forming explicit dependencies (case 2). However, the involvement of auxiliary services and additional dependencies make it difficult to capture a holistic snapshot.

Beaver offers a practical abstraction to test distributed applications by enabling partial deployment and capturing causal dependencies relevant to the local service. By snapshotting states in post-storage and notifier services, developers can write test cases to verify the crucial invariant above: the presence of a post in the storage must always precede its corresponding notification in the notifier service. In particular, Beaver's guarantee of causal consistency means that if a canary solution is correct, a partial snapshot observing a log in the notifier must have captured the data entry of the corresponding version in post-storage. Therefore, a single violating test case will suggest the presence of bugs.

7.4.4 In-flight Message Tracking

We also revisit the example in Figure 3. As mentioned in §2.2, a useful query is to estimate the number of concurrent requests, which can inform resource provision decisions. Figure 18a illustrates a scenario with only one active request. In theory, traditional snapshots, which fail to capture the causality between the client's follow-up request and the prior response, can give an overestimation of 2 in-flight messages (indicated by the cut in red). Beaver, in contrast, can capture the external causality and results in an estimation of no more than 1 message in flight (indicated by the cut in green).

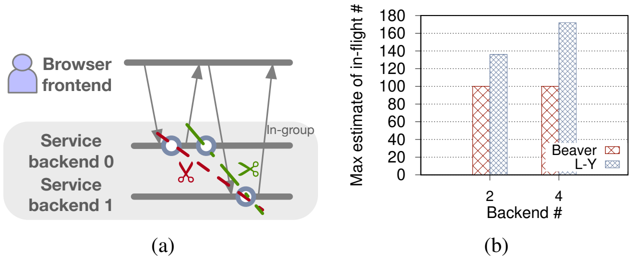

Figure 18: (a) Example snapshots for in-flight message tracking. (b) Comparison of estimated number of in-flight requests with and without Beaver.

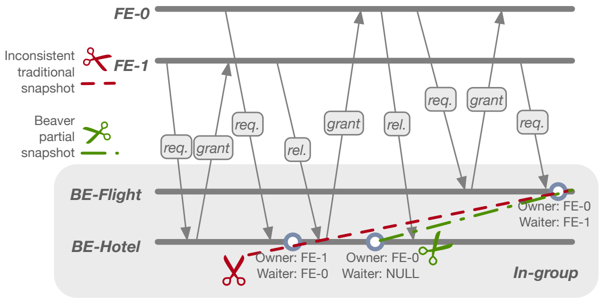

Figure 19: An example of deadlock detection using distributed snapshots.

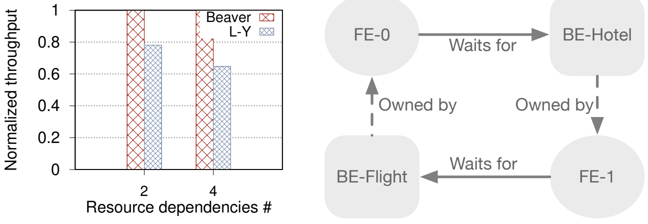
To validate the behavior in practice, we run 100 clients concurrently that conform to the poisson arrival pattern on our testbed. Each backend process maintains a total request and response count value using a BPF map. Thus, the difference between the two counters indicates the number of messages in flight. The controller then collects the snapshot of counter values and then obtains the aggregate estimate. Figure 18b shows that traditional snapshots can overestimate the number of concurrent requests by more than 30%, while Beaver's result consistently matches the ground truth. Worse, a higher number of backends will lead to an overestimation further divorced from reality.

7.4.5 Distributed Deadlock Detection

A classic use of distributed snapshots is deadlock detection, a fundamental problem in distributed systems. Consider the scenario in Figure 19, where the machines of a frontend service interact with a reservation microservice to book flights and hotels on behalf of its clients. Here, a frontend server acquires a lock from the backend server for a target resource ID and



(a) (b)

Figure 20: (a) Comparison of transaction throughput (normalized to Beaver). (b) WFG for the inconsistent snapshot in Figure 19.

releases it after completing its transaction. A deadlock may occur when a client requests resources that are held by others, forming a directed cycle in the resource dependency graph (known as Wait-For Graphs or WFGs). As these systems (such as those used by Airbnb and Uber) encompass thousands of microservices, each with its own sovereignty [20,64], global snapshots are challenging and expensive to enforce.

Beaver, however, is amenable to only taking partial snapshots of the reservation service. To illustrate, we run backend processes that maintain the ID list of client(s) currently owning/waiting for the local resources in memory. When the controller detects a deadlock based on a snapshot, it informs backend processes to abort the current transaction. We emulate clients that request backend resources in random order and measure the resulting transaction throughput. Figure 20a shows that the traditional snapshot algorithm can suffer from more than 20% throughput drops compared to Beaver. This is because, without accounting for the external message dependencies, it can render a snapshot that is inconsistent (Figure 19), which leads to false deadlocks (Figure 20b) and the unnecessary costs of deadlock resolution operations. Beaver, on the other hand, guarantees safe detection.

8 Discussion

Instantiating Beaver gateways. Beaver focuses on public clouds, which already contain SLBs, imposing minimal changes and costs to integrate its functionality. We argue that these are where partial snapshots are most important as smaller private clouds are easier to modify wholesale [51]. Without cloud providers' support, cloud tenants could also deploy their own Beaver-compatible gateways on virtual machines (e.g., Network Virtual Appliances (NVAs) [7]) to ensure consistency under external communication with clients and human users. This involves additional costs and complexities and can be suitable if NVAs are already in use, e.g., to provide firewall functionality.

Optimizing local record operations. Similar to classic distributed snapshot protocols (§2.2), Beaver is agnostic to the semantics of local record operations. An interesting problem—orthogonal to the core mechanism of Beaver—is to enable efficient local-state capturing mechanisms, especially when the user desires a large target state or a high snapshot frequency. Besides application-specific practices in §7.4, we postulate that a more generic and opportunistic approach may minimize their online impacts by focusing on state changes during IDLE times of the application. We leave a complete exploration for future work.

9 Related Work

Distributed snapshots. This work builds on the large array of classic distributed snapshot algorithms [11,26,33,34,41,56,57,60]. To the best of our knowledge, Beaver formalizes, designs, and implements the first partial snapshot primitive that extends their capabilities for practical usage.

Cloud data centers. Beaver is also related to works on various facets of cloud data centers, including layer-4 load balancers [10,15,22,43,50,63] and its clock services [13,23,25,36,38,42,44,48,59,62]. For the former, Beaver integrates its gateway marking logic based on the behaviors of SLBs fundamental to cloud data center services and implements a practical prototype aligned with today's setups. Meanwhile, Beaver builds on extensive measurement studies that highlight the reliable properties of frequency drifts of a single clock. Combined, Beaver presents a unique design without making any assumptions about clock synchronization that ensures consistent, high-rate partial snapshots under external interactions while incurring minimal changes and impacts to current operations and service traffic.

10 Conclusion

This paper rethinks the classic distributed snapshots and observes the mismatch of their assumptions with today's cloud services. With it, we present Beaver, the first partial snapshot primitive that advances the capabilities of existing snapshots for practical usage in distributed cloud services. Central to Beaver is the design and instantiation of a novel optimistic gateway marking primitive. Beaver presents a unique design point by tightly integrating the protocol with the regularities of data center networks. Our evaluation demonstrates that Beaver not only can capture partial snapshots at high speed, but it also incurs near-zero costs to existing service traffic.

Abstract

Distributed lock services are extensively utilized in distributed systems to serialize concurrent accesses to shared resources. The need for fast and scalable lock services has become more pronounced with decreasing task execution times and expanding dataset scales. However, traditional lock managers, reliant on server CPUs to handle lock requests, experience significant queuing delays in lock grant latency. Advanced network hardware (e.g. programmable switches) presents an avenue to manage locks without queuing delays due to their high packet processing power. Nevertheless, their constrained memory capacity restricts the manageable lock scale, thereby limiting their effect in large-scale workloads.

This paper presents FISSLOCK, a fast and scalable distributed lock service that exploits the programmable switch to improve (tail) latency and peak throughput for millions of locks. The key idea behind FISSLOCK is the concept of lock fission, which decouples lock management into grant decision and participant maintenance. FISSLOCK leverages the programmable switch to decide lock grants synchronously and relies on servers to maintain participants (i.e., holders and waiters) asynchronously. By using the programmable switch for routing, FISSLOCK enables on-demand fine-grained lock migration, thereby reducing the lock grant and release delays. FISSLOCK carefully designs and implements grant decision procedure on the programmable switch, supporting over one million locks. Evaluation using various benchmarks and a real-world application shows the efficiency of FISSLOCK. Compared to the state-of-the-art switch-based approach (NetLock), FISSLOCK cuts up to 79.1% (from 43.0%) of median lock grant time in the microbenchmark and improves transaction throughput for TATP and TPC-C by 1.76× and 2.28×, respectively.

1 Introduction

Distributed lock services are essential building blocks for coordinating concurrent access to shared resources in numerous distributed systems, such as OLTP databases [23, 62, 67], file systems [18, 51], and rich cloud-based systems [1, 22, 25, 52]. Modern distributed systems commonly rely on fine-grained locks to concurrently access near-billion-scale datasets, such as files and directories [57, 58, 61], database tuples [10, 12, 14], and knowledge graphs [2, 4, 15].

With the prevalence of affordable high-performance networks (e.g., RDMA) and high-capacity persistent memory (e.g., Intel Optane) in modern datacenters, it is not uncommon to see microsecond-scale execution time in distributed in-memory systems [20, 60, 66, 71–73, 78] (see Table 1). As a result, the overhead of granting locks (10–100 µs) becomes non-trivial (e.g., comparable to task execution time) and even dominates the end-to-end performance [62, 75, 76].

Distributed lock managers [6, 13, 30, 54, 55, 65, 76] are commonly designed in a centralized manner to handle lock requests and grant locks. This makes it easy to enable powerful features such as latency predictability [31, 38, 46], starvation freedom [36], and performance isolation [76]. Specifically, before and after accessing a set of objects, the corresponding locks must be acquired from and released to the lock manager, which acts as a central point for granting and managing locks. Traditional lock managers rely on commodity servers to serve lock requests, which imposes one network round-trip overhead in granting locks and often incurs significant queueing delay due to limited request processing throughput of the server CPUs.

To overcome these drawbacks, it has recently been proposed to use the programmable switch as a centralized lock manager to host part of locks [76], as it offers lower latency and higher throughput than servers for packet processing. Further, using the switch to handle lock requests halves the network overhead due to its central network location. However, due to the limited switch memory (typically just a few MB), only a small fraction of locks (e.g., less than 10,000 [76]) can be hosted on a programmable switch for large-scale workloads. This is mainly because the variable-size metadata of a lock—a set for holders and a queue for waiters—consumes several hundred bytes of switch memory. Moreover, the performance of existing switch-based approaches is heavily dependent on the workloads, which must be both highly skewed and predictable to achieve significant improvement. It is also difficult, or even impossible, to dynamically update the data plane model of a programmable switch for exchanging locks.

Key insight. The centralized lock manager can be divided into two phases: *synchronous* grant decision and *asynchronous* participant maintenance. Making a grant decision is based solely on the *fixed-size* metadata (lock mode),

Table 1: *Task execution time of distributed in-memory systems.*

Systems	Workload	Exec. Time
Txn. Processing [37, 73]	TPC-C / TATP	7 / 2.8 µs
File System [18, 51]	Read / Write / Mkdir	1 / 10 / 20 µs
Key-value Store [71, 78]	Search / Insert / Delete	8 / 15 / 12 µs
Online Trading [20]	Trade Execution	10 µs

while maintaining participants also requires the remaining *variable-size* metadata (holders and waiters).

Our approach. Armed with the above insight, we design FissLock, a *switch-centric* lock managing system that also leverages programmable switches but in a new way to offer significant performance improvement (both latency and throughput) and memory efficiency for millions of locks. The key idea is *lock fission*, which decouples grant decision and participant maintenance procedures of the lock manager and deploys the two parts on the programmable switch and commodity servers, respectively. Specifically, the switch acts as the *decider* that immediately makes a decision and replies to the requester if the lock is granted. Meanwhile, the lock request is further routed to the server, hosting the *agent* of the lock, for updating lock holders and waiters with rich semantics. The main advantages of lock fission are three-folds. First, it stores only a small, fixed-size lock mode in switch memory to accelerate millions of locks, which is two orders of magnitude larger than existing switch-based approaches. Second, it leverages high-speed, line-rate request processing of the switch to concurrently grant locks with lower latency and higher throughput than server-based approaches. Third, it delegates lock management tasks (i.e., maintaining holders and waiters) to the server of the lock holder, enhancing load balance and data locality for diverse workloads.

FissLock proposes the first design of the lock fission protocol, which splits the lock manager into a centralized, stationary decider on the switch, and migratable agents for each lock on the servers. The protocol introduces new workflows for acquiring and releasing locks, which allow for halfway responses from the switch when acquiring grantable locks and migrating agents among servers to exploit locality and balance lock management loads. FissLock further addresses the anomalies in the protocol caused by network exceptions using incarnation checks.

FissLock stores small fixed-size metadata (e.g., lock mode) for each lock in the switch memory. By carefully designing on-switch metadata structure, a single switch with a few MB of memory can host millions of locks. To implement the decider of the lock fission protocol on an ASIC-based programmable switch (e.g., Intel Tofino [16]), FissLock devises a 6-stage pipeline to process four types of packets in the protocol. Each stage employs one or more match-action units in the switch data plane to perform simple operations that a programmable switch can afford, such as metadata matching and updating, and packet destination selection.

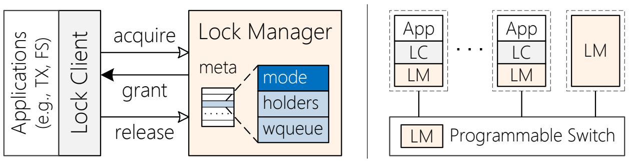

Fig. 1: *Distributed lock management.*

We implemented FissLock from scratch on a Tofino switch [16] and evaluated it using a microbenchmark, two transaction benchmarks, and a real-world application. Our experimental results show that FissLock cuts up to 79.1% (from 43.0%) of median lock grant time in the microbenchmark and improves the transaction throughput of TATP [12] and TPC-C [14] by 1.76× and 2.28×, respectively, compared to the state-of-the-art switch-based approach (NetLock [76]). We built a Redis-backed mobile banking application [11] with FissLock, which is one order of magnitude faster than Redis's official implementation (RedLock [5]).

Contributions. We summarize our contributions as follows:

- An in-depth analysis of performance issues in existing lock manager designs for modern distributed in-memory systems (§2).
- A new centralized lock management scheme, *lock fission*, which decouples grant decision and participant maintenance to embrace the best of both programmable switches and servers (§3).
- A switch-centric lock manager design that enables the lock fission protocol (§4) and implements grant decision for millions of locks on the programmable switch (§5).
- A prototype implementation and evaluation that demonstrates the efficacy of FissLock over state-of-the-art (§7).

2 Background

2.1 Distributed Lock Management

The distributed lock service commonly uses a centralized lock manager (LM) to handle all requests and grant the lock for various applications, such as transactions and file systems. As shown in the left part of Fig. 1, before reading or updating the protected data, applications—through the lock client (LC)—*acquire* the lock in shared or exclusive mode by sending the request to the lock manager, and waits until the lock manager *grants* the lock. After accessing the data, applications *release* the lock to the lock manager asynchronously. The lock manager maintains the metadata of locks (*meta*) identified by a unique lock ID. The metadata of each lock contains a mode of lock (*mode*), a set of lock holders (*holders*), and a queue for waiters (*wqueue*) [13]. The mode is a small, fixed-size flag (2 bits) that represents the current lock state (i.e., free, exclusive, or shared) and decides the grant of locks. Both holders and wqueue require large, variable-size data structures (up to hundreds of bytes) that represents the current lock participants and enables flexible locking policies (e.g., priority and fairness).

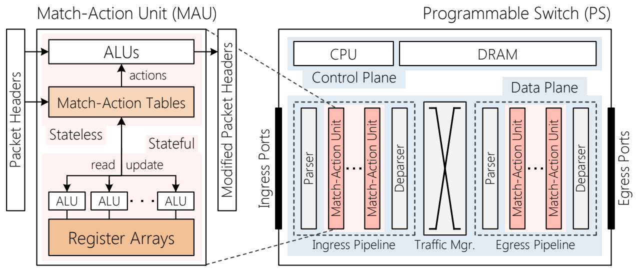

Fig. 2: *The architecture of programmable switches (PS) and the internal structure of match-action units (MAU).*

The lock manager can run on dedicated servers to avoid interference with applications [54, 55, 65] (called SrvLock). However, it may not scale well with fast-growing application workloads and datasets. Therefore, the lock manager can also be partitioned and co-located with applications to further exploit locality [6, 13, 30] (called ParLock), but it may suffer from load imbalance under skewed workloads. Recently, the programmable switch has been proposed to handle skewed workloads by managing a small fraction of hot locks (e.g., less than 10,000) directly on the switch (i.e., NetLock [76]), because it provides higher throughput than servers, halves the network latency, and saves server resources. However, due to the limited memory resources of programmable switches (a few MB), just a part of the workload can be accelerated, and the rest will be downgraded to server-based solutions. The right part of Fig. 1 illustrates the above three solutions for distributed lock management.

2.2 Programmable Switch (PSwitch)

Programmability is becoming a trend in modern network switch design, with support from major manufacturers like Cisco [3], Broadcom [33], and Intel [16]. Compared with commodity servers, programmable switches possess orders of magnitudes higher throughput (several billion packets per second) and lower delay (less than 1 µs) for packet processing [34]. Yet, only very limited memory resources (a few MB) are available. As shown in Fig. 2, modern programmable switches have a general-purpose CPU with DRAM (i.e., the *control plane*) attached to the switch ASIC (i.e., the *data plane*) via a PCIe bus. The control plane hosts a Linux-based operating system that manipulates the switch ASIC as a device. The data plane is programmable via P4 Language [19], which describes the logic of packet parsing, processing, and forwarding. Specifically, packet processing is realized as pipelines of *match-action units* (MAUs), which perform pre-defined packet modifications (*actions*) according to the value of specific fields in the packet header. Incoming packets can be either forwarded to a single egress port (*unicast*) or replicated to multiple egress ports (*multicast*). Each MAU reads and updates user-defined data stored in *register arrays* (hundreds of KB) once for each packet, and conditionally modifies packet header fields according to *match-action tables* (up to over 1 MB).

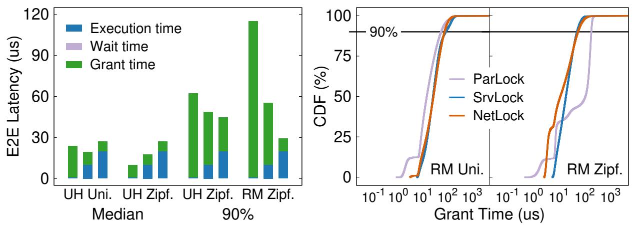

Fig. 3: *The end-to-end median and 90^{th} percentile latency breakdown with different task execution times (1 µs, 10 µs, and 20 µs) under update-heavy (UH) and read-mostly (RM) workloads (left), and the lock grant time distribution under read-mostly Uniform (Uni.) and Zipfian (Zipf.) workloads when using different LMs (right).* **Testbed:** *An 8-node cluster with an Intel Tofino switch.* **Workload:** *A microbenchmark with one million locks (see §7.1 for details).*

2.3 Performance Analysis

Grant time becomes increasingly important. The end-to-end latency of typical distributed tasks is mainly composed of execution time and lock acquire/release time. Lock release time is irrelevant as locks are typically released asynchronously. Lock acquire time consists of two parts—*wait time* and *grant time*, which denotes the duration that the request is suspended in wqueue and the rest, respectively. Nowadays, microsecond-scale execution time becomes common in distributed in-memory systems [18, 51, 60, 66, 71–73, 78]. Meanwhile, the rapidly increasing size of datasets (e.g., millions of objects per thread [29, 66]) dramatically enlarges the lock space, resulting in lower lock contention rate and less wait time. Consequently, grant time becomes non-negligible in the end-to-end task latency. As shown in Fig. 3 (left), grant time accounts for a significant portion of the median and tail end-to-end task latency under workloads with varied read-write ratio and skewness, while wait time is negligible because of the low lock contention.

Despite its importance, grant time has not drawn enough attention in existing lock manager designs, in which we observe three major performance issues (see Fig. 3 (right)).

Issue#1: Unstable latency. All existing approaches rely on server CPUs to process (partial or all) lock requests, introducing significant queueing delay that makes the grant time unstable. Since the server receives and processes packets in batches, the handling latency of requests is proportional to their positions in the batch. Due to the limited packet processing power of server CPUs, this results in non-trivial grant time variance, from a few µs to over 100 µs in our testbed. Note that requests handled by the switch do not exhibit apparent queueing delay because of line-rate processing.

Issue#2: Limited acceleration. Both ParLock and NetLock adopt fast-path request handling to accelerate a part of lock requests, but the portion of accelerated requests is rather limited. ParLock partitions the locks to handle some lock requests locally, which saves 1 RT as compared with SrvLock. However, the portion of locally handled requests is inversely proportional to the cluster size (e.g., 12.5% in our 8-node setup). NetLock manages hot locks on the programmable switch, halving the required round trips and eliminating queueing delay. However, due to limited switch memory capacity, the switch can only manage thousands of locks, which are insufficient for protecting million-scale datasets without exhibiting significant contention (see §7.7). When managing 1 million locks, even with workload profiling in advance, NetLock only accelerates 1% and 27% of grants under the Uniform and Zipfian workloads, respectively, as most requests are handled by the lock server instead of the switch.

Issue#3: Workload sensitivity. The performance of ParLock and NetLock are sensitive to workload attributes, which results in their dependence on prior knowledge of the workload. ParLock partitions locks statically, which incurs severe load imbalance problem under skewed workloads. In our experiment on the Zipfian read-mostly workload, 56.7% of requests are processed by one server, which throttles the LM and results in extremely high grant time. Due to the limited switch capacity, NetLock prefers skewed workloads and heavily relies on workload profiling for detecting hot locks. It falls back to SrvLock on occasions that the workload is uniform or has dynamic patterns (e.g., e-commerce).

3 Approach and Overview

System model and design goals. FISSLOCK is a distributed lock management system that uses programmable switches to accelerate the processing of millions of locks across diverse workloads. It is designed for distributed in-memory systems that rely on a centralized lock service to coordinate concurrent access of microsecond-scale tasks to large-scale shared datasets. Unlike lock-based coordination services like Zookeeper [32] and Chubby [21], which aim for reliable but coarse-grained coordination, FISSLOCK is not designed to achieve high availability. Instead, FISSLOCK has three high-level design goals:

- **Efficiency**: Grant locks in single-digit microseconds to meet the common needs of microsecond-scale tasks.
- **Pervasiveness**: Unleash full-scale acceleration for million-scale locks, making it feasible for large-scale systems.
- **Robustness**: Ensure good yet stable performance for diverse or dynamic workloads without prior knowledge.

Key insight. The lock management can be divided into two phases: grant *decision* and participant *maintenance*. The decision phase determines whether the lock can be granted with regard to the current lock mode, while the maintenance phase manages lock participants (i.e., holders and waiters) accordingly. We recognize two key insights that motivate the split design of a centralized lock manager. First, decision making must be *synchronous* (i.e., executed before handling other requests) to ensure the correctness of lock semantics, while participant maintenance can be *asynchronous* to shorten the critical path of granting a lock. Second, decision making relies solely on the *fixed-size* metadata (shared or exclusive), while participant maintenance also requires the remaining *variable-size* metadata (holders and waiters).

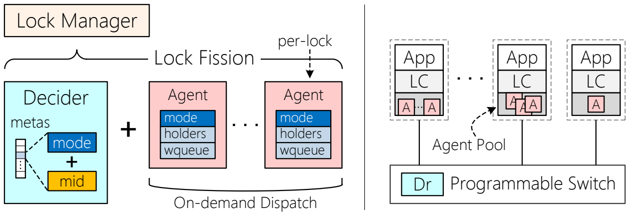

Fig. 4: *The lock fission scheme (left) and the system architecture of* FISSLOCK *(right).*

Our approach. We propose *lock fission* as a technique that decouples decision and maintenance in terms of both functionality and metadata. Specifically, the lock manager is split into a centralized *decider* and multiple per-lock *agents* (see Fig. 4 (left)). The decider records each lock's mode and makes granting decisions for lock requests accordingly, while the agent stores and maintains the remaining lock metadata (e.g., holders and waiters) of the corresponding lock. The lock acquisition request is first sent to the decider, which makes decisions and replies instantly if the lock is granted. Simultaneously, the decider forwards the request to the responsible lock agent, which updates holders and waiters according to the decision. Release requests are also sent to the decider and forwarded to the agent. When the last holder releases, the agent grants the lock to the next holder or frees the lock. In both cases, the decider is notified in advance to update the lock mode.

Lock fission provides the opportunity to accustom workload attributes without prior knowledge. By recording the resident machine ID (*mid*) of each lock's agent, the decider is always able to route requests to the latest location of agents, which supports the dynamic migration of lock agents among machines. To balance the request handling load among machines, agents are *on-demand dispatched* to the lock holder's machine. When the lock is freed or transferred to waiters, the agent is deconstructed or migrated to the waiter's machine. The migration of agents also enables most release requests to be processed by local agents, thereby shortening the network path of lock release operations.

Lock fission meets the design goals by exploiting the *packet processing strengths* of programmable switches and the *high memory capacity* of commodity servers simultaneously. First, metadata for decision is small, fixed-size data, which enables decision making for million-scale locks with limited switch memory capacity. Second, since maintenance is decoupled with decision, servers are not involved in the lock granting critical path, which eliminates the queueing delay. Third, lock fission does not require any prior knowledge of the workload and resolves the load imbalance problem by dynamic lock agent migration.

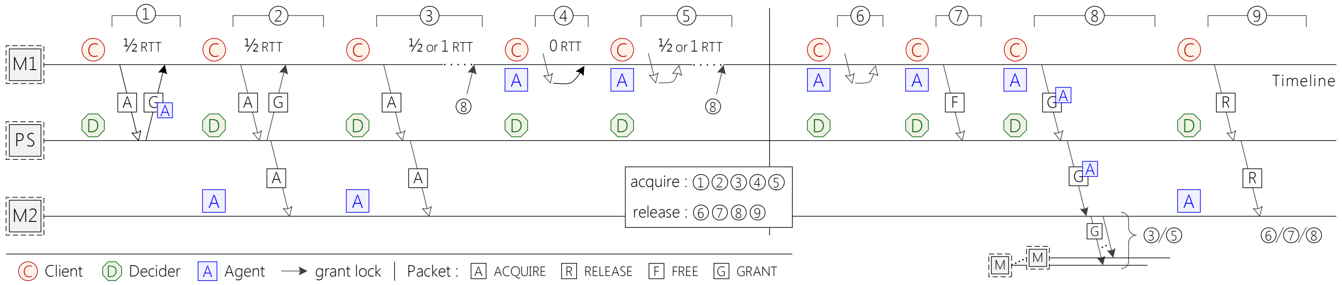

Fig. 5: *The lock acquisition and release workflow in the lock fission protocol.*

System overview. FISSLOCK is a switch-centric lock management system that applies lock fission to enable efficient and centralized management of million-scale locks. As shown in Fig. 4 (right), FISSLOCK is composed of lock clients (LC), a decider (Dr), and lock agents (A). Lock clients are libraries that encapsulate lock acquire/release requesting functionalities into APIs. The decider resides on the switch for accelerating lock grants and routing requests to agents. Each machine owns an agent pool that manages all agents on it. Lock requests forwarded from the decider are received by the agent pool, which finds the responsible agent for each request and hands over the request. The agent subsequently updates the lock metadata.

Applications acquire locks via the LC, which sends the request to the decider, or if the lock agent can be found locally, the lock agent. The decider makes decision and replies instantly, *multicasting* the request to the lock agent's resident machine at the same time. Packets arriving at machines are dispatched to the lock client (grant replies) and the agent pool (lock requests), which wakes up application tasks and calls agent functions to update the lock metadata respectively. When the lock is released, similar to the acquire case, the request is forwarded to or directly handed over to the lock agent. If the lock needs to be granted to the next holder, the agent is transferred along with the lock ownership.

4 FISSLOCK

This section describes the lock fission protocol implemented by FISSLOCK. Although the design principles of lock fission are independent of specific lock mechanisms used, we elaborate on the read-preferring design as an example, and briefly discuss the write-preferring design in §6.

4.1 Lock Operation Workflow

Fig. 5 illustrates the nine possible workflows (①–⑨) for acquiring and releasing locks in the lock fission protocol. The branches executed in each workflow are marked on the pseudocode presented in Fig. 6, Fig. 7, and Fig. 8.

```
# lid|mid|tid: lock|machine|task ID
# mode: lock mode in {FREE=00, EXCLUSIVE=10, SHARED=11}

sslock_acquire(lid, mid, tid, mode)                         ①②③④⑤
1    if agents.find(lid) then    # local agent (rare)        ④⑤
2      | if acquire(lid, mid, tid, mode) then
3      |   | return    # local grant                           ④
4    else    # remote agent                                  ①②③
5      | net_send(ACQUIRE, {lid, mid, tid, mode})
     # wait for grant
6    pkt = net_recv(GRANT, lid, mid, tid)                   ①②③⑤
7    if pkt.agent != nil then    # add agent
8      | grant(lid, mid, tid, mode, pkt.agent)                 ①③

sslock_release(lid, mid, tid)                               ⑥⑦⑧⑨
9    if agents.find(lid) then    # local agent               ⑥⑦⑧
10     | release(lid, mid, tid)
11   else    # remote agent (rare)                             ⑨
12     | net_send(RELEASE, {lid, mid, tid})
```

Fig. 6: *Pseudocode of* FISSLOCK *client lib implementation.*

Lock acquisition workflow (①–⑤). To acquire a lock, the lock client (C) sends an ACQUIRE request to the lock decider (D) (Line 5 in Fig. 6). The decider makes a lock granting decision by examining the mode of the lock (*meta.mode*) and the requested mode in the packet (*pkt.mode*). If the lock is free (①), the decider will update the lock mode and immediately grant a lock with an empty agent (A) to the client by returning a GRANT packet (Lines 2–6 in Fig. 8). After receiving the packet, the client calls the grant function of the agent pool to initialize the agent and add it to the pool (Lines 17–19 in Fig. 7). If the lock is being held and both modes are SHARED (②), the decider will still immediately grant the lock to the client and multicasts the ACQUIRE request to the agent (Lines 8–11 in Fig. 8). The agent will add the requester to holders later (Lines 2–4 in Fig. 7). Finally, if the lock cannot be granted immediately (③), the decider will forward the request to the agent, and the agent will append the requester to the wait queue (Line 6 in Fig. 7). In rare cases (④ and ⑤), the agent is on the same machine since another client on the machine is hosting the lock, such that the client will locally acquire the lock by calling the acquire function of the agent pool (Line 2 in Fig. 6). The agent can make a decision by itself—to grant (④) or to wait (⑤)—without consulting the decider. This is because the agent always has the latest lock mode and does not need to update the decider.

Lock release workflow (⑥–⑨). In the lock fission protocol, the agent (A) is always located on the same machine as the current holder (e.g., the first holder of the shared lock).

```
# agent:
#   mode: lock mode in {FREE=00, EXCLUSIVE=10, SHARED=11}
#   holders: a set of lock holders {mid, tid}
#   wqueue: a queue of waiters {mid, tid, mode}

acquire(lid, mid, tid, mode)                            ②③④⑤
1   agent = agents[lid]
2   if mode == SHARED && agent.mode == SHARED then      ②④
3     agent.holders.add({mid, tid})
4     return TRUE   # grant lock
5   else                                                ③⑤
6     agent.wqueue.append({mid, tid, mode})
7     return FALSE   # wait for grant

release(lid, mid, tid)                                  ⑥⑦⑧
8   agent = agents[lid]
9   agent.holders.remove({mid, tid})
10  if agent.holders.empty() then                       ⑦⑧
11    agents.remove(lid)   # remove agent
12    if agent.wqueue.empty() then                      ⑦
13      net_send(FREE, {lid})   # free agent
14    else   # transfer agent and grant lock            ⑧
15      next = agent.wqueue.pop()
16      net_send(GRANT, {lid, next.mid, next.tid,
                         next.mode, agent})

grant(lid, mid, tid, mode, agent)                       ①③
17  agent.mode = mode
18  agent.holders.add({mid, tid})   # grant lock
19  agents.add(lid, agent)   # add agent
20  if agent.mode == SHARED then   # grant others
21    ..   # pop shared waiters and add to holders
22    ..   # send grant lock (w/o agent) to them
```

Fig. 7: *Pseudocode of* FISSLOCK *agent pool implementation.*

```
# meta:
#   mode: lock mode in {FREE=00, EXCLUSIVE=10, SHARED=11}
#   mid: machine ID

process_acquire(pkt): # pkt: {lid, mid, tid, mode}  ①②③
1   meta = metas[pkt.lid]
2   if meta.mode == FREE then   # lock is free           ①
3     meta = {pkt.mode, pkt.mid}   # alloc agent
      # grant lock and assign (empty) agent
4     agent = {pkt.mode, {}, {}}
5     grant_pkt = pkt.append(agent)
6     forward_packet_to(GRANT, pkt.mid, grant_pkt)
7     return
8   if meta.mode == SHARED && pkt.mode == SHARED then    ②
      # grant lock
9     grant_pkt = pkt.append(nil)
10    forward_packet_to(GRANT, pkt.mid, grant_pkt)
    # acquire lock on agent
11  forward_packet_to(ACQUIRE, meta.mid, pkt)            ②③

process_release(pkt): # pkt: {lid, mid, tid}            ⑨
12  meta = metas[pkt.lid]
    # release lock on agent
13  forward_packet_to(RELEASE, meta.mid, pkt)

process_free(pkt): # pkt: {lid}                          ⑦
14  metas[pkt.lid] = {FREE, nil}   # free agent
15  drop_packet(pkt)

process_grant(pkt): # pkt: {lid, mid, tid, mode, agent}⑧
16  meta = metas[pkt.lid]
17  if pkt.agent != nil then   # transfer agent
18    meta = {pkt.mode, pkt.mid}
    # grant lock and assign agent
19  forward_packet_to(GRANT, pkt.mid, pkt)
```

Fig. 8: *Pseudocode of* FISSLOCK *decider implementation.*

Therefore, when releasing a lock, its agent is highly probable to be local to the requester. The client requests the local agent to release a lock through calling the `release` function of the agent pool (Lines 9–10 in Fig. 6). If the lock is also held by other clients of the machine (⑥), the release completes immediately (Line 9 in Fig. 7). If there is no waiter (⑦), the agent pool will remove the local agent and send a `FREE` request to the decider (Lines 11–13 in Fig. 7). The decider will free the lock and drop the packet directly (Lines 14–15 in Fig. 8). If there are waiters (⑧), the lock with its agent will be transferred to the next holder, popping from the wait queue, by sending a `GRANT` packet to the decider (Lines 15–16 in Fig. 7). The decider updates the lock metadata and forwards the packet to the machine of the next holder (Lines 17–19 in Fig. 8). After receiving the packet, the client calls the `grant` function of the agent pool to maintain the agent and add it to the pool (Lines 17–19 in Fig. 7). Furthermore, if the lock could be shared with subsequent waiters, the client will pop them from the wait queue and add to the holders, sending a `GRANT` packet to each of them (Lines 20–22 in Fig. 7). If the client, without a local agent (e.g., one holder of a shared lock), releases the lock (⑨), it will send a `RELEASE` request to the decider (Line 12 in Fig. 6). The decider will then forward the request to the agent (Line 13 in Fig. 8), and the agent will call the `release` function (Lines 8–16 in Fig. 7) to release the lock, as in the above workflows (⑥–⑧).

4.2 Network Exceptions

The lock fission protocol splits the lock manager into a stationary decider on the switch and migratable agents for each lock on the servers. Since they are connected via the network, network exceptions including lost, out-of-order, and delayed packets may cause some anomalies. FISSLOCK addresses these anomalies by retransmission, rerouting, and incarnation checks, respectively. As requests for different locks do not interfere with each other, we only consider out-of-order and delayed packets pertaining to the same lock.

Lost packets. FISSLOCK uses different approaches to handle the loss of packets initially sent by the switch and servers.

Server-initiated packets. FISSLOCK addresses the loss of packets initially sent by servers through TCP-based retransmission. When a server receives a packet, it sends an acknowledgement (ACK) to the origin of the packet. The switch forwards ACKs without updating on-switch metadata. Specifically, the destination of `FREE` packets (⑦) is the switch instead of servers, in which case the switch sends the packet back as an ACK. Servers monitor the arrival of ACKs for each packet regularly and retransmit packets that are not ACKed within a certain time frame.

In cases where the ACK is lost or delayed, the retransmis-

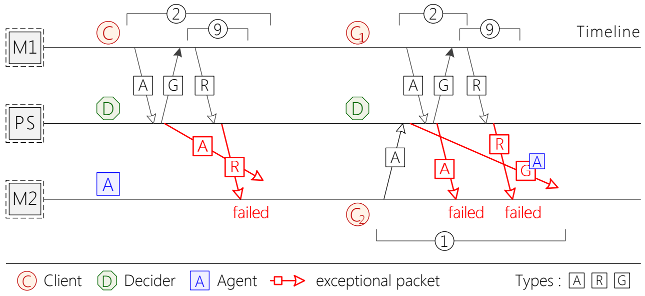

Fig. 9: *Two anomalies in the protocol due to out-of-order packets.*

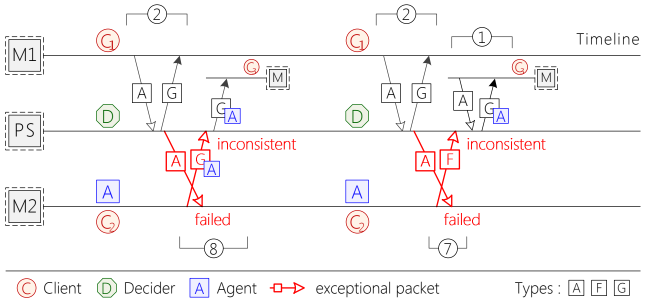

Fig. 10: *Two anomalies in the protocol due to delayed packets.*

sion mechanism can cause packet duplication, which is handled by servers through TCP. To prevent duplicated packets from corrupting on-switch metadata, the switch maintains a sequence number for each server to signify the number of processed packets. Servers track the number of packets sent to the switch, excluding retransmitted ones, and embed this number into all packets. If the incoming packet's number is not larger than the on-switch number, indicating that the packet is a duplicate, the switch does not update the lock metadata when processing the packet.

Switch-initiated packets. In workflows ① and ②, the lock request is granted by the switch instead of servers. Therefore, the GRANT packets in these workflows are considered switch-initiated. To avoid the complexities of monitoring ACK arrivals and executing retransmissions on the switch, FISSLOCK addresses the loss of switch-initiated packets in an alternative way—by setting a fixed timeout for lock acquisition operations. If an acquisition operation times out due to the absence of the GRANT packet, the client releases the lock (⑨) and retries the acquisition operation later. When processing the RELEASE packet, the switch frees the lock and drops the packet if it originates from the agent's server (①). If the RELEASE packet arrives at the agent, the agent removes the client from holders (②) or, if the client is not in holders (③), the wait queue.

Out-of-order packets. Packets with dependencies arriving out of order may lead to two anomalies. If ACQUIRE and RELEASE requests from the same requester are reordered (Fig. 9 (left)), the agent pool will fail to process the RELEASE request because the requester is not yet the holder or waiter of the lock. Further, the lock will never be released after granting it to the requester. If the ACQUIRE (and RELEASE) packet arrives before the agent is granted (Fig. 9 (right)), the agent pool will fail to process the ACQUIRE (and RELEASE) request because the agent does not exist. To avoid extra on-switch design, FISSLOCK resolves these anomalies by simply sending failed requests back to the decider. The decider then routes the request to the agent again, correcting the order.

Delayed packets. The ACQUIRE packet, which is immediately granted by the decider (②), may lead to anomalies when it arrives after the agent has been transferred (⑧) or freed (⑦). Note that the lock mode and the ACQUIRE packet must be both shared, as the lock is immediately granted. As shown in Fig. 10, the decider will incorrectly transfer the lock with its agent to the next holder (⑧) or grant the freed lock to a new client (①). The agent pool will fail to process the delayed packet.

FISSLOCK uses incarnation checks [68] to detect anomalies on the decider. Both the decider and the agent have a per-lock *incarnation* that is initially zero and is incremented when receiving a shared ACQUIRE request (②). The agent pool will include the expected incarnation in the GRANT and FREE packets. When the decider receives these packets and the lock is shared, it will check if its own incarnation matches the incarnation in the packet. If they match, the decider resets the incarnation and handles the request as normal. Otherwise, it refuses the packets, and the agent pool restores the agent to continue handling lock requests. Moreover, the failed ACQUIRE request will also be sent back to the decider, which will then route the request to the agent again.

4.3 Protocol Correctness

The lock fission protocol introduces two changes to the traditional reader-writer lock design: decoupling the decision process from the lock manager and allowing lock agents to migrate among servers. We argue the correctness of our lock fission protocol by showing that these changes preserve the reader-writer property [24, 53]. Specifically, we prove that the following two invariants always hold.

Invariant 1 (reader-writer exclusion): *Locks held in exclusive mode do not have any other holders; locks held in shared mode do not have any exclusive holders.*

In the traditional reader-writer lock design, all acquisition requests are processed by the lock manager, which maintains Invariant 1. In the lock fission protocol, requests are either processed by the local agent or sent to the decider. Both of them grant or suspend lock requests following the same criteria as traditional lock managers. Hence, Invariant 1 holds as long as the local agent and the decider always have consistent lock mode, and the lock mode correctly reflects the number of holders, which we prove as follows.

Lemma 1: *If the local agent exists, it has the same lock mode as the decider.*

Proof: The lock mode in the decider becomes shared or exclusive when a free lock is acquired for the first time (①) or the lock is transferred to a shared or exclusive waiter (⑧). In both cases, the agent is carried by the `GRANT` packet, so the local agent does not exist until the `GRANT` packet is received by the requester's machine. Moreover, the lock mode in the carried agent, which subsequently becomes the local agent, is identical to the updated lock mode in the decider. Before the local agent is removed, the decider only receives `ACQUIRE` and `RELEASE` packets, which do not change the lock mode. Hence, the lock mode in the decider remains consistent with the lock mode in the local agent.

Lemma 2: *The lock mode in the decider always correctly reflects the number of holders.*

Proof: We enumerate all possible lock mode transitions to prove Lemma 2. Initially, each lock is free and has no holders. The lock mode transits from free to shared or exclusive only when the lock is granted to a requester, which guarantees that the lock has at least one holder. If the lock mode is exclusive, subsequent `ACQUIRE` packets will not be granted. Hence, exclusive locks have at most one holder. The lock mode transits back to free only when receiving `FREE` packets whose incarnation matches the decider's incarnation, which indicates that all holders have released the lock. Similarly, the lock mode transits between shared and exclusive when receiving `GRANT` packets that have matched incarnation. In this case, all former holders have released the lock, and the destination of the `GRANT` packet becomes the new holder.

Invariant 2 (finite wait): *Waiters of the lock will be granted in finite time.*

Traditional lock managers decide to suspend a lock request and add the requester to the wait queue simultaneously. However, in the lock fission protocol, these two operations are decoupled and executed by different entities, i.e., the decider and the agent. We show that Invariant 2 still holds in the decoupled setup, which allows the agent to migrate among servers, by proving Lemma 3 and 4.

Lemma 3: *Lock acquisition requests that are suspended will eventually be added to the wait queue.*

Proof: Lock acquisition requests may be suspended by the agent locally (⑤) or remotely (③). In the former case (⑤), the local agent directly adds the requester to the wait queue when suspending the request. In the latter case (③), the decider, after deciding not to grant the lock, forwards the `ACQUIRE` request to the agent, which adds it to the wait queue. If the agent is not present due to packet reordering, the request is sent back to the decider. The decider then forwards it to the agent's latest location, guaranteeing that it will eventually be recorded in the agent's wait queue.

Lemma 4: *Waiters recorded in the wait queue will eventually be granted.*

Proof: All holders of a lock will eventually release it, either locally (⑥) or remotely (⑨). Therefore, the number of holders will eventually become zero, unless the lock is continuously granted to new shared holders (②), which FissLock averts by adopting a starvation prevention mechanism (see §6). When the number of holders reaches zero, at least one waiter is granted and becomes the new holder (⑧). Thus, according to induction, all waiters will eventually be granted.

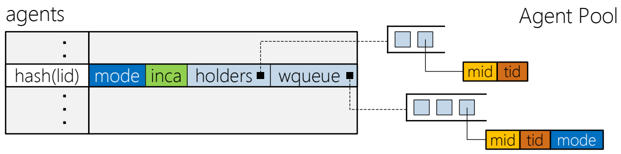

Fig. 11: *The main structures in the agent pool.*

5 Design

5.1 On-server Agent Pool

Data structures. As shown in Fig. 11, the agent pool uses a hash table to store granted agents, which is shared by all clients on the same machine. Each agent maintains complete lock metadata, including mode, incarnation, holders, and wqueue. The holders is an unordered set of current lock holders (*mid*, *tid*), and the wqueue is a FIFO queue of pending lock requests (*mid*, *tid*, *mode*). The incarnation (*inca*) is used to handle delayed packets.

Agent operations. The agent pool adds an agent when receiving a `GRANT` packet with agent information (Lines 17–19 in Fig. 7) and removes an agent when the lock is freed or granted to the next holder (Line 11 in Fig. 7). Furthermore, if the agent pool fails to process packets due to network exceptions (see §4.2), it sends such packets back to the decider. For incarnation checking, the agent pool includes the expected incarnation in the `GRANT` and `FREE` packets and restores the agent if the decider refuses these packets.

5.2 On-Switch Lock Decider

Data structures. The metadata of all locks (*metas*) is stored in register arrays of MAUs (RA in Fig. 12). When lock packets pass through the MAU, predefined actions read and update lock metadata via ALUs attached to the RA. To guarantee line-rate packet processing, each RA can only be accessed once per packet, and the ALU is allowed to perform a few simple arithmetic operations. Therefore, the lock decider functionality and metadata must be split into multiple MAUs, creating a pipeline. Each MAU stores a piece of metadata and performs the corresponding logic. All RAs are indexed by the lock ID (*lid*).

FissLock carefully selects the register size of RA for minimal memory consumption. The allowed register size includes 1 bit and a specific amount of bytes (1, 2, 4, or 8). An intuitive design is to store all of the lock *mode*, machine ID (*mid*), and incarnation (*inca*) into 1-byte RAs, while it wastes 6 bits for each lock mode. Instead, FissLock stores the lock mode with two 1-bit RAs (*free RA* and *r/w RA* in

Table 2: *Packet types used in* FISSLOCK.

Type	Contents
ACQUIRE	lock ID and mode to be acquired, machine ID and task ID of the requester
RELEASE	lock ID to be released, machine ID and task ID of the requester
FREE	lock ID to be freed, INCA, and lock mode before free
GRANT	lock ID to be granted to machine ID and task ID, INCA, and agent of the lock (optional)

Fig. 12), indicating whether the lock is held and whether the lock is shared, respectively. Both *inca* and *mid* use 1-byte RAs (*inca RA* and *mid RA* in Fig. 12). Although 8 bits are still over-sufficient, there are unfortunately no smaller register units in the RA to store them. Packing multiple *mid*s (or *inca*s) in one register is not feasible due to memory accessing restrictions. In summary, FISSLOCK compresses the switch memory consumption of each lock to 18 bits, which is two orders of magnitudes smaller than prior work [76].

Using 1-byte registers for *mid* and *inca*, a single MAU is not enough for the million-scale lock amount. Therefore, FISSLOCK splits them into multiple MAUs, each storing a fixed range of locks. For these MAUs, the lock ID is translated into a MAU *index* and an *offset* within the MAU (*MAU-selection* stage in Fig. 12).

Packet processing pipeline. The decider is realized as a 6-stage pipeline that processes four types of packets in FISSLOCK (see Table 2), where all packets share the same header format but use different header fields. Each stage checks the metadata in the packet or loaded from former stages for selecting proper actions to execute. Actions leverage the ALUs attached to RAs to read, update, and write back the metadata simultaneously. FISSLOCK organizes the MAU order to ensure that all metadata is loaded from RAs before being used by subsequent stages. Only packet types marked in Fig. 12 are processed in corresponding stages. The logic of each stage is described as follows.[1]

MAU-selection stage translates the lock ID into the MAU *index* and the *offset* in the MAU in Fig. 12 for Check stage and MID stage. In Check stage and MID stage, MAUs other than the indexed MAU are skipped.

Check stage checks and updates the incarnation. `ACQUIRE` packets for a shared lock increment the incarnation by 1. `GRANT` packets with agent and `FREE` packets reset the incarnation if the current lock mode is exclusive[2] or the incarnation in the packet is matched, i.e., there are no delayed packets. Otherwise, the packet is marked as invalid and will be skipped by the rest stages except for Destination stage.

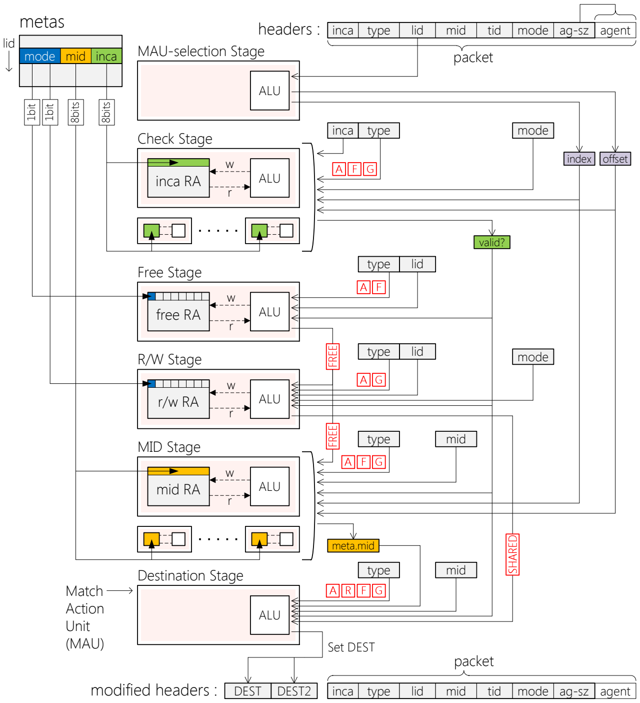

Fig. 12: *The metadata of locks stored in register array of MAUs and packet processing pipeline (data flow) in programmable switch.*

Free stage updates the free register in RA and loads its original value to the FREE flag in Fig. 12. `ACQUIRE` and `FREE` packets set the free register to 0 (held) and 1 (free) despite its original value, respectively, as 1-bit RAs do not support conditional updates with regard to the original register value.

R/W stage updates the r/w register in RA. `GRANT` packets update the r/w register to the next holder's mode. `ACQUIRE` packets only update the r/w register to the requester's mode when the lock is free (Line 3 in Fig. 8), i.e., the FREE flag is 1. This stage sets the SHARED flag in Fig. 12 that indicates whether both the *pkt.mode* and the r/w register are `SHARED`, which determines packet destinations later.

MID stage loads and updates *meta.mid* in mid RA.`ACQUIRE` and `GRANT` packets store the *pkt.mid* into mid RA as the new agent's location when the lock is free (Line 3 in Fig. 8) and when carrying the agent (Lines 17–18 in Fig. 8), respectively. `FREE` packets reset *meta.mid* to 0 (Line 14 in Fig. 8).

Destination stage routes packets to correct egress ports. The destination is controlled by two fields defined by the switch (*DEST* and *DEST2* in Fig. 12), which specify the ports that the packet should be replicated and forwarded to. Both fields can be null for dropping the corresponding packet replica. Packets specify their destination in DEST and the multicasted packet's destination in DEST2. Programmed egress pipelines update the type of multicasted packets to `GRANT`.

`ACQUIRE` packets are forwarded to the *pkt.mid* when the lock is free (Line 6 in Fig. 8), *meta.mid* when the request is suspended (Line 11 in Fig. 8), and both *mids* when a shared lock is granted to a shared requester (Lines 10–11 in Fig. 8).

[1] Stages for identifying lock packets and supporting retransmissions are not included for convenience.

[2] The mode field of packet header is used to transfer the current lock mode.

RELEASE packets are always forwarded to *meta.mid* (Line 13 in Fig. 8). GRANT and FREE packets are forwarded to *pkt.mid* (Line 19 in Fig. 8) and dropped (Line 15 in Fig. 8), respectively, unless marked as invalid in Check stage, in which case they are forwarded back to *meta.mid*.

5.3 Failure Handling

Failure model. FissLock can tolerate individual and simultaneous switch and server failures, but it does not guarantee availability (without data replication). Switch and server failures are detected by a reliable external coordinator using heartbeats. On failed servers, the granted locks are considered expired, and pending lock acquire operations are considered aborted. FissLock assumes that applications will handle lock expiration and aborted operations, such as manually aborting ongoing transactions. The availability of FissLock can be achieved through existing methods that replicate the switch data plane to backup switches [39], which are orthogonal to our work.

Failure recovery. Switch and server failures in FissLock may result in the loss of network packets (see Table 2), switch states (*metas*), lock agent states (*agents*), and lock client states (granted and pending lock requests). When a failure is detected by the coordinator, FissLock will restart the failed switch if necessary and perform three steps sequentially to recover the aforementioned states.

- **Server data aggregation (S1)**. All surviving servers pause lock operations and submit lock agent states and lock client states to the coordinator.
- **Server data recovery (S2)**. All surviving servers recover the lost and inconsistent states by referring to the aggregated states from the coordinator.
- **Switch data recovery (S3)**. The switch recovers its states by referring to lock agent states from all surviving servers.

5.4 Scale to Multiple Racks

FissLock can be scaled out by partitioning locks to each ToR switch. Each switch only handles requests for the locks it manages and routes other requests to responsible racks. Each machine has a global *mid*, which is translated by the switch to an egress port for the next-hop switch or the machine. In the current implementation of FissLock, these translation rules are statically predetermined, which disables on-demand scaling. However, on-demand scaling could potentially be achieved by updating these rules through the switch control plane. Although requests for remote-rack locks may experience higher network latency, they still have a stable grant time without any queueing delay. The imbalance of loads among switches is not a significant concern, as switches have orders-of-magnitude higher packet processing speed than servers. Even under heavy loads, servers would reach saturation before a hotspot switch does.

6 Implementation

We implemented FissLock from scratch using roughly 1,200 lines of P4 code and 5,000 lines of C++ code.[3] DPDK is used for packet sending and receiving.

Non-linear lock IDs. The lock ID can be sparse and inefficient for indexing RAs. In this case, FissLock maps lock IDs to linear RA indexes with an RPC daemon. Lock clients cache the mapping and embeds the RA index in packets.

Lock scales. FissLock supports efficient management of over 1 million on-switch locks. In our experiments on TPC-C, we use them to protect billion-scale data by protecting a range of data objects with each lock (see §7.4). To support out-of-range locks that exceed the switch capacity, FissLock adopts ParLock as a fallback, i.e., these locks are handled by on-server LMs, and the switch forwards their requests to the server (see §7.6).

Read/Write preference. FissLock is implemented as read-preferring since it is common. For a write-preferring design, the switch requires an additional 1-bit state *ww* (write-waiter) to indicate the existence of exclusive waiters. When encountering an exclusive waiter, the decider sets *ww* to true, so subsequent shared requests are not granted even if all holders are shared. The server-side write-preferring implementation is identical to server-based lock managers [24, 53].

Policy support. In FissLock, the on-server lock agents are tasked with enabling various lock policies (e.g., fairness), as they determine the next holders when the current holders release the lock. For example, FissLock ensures first-come-first-served fairness by using a FIFO wait queue, which prioritizes waiters that are enqueued earlier.

Starvation prevention. In the read-preferring design, FissLock uses an additional 1-bit state per lock on the switch to prevent readers from starving writers. This state is periodically set by the agent if there exists a writer in the wait queue and is cleared when all current holders release the lock. In the write-preferring design, readers are not starved. When the lock is held by a writer, all incoming lock requests are appended to the agent's FIFO wait queue. This guarantees that writers are not granted ahead of preceding readers.

Deadlocks. FissLock offers a lock aborting mechanism to assist applications resolve deadlocks. Specifically, it sets a local timeout for each lock request and aborts pending lock requests that have not been granted after the timeout.

7 Evaluation

7.1 Experimental Setup

Testbed. The experiments were conducted on a cluster consisting of four machines, each has two 12-core Intel CPUs, 128 GB of RAM, and two ConnectX-5 100 Gbps NICs. All

[3] The source code of FissLock is available at https://github.com/SJTU-IPADS/fisslock.

Table 3: *Workload description.*

	W	0%	IF	W	2%			
			DF	W	2%			

NICs are connected to a Top-of-Rack (ToR) wedge100BF-32x programmable switch, which is equipped with an Intel Tofino ASIC [16]. Each machine hosts two logical nodes, each has one CPU connected with one NIC used by all threads running on it. For each node, we assign 10 cores to application threads for issuing lock requests and receiving grant replies, and 1 core to FissLock's agent pool for maintaining lock metadata. Incoming packets are triaged utilizing DPDK Flow Director and Receive Side Scaling. To further adjust the degree of concurrency, we use coroutines in each application thread to simulate multiple clients.

Comparing targets. We compare FissLock with the state-of-the-art centralized lock manager NetLock [76] and two traditional server-based lock managers, namely SrvLock and ParLock. We re-implemented NetLock following its open-sourced artifact [9], which is not compatible with our programmable switch. The maximum number of locks that NetLock manages on the switch is determined by the scripts in its artifact. Due to the lack of open-source artifacts, we hand-crafted ParLock following the specification of popular commercial systems [6, 13], and used the lock server implementation of NetLock as SrvLock. ParLock uses the same allocation of CPU cores as FissLock, while NetLock and SrvLock use one node as the dedicated lock server and the other seven nodes as clients. For fairness, all systems are assigned the same total amount of CPU cores, i.e., 8 cores as lock managers and 80 cores as lock clients.

Workloads. We use one microbenchmark to evaluate lock granting performance, and two transaction benchmarks to study the impact on accelerating transaction execution (see Table 3). We trace all lock requests during a pre-execution phase for NetLock to profile the workload. To maintain fairness, we evaluate all lock managers using the same lock request traces and report the actual execution performance, like prior work [75, 76].

Microbenchmark. We built a microbenchmark to emulate the typical use of locks in modern distributed in-memory systems, where shared (resp. exclusive) locks are acquired before and released after data reads (resp. updates) to serialize these operations. To study the lock granting performance of lock managers under different read-write ratios and workload skewness, the microbenchmark includes three representative workloads: update-heavy (UH), read-mostly (RM), and read-only (RO). Each workload has both Uniform (Uni.) and Zipfian (Zipf.) lock request distributions.

Transaction benchmarks. TATP [12] and TPC-C [14] are evaluated to study the impact of lock managers on the end-to-end performance of distributed in-memory systems. TATP represents low-locality[4] and read-intensive (80% of transactions are read-only) workload, while TPC-C represents high-locality (∼90% of transactions only access local tables [14, 37]) and write-intensive (8% of transactions are read-only) workload. We use the default population size (100,000 subscribers) for TATP and adopt the same per-client warehouse number as prior work [29, 66] for TPC-C. We protect a range of records with each lock to control the total amount of locks in the benchmark. We run 160 clients for TATP and 1,200 clients for TPC-C, all clients issue lock requests synchronously. We adopt the two-phase locking (2PL) protocol when executing transactions. After acquiring all locks required by each transaction, we delay around 2 µs for TATP and 10 µs for TPC-C to simulate the execution time in Table 1. Transactions executed over 10 ms are aborted to avoid deadlocks.

7.2 Memory Consumption

We first study the switch memory usage of FissLock, which limits the maximum number of locks a programmable switch can host. Following the internal structure of programmable switch ASICs (see Fig. 2), two factors collectively impact the limitation: the number of MAUs and the memory capacity of each MAU. Let N be the number of locks in the system, C be the per-MAU memory capacity in bits, then the amount of MAUs required M can be described as:

$$M = \left\lceil \frac{N}{C} \right\rceil \times 2 + \left\lceil \frac{N \times 8}{C} \right\rceil \times 2 + 4$$

where 4 MAUs are occupied by the control and computing logic of the lock decider, and others denote MAUs for lock mode (*mode*), machine ID (*mid*), and incarnation (*inca*). The switch ASIC in our testbed has 12 MAUs at the ingress pipeline, each providing about 560 KB stateful storage (i.e., register array). Assuming that all MAUs are used by FissLock and following an optimal allocation scheme (i.e., 2 MAUs for *mode*, 3 MAUs for *mid*, and 3 MAUs for *inca*), the maximum number of locks that can be hosted is 1.68 million. In contrast, NetLock can only manage a few thousand locks on the same switch ASIC throughout our experiments.

7.3 Lock Granting Performance

We study the lock granting performance of FissLock and baselines through the grant time distribution (Fig. 13) and lock request throughput (Fig. 14 (left)) in the microbenchmark. All experiments use 160 clients and 1 million locks.

[4] Like prior work [29, 37], we do not improve the locality by deliberately partitioning TATP tables.

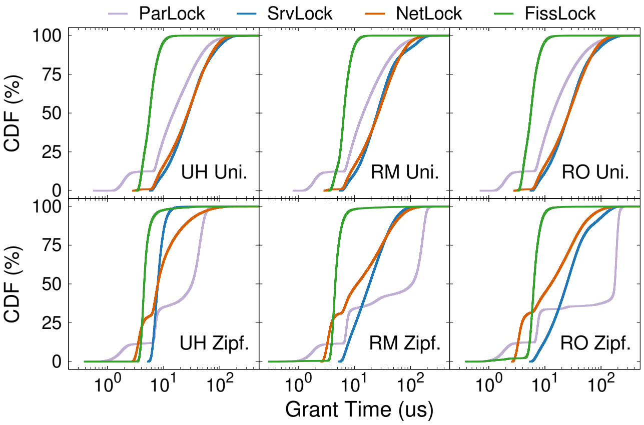

Fig. 13: *The CDF of lock grant time in the microbenchmark when using different lock managers.*

Overall, FissLock achieves low and stable grant time under all workloads. Compared with baselines, it cuts down the median grant time by up to 79.5% (SrvLock), 79.1% (NetLock), and 96.4% (ParLock), and the 90^{th} percentile grant time by up to 89.7% (SrvLock), 88.9% (NetLock), and 96.5% (ParLock). Consequently, FissLock outperforms baselines on lock request throughput by up to 4.08× (ParLock), 4.79× (SrvLock), and 4.99× (NetLock). The performance gain of FissLock mainly comes from three aspects: (1) the elimination of queueing delay by switch-based grant deciding, (2) the pervasiveness of acceleration by lock fission, and (3) the automatic load balancing by dynamic agent migration.

Uniform workloads. FissLock mainly benefits from (1) and (2) under Uniform workloads. The queueing delay dominates the grant time of all three baseline systems, which grows to up to 84.5 µs (SrvLock), 76.2 µs (NetLock), and 54.8 µs (ParLock) at 90^{th} percentile. Oppositely, FissLock controls the 90^{th} percentile grant time of all workloads under 9.42µs by eliminating queueing delay. NetLock falls back to SrvLock under Uniform workloads because only ∼1% of requests are handled by the switch, while FissLock accelerates all requests. ParLock handles around 12.5% of requests locally, which alleviates the remote LM's load and helps it slightly outperform SrvLock and NetLock.

Zipfian workloads. FissLock benefits from all three aspects under Zipfian workloads. Even with workload profiling, NetLock accelerates merely ∼27% of requests under Zipfian workloads. Although these requests have slightly (0–2µs) lower grant time than FissLock because FissLock devotes additional time to skim through the agent pool, the other 73% of requests are still handled by the server and have similar performance to SrvLock. Oppositely, FissLock makes grant decisions on the switch for all lock requests. ParLock suffers from severe load imbalance under Zipfian workloads, which significantly increases its grant time. Meanwhile, FissLock balances the load among servers and minimizes the impact of workload skewness, achieving up to 96.4% lower grant time than ParLock. The R/W lock contention becomes the main restriction of FissLock's throughput under Zipfian workloads and significantly reduces the lead of FissLock.

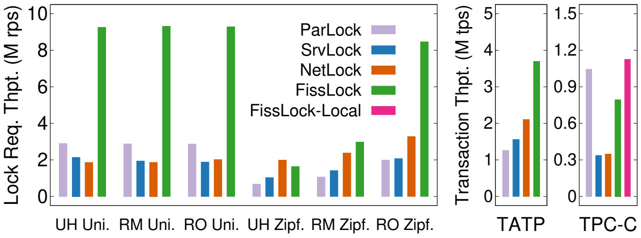

Fig. 14: *The lock request throughput in the microbenchmark, and the transaction throughput on TATP and TPC-C with different lock managers.*

7.4 Distributed Transaction Performance

We study the impact of lock managers on the end-to-end latency (Fig. 15) and throughput (Fig. 14 (right)) of transaction execution with TATP and TPC-C benchmarks. We show the latency distribution of each type of transaction individually.

TATP. TATP is a read-dominated workload containing 7 short transactions. Overall, FissLock outperforms baseline systems by 2.93× (ParLock), 2.37× (SrvLock), and 1.76× (NetLock) on transaction throughput. Since most transactions acquire only one or two locks, there were no deadlocks throughout the test. When executing transactions that only acquire one lock, FissLock exhibits similar performance to the microbenchmark case, i.e., the latency remains low for 99% of GS (17.5 µs), GA (15.4 µs), and UL (27.7 µs) transactions. For multi-lock transactions (GD, US, IF, and DF), the latency of FissLock is proportional to the average amount of locks acquired when executing the transaction. ParLock suffers from severe load imbalance when executing GS, US, UL, IF, and DF transactions, which drags down its throughput and results in lower queueing delay in GD and GA. Moreover, the effect of ParLock's local fast-path is less apparent in multi-lock transactions as the possibility of local grants is powered. NetLock has similar performance to SrvLock because the switch LM has limited acceleration proportion (17% in total), even if all rows are selected in a non-uniform manner, because the on-switch lock proportion is too restricted (0.09%). Queueing delay dominates the transaction latency of both systems.

TPC-C. TPC-C is a write-dominated workload containing 5 types of complicated transactions, where 90% of transactions solely acquire local locks. Given this workload locality information, ParLock can serve most requests with local lock servers, achieving superior performance. To show that FissLock can also benefit from this workload-aware optimization, we additionally evaluate FissLock-Local, which follows ParLock's method of co-locating locks with the clients acquiring them. Among lock managers that do not exploit

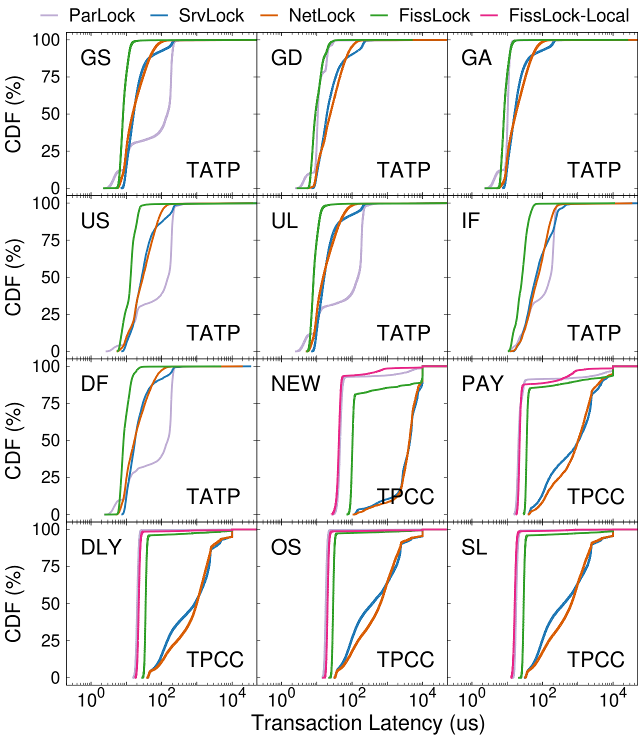

Fig. 15: *The CDF of transaction latency on TATP and TPC-C workloads when using different LMs.*

workload locality, FISSLOCK outperforms SrvLock and NetLock by 2.36× and 2.28× on transaction throughput, respectively. Both FISSLOCK-Local and ParLock handle over 90% of requests locally, where they have similar performance. However, FISSLOCK-Local still has 1.08× higher throughput than ParLock because of better remote lock requesting performance. We analyze the latency of write-intensive and read-only transactions separately as follows.

Write-intensive transactions (NEW and PAY). NEW and PAY acquire 14 and 4 locks on average. Even when acquiring almost all locks remotely, FISSLOCK still achieves fairly low and stable latency for 81% of NEW (< 125.5 µs) and 85% of PAY (< 44.5 µs) transactions. The latency of other transactions is dominated by the wait time due to lock contention. NetLock falls back to SrvLock because only 6% of requests to 0.3% of locks are handled by the switch, due to sparse data accesses in large datasets [29, 66]. Both LMs have over an order-of-magnitude higher transaction latency than FISSLOCK because of queueing delay. ParLock and FISSLOCK-Local have 40%–60% lower transaction latency than FISSLOCK due to local lock request handling. FISSLOCK-Local exhibits a shorter tail than ParLock because of higher remote lock acquire performance.

Read-only transactions (DLY, OS, and SL). All read-only transactions are local, which explains the identical performance of ParLock and FISSLOCK-Local. The latency turning point of FISSLOCK appears later (96.5%, 97.7%, and 96.2% for DLY, OS, and SL) because of lower wait time when acquiring shared locks. The performance of NetLock and SrvLock is similar to the write-intensive case as the queueing delay instead of wait time dominates the latency.

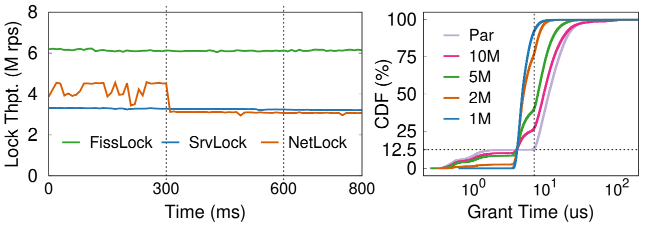

Fig. 16: *The timeline of lock request throughput on a dynamic workload (left), and the CDF of lock grant time with various lock scales when using a uniform RM workload (right).*

7.5 Dynamic Workload

To study the robustness of lock managers under dynamic workloads, we alter the hotspot of 1 million locks every 300 ms (i.e., 2,500 hot locks). In this workload, half of the requests target the hotspot, while the other half are evenly distributed to the remaining locks. As shown in Fig. 16 (left), FISSLOCK achieves a consistently high throughput of over 6 million requests per second (M rps) regardless of hotspot changes, thanks to its pervasive acceleration. In contrast, NetLock's throughput fluctuates between 3.44 M and 4.58 M rps, as the switch only handles half of the requests. When the hotspot changes at 300 ms, the throughput instantly drops to around 3 M rps, close to SrvLock (its fallback), and remains low until the hotspot returns.[5]

7.6 Lock Scales

We further evaluate the lock granting performance of FISSLOCK as the number of locks increases, using a uniform RM workload. We also report the result of ParLock, the fallback approach of FISSLOCK, with 10M locks as a reference. As shown in Fig. 16 (right), as expected, the performance of FISSLOCK gradually approaches that of ParLock as the number of locks increases. We found that FISSLOCK still achieves 39.9% lower 20^{th} percentile and 9.9% lower 90^{th} percentile grant time compared to ParLock for 10M locks by shipping the load of around 10% requests to the switch and thereby relieving server CPUs. At 0–12.5 percentiles, workloads with fewer locks perform worse because almost all requests for on-switch locks are handled by the switch, while around 12.5% of requests for out-of-range locks are handled locally.

7.7 Lock Granularity

To justify the necessity of using fine-grained locks for large-scale datasets, we conduct an experiment that varies the number of locks used to protect accesses to 10 million objects. These objects are evenly distributed among the locks. As shown in Fig. 17 (left), when using coarse-grained locks,

[5] Due to space limitations, we omit this part in Fig. 16 (left).

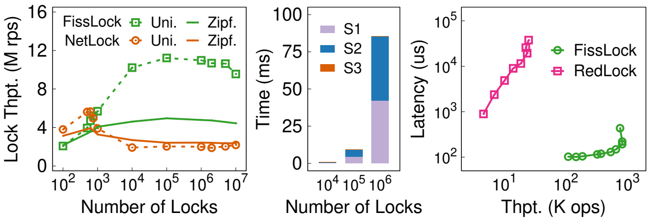

Fig. 17: *The throughput of* FissLock *and NetLock using different number of locks for a 10-million dataset (left), the recovery time breakdown for* FissLock *(mid), and the performance of mobile banking application using* FissLock *and RedLock (right).*

the lock granting throughput of FissLock is significantly dragged down (up to 5.40×) by lock contention in a uniform RM workload. NetLock achieves the peak throughput when using around 1,000 locks due to limited switch memory. However, the peak throughput is only 5.65 M rps due to severe lock contention. In contrast, FissLock unleashes full-scale acceleration with over one million fine-grained locks, thereby resulting in 1.99× (Uniform) and 1.26× (Zipfian) higher peak throughput than NetLock.

7.8 Failure Recovery

To study the performance of failure recovery, we manually inject a simultaneous failure of one switch and one server into the experiment used in §7.7. As shown in Fig. 17 (mid), the recovery time mainly comes from aggregating states of surviving servers (S1) and repairing them (S2), and is proportional to the number of locks due to scanning the metadata (e.g., granted requests) of all locks. The recovery time for switch states (S3) is trivial, as it only involves held locks.

7.9 Application: Mobile Banking

We build a mobile banking application that supports common banking operations like balance checking (BC) and funds transferring (FT) [7, 8]. The application server uses FissLock following the 2PL protocol for transactions and uses Redis-backed in-memory store [11]. It combines Redis asynchronous APIs and coroutines to hide network latency and maximize throughput when serving massive clients. We use Redis's official implementation of distributed locks (RedLock [5]) as the baseline and use a mixed workload containing 90% BC and 10% FT operations, which reflects the user behavior that checks balance much more frequent than transferring funds [11]. We initialize the bank with 1 million accounts. By adjusting the number of clients that issue operations, we compare accumulative throughput of all clients and median latency of the application using FissLock and RedLock. As shown in Fig. 17 (right), the operation throughput when using RedLock peaks at 24.8 K ops due to lock contention. Conversely, when using FissLock, the operation throughput scales to 825.4 K ops because FissLock grants and transfers locks faster. Additionally, FissLock cuts down the median latency of banking operations by at least one order of magnitude.

8 Related Work

Distributed lock management. There have been many efforts to investigate distributed lock management which are classified into two categories, centralized LM [6, 13, 21, 30, 54, 55, 65, 76] and decentralized LM [28, 56, 73, 75]. Centralized LMs are widely used because they enable rich properties such as latency predictability [31, 38, 46], starvation freedom [36], and performance isolation [76]. Decentralized LMs leverage one-sided RDMA primitives to bypass the CPU bottleneck of lock managers [28, 56, 73, 75], which offers better performance but loses support to the properties above. Prior work [76] uses programmable switches to host part of locks, achieving desired performance without sacrificing centralized properties. However, it assumes that the workload is highly skewed and predictable. Differently, FissLock can accelerate million-scale locks for diverse workloads without prior knowledge.

In-network optimization. The emergence of programmable switches [3, 16, 33] inspires numerous in-network designs for distributed systems, including distributed cache [35, 42, 47, 49, 50], consensus and concurrency control [26, 27, 34, 43, 44, 59, 76], machine learning [17, 40, 48, 63, 64, 77], task scheduling [69, 74], and distributed data coherence [41, 45, 70]. These systems primarily leverage the stronger packet processing power and shorter network round trip of switches to achieve higher performance for a portion of workloads. NetLock [76], the system most relevant to FissLock, implements a full lock manager on the switch to handle requests on hot locks. However, due to limited switch memory, the on-switch lock manager can only optimize thousands of locks. In contrast, FissLock achieves consistent performance improvement for millions of locks via lock fission.

9 Conclusion

This paper presents FissLock, a switch-centric lock service that enables lock fission scheme to provide microsecond-scale lock grant time for millions of locks. The concept of lock fission—decoupling the locking process to align with the characteristics of heterogeneous hardware—could be applied to other contexts. For instance, the locking process can be decoupled differently in various heterogeneous environments, such as disaggregated memory. We leave the investigation of these to future work.

Chop Chop: Byzantine Atomic Broadcast to the Network Limit

Martina Camaioni Rachid Guerraoui Matteo Monti
Pierre-Louis Roman Manuel Vidigueira Gauthier Voron
Ecole Polytechnique Fédérale de Lausanne (EPFL)

Abstract

At the heart of state machine replication, the celebrated technique enabling decentralized and secure universal computation, lies Atomic Broadcast, a fundamental communication primitive that orders, authenticates, and deduplicates messages. This paper presents Chop Chop, a Byzantine Atomic Broadcast system that uses a novel authenticated memory pool to amortize the cost of ordering, authenticating and deduplicating messages, achieving "line rate" (i.e., closely matching the complexity of a protocol that does not ensure any ordering, authentication or Byzantine resilience) even when processing messages as small as 8 bytes. Chop Chop attains this performance by means of a new form of batching we call *distillation*. A distilled batch is a set of messages that are fast to authenticate, deduplicate, and order. Batches are distilled using a novel interactive protocol involving *brokers*, an untrusted layer of facilitating processes between clients and servers. In a geo-distributed deployment of 64 medium-sized servers, Chop Chop processes 43,600,000 messages per second with an average latency of 3.6 seconds. Under the same conditions, state-of-the-art alternatives offer two orders of magnitude less throughput for the same latency. We showcase three simple Chop Chop applications: a Payment system, an Auction house and a "Pixel war" game, respectively achieving 32, 2.3 and 35 million operations per second.

1 Introduction

Is an Internet computer feasible? A computer that is highly-available, decentralized, secure, universal and shared by all? Theory says yes: state machine replication (SMR) [28, 66] enables decentralized universal computation in the face of arbitrary failures [50, 68]. In practice, however, SMR's inefficiency still makes for limited throughput. At the heart of SMR lies Atomic Broadcast [24], a powerful consensus-equivalent primitive that comes with fundamental bounds [29] and constraints [32], hindering its real-world performance despite decades of extensive research [5, 9, 14, 18, 20, 47, 53, 62, 79, 80, 82] and attention from industry, where SMR powers a myriad of blockchains and ledgers [4, 35, 46, 48, 52, 58, 72–74, 77, 78].

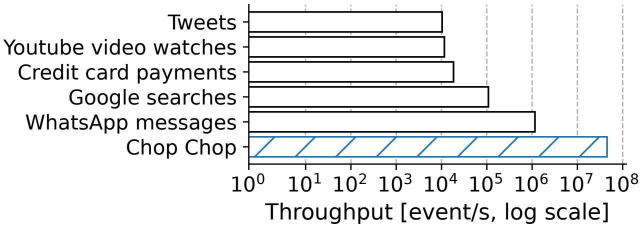

Figure 1: **Throughput of Internet-scale services.**

When deployed globally, seminal Atomic Broadcast implementations, such as BFT-SMaRt [9] and HotStuff [80], can deliver a few thousand messages per second, three orders of magnitude short of the millions of requests per second collectively handled by the Internet's largest, centralized services (Fig. 1). Pushing Atomic Broadcast's throughput into the tens of millions of messages per second seems a necessary stepping stone towards achieving an Internet-scale computer.

Towards line rate. While slow and expensive, ordering messages in Atomic Broadcast is amenable to *batching* [18]: order once, deliver in bulk. This observation motivated the development of *memory pool* (mempool) protocols [26, 34, 69], as initiated by Narwhal [26], designed to amortize ordering. This strategy proved effective, e.g., Bullshark [69] delivers in the order of 380,000 messages per second when accelerated by Narwhal. Despite this improvement, however, state-of-the-art batching still falls short of achieving *line rate*, i.e., matching the communication complexity of a protocol that does not ensure any ordering, authentication, or Byzantine resilience. In such a simplified setting, a server could simply deliver a sequence of application messages as it receives them from the network: b bits received, b bits delivered. Modern connections have enough bandwidth to receive tens of millions of application messages per second:[1] 2.5 orders of magnitude of gap still exist between Atomic Broadcast and unordered, unauthenticated dissemination. It is natural to ask

[1] Payloads as small as 12 bytes can have real-world applications (see §2.1). A 5 Gbit/s link can receive 52 millions such payloads per second.

if such a large gap is inherent to atomicity's unavoidable cost of ordering, authenticating and deduplicating messages. This paper answers in the negative, accelerating Atomic Broadcast by a further two orders of magnitude with a system that performs close to optimal efficiency, i.e., within 8% of line-rate, even when handling 40 million requests per second.

Chop Chop. We present Chop Chop, a Byzantine Atomic Broadcast system using a novel authenticated mempool. Mempools amortize the cost of ordering by having an underlying instance of Atomic Broadcast order batches. Classic methods of batching, however, fail to also amortize authentication and deduplication: each payload in a batch still carries an individual public key, signature and sequence number.

Chop Chop addresses this shortcoming with a new form of batches: *distilled batches*. Unlike a classic batch, a distilled batch contains condensed information that allows to authenticate and deduplicate its messages in bulk, much faster than in existing schemes. Distilled batches leverage the strong ordering of Atomic Broadcast to minimize redundant information.

Trustless brokers. Chop Chop produces distilled batches using a novel interactive protocol involving *brokers*, a layer of facilitating processes between clients and servers. Distilled batches are faster for servers to receive and process, but expensive for brokers to produce: distillation is interactive and relies on expensive cryptographic operations for brokers.

Importantly, however, incorrectly distilled batches are visibly malformed. As such, brokers can be *untrusted*: good brokers take load off the servers; bad ones cannot compromise the system's safety. Servers are exposed to every message in the system, bottleneck easily, and only a threshold of them can be compromised before the system loses safety. Brokers, instead, can be spun up by anyone, outside of Chop Chop's security perimeter, to meet the load produced by clients.

Evaluation. We evaluate Chop Chop in a cross-cloud, geo-distributed environment including 320 medium-sized AWS EC2 machines and 64 OVH machines. We simulate up to 257 million clients and consider 12 experimental environments. Setting up each environment requires the installation of 13 TB of synthetic workload. A naive installation using `scp` from a single machine would take 68 hours. We designed `silk`, a one-to-many peer-to-peer file transfer tool optimized for high latency connections, to install the files in 30 minutes instead.

We compare Chop Chop's throughput and end-to-end latency against its baselines in multiple real-world scenarios including server failures, adverse network conditions, and applications running. In all scenarios, Chop Chop's throughput outperforms its closest competitor by up to two orders of magnitude, with no penalty in terms of latency. When put under stress, Chop Chop orders, authenticates and deduplicates upwards of 43,600,000 messages per second with a mean latency of 3.6 seconds. Except under the most adverse network conditions and proportions of faulty clients, Chop Chop still achieves millions of operations per second.

Applications. Unlike most Atomic Broadcast implementations [9, 26, 69, 80], Chop Chop does not offload authentication and deduplication to the application. This allows Chop Chop-based applications to focus entirely on their core logic without ever engaging in expensive, and easy to get wrong, cryptography. To showcase this, we implement three simple applications to evaluate on top of Chop Chop: a Payment system, an Auction house and an instance of the game "Pixel war". These three simple applications (300 lines of logic) work effectively with messages as small as 8 bytes, further underlying the communication overhead represented by public keys, signatures and sequence numbers in non-distilled systems. Both Payments and Pixel war inherit Chop Chop's throughput, respectively processing over 32 and 35 million operations per second. Even the Auction house, which is single-threaded, achieves 2.3 million operations per second. (These applications are meant as examples, and further optimization is beyond the scope of this paper.)

Contributions. We identify authentication and deduplication as the main bottlenecks of batched Atomic Broadcast; we introduce distilled batches to extend the amortizing properties of batching to authentication and deduplication; we present distillation, an interactive protocol to produce distilled batches, and identify the opportunity to offload it to an untrusted set of brokers; we implement Chop Chop, a Byzantine Atomic Broadcast system that takes advantage of distillation through an authenticated mempool; we thoroughly evaluate Chop Chop, improving state-of-the-art Atomic Broadcast throughput by two orders of magnitude, maintaining near line-rate performance up to 40 million requests per second; we showcase Chop Chop through a Payment system, an Auction house and an instance of the "Pixel war" game, respectively achieving 32, 2.3 and 35 million operations per second.

Roadmap. §2 introduces Atomic Broadcast, discusses classic batching mechanisms and highlights the cost of authenticating and deduplicating messages in the resulting batches. §3 presents distilled batches and introduces a simplified failure-free version of Chop Chop's protocol. §4 describes Chop Chop's fault-tolerant protocol in detail. §5 discusses Chop Chop's implementation. §6 discusses Chop Chop's empirical evaluation, highlighting the challenges of such large scale experiments. We summarize related work in §7 and future work in §8. Appendix A describes Chop Chop's artifact. The full correctness proof of Chop Chop is available online [15].

2 Atomic Broadcast

In an Atomic Broadcast system [19], *clients* broadcast messages that are delivered by *servers*.

Properties [13]. Correct servers deliver the same messages in the same order (*agreement*). Messages from correct clients are eventually delivered (*validity*). Spurious messages cannot be attributed to correct clients (*integrity*). No message is delivered more than once (*no duplication*).

2.1 Cost of Atomic Broadcast

Informally, Atomic Broadcast's most distinctive property, agreement, is also the most challenging to satisfy. Correct servers must coordinate to *order* messages without compromising liveness. A great deal of research effort has been put in developing ordering techniques, optimizing for latency [47, 56] or communication complexity [55, 63].

Integrity and no duplication, instead, allow for simple solutions. Clients can ensure integrity by *authenticating* their messages using digital signatures: servers simply ignore incorrectly authenticated messages. For no duplication, clients can tag each message with a strictly increasing *sequence number*: after ordering, servers discard old messages as replays.

Both techniques—we call them *classic authentication* and *classic sequencing*—are non-interactive, easy to implement, and agnostic of the protocol employed to order messages. Arguably due to the simplicity and effectiveness of classic authentication and sequencing, most Atomic Broadcast implementations overlook integrity and no duplication entirely: they offload authentication and sequencing to the application, focusing on the more challenging task of ordering.

Batching for ordering. Lacking an efficient technique to minimize its complexity, ordering could be Atomic Broadcast's main bottleneck.[2] The well-known strategy of *batching*, however, is both general and effective at amortizing the agreement cost of an Atomic Broadcast implementation [18, 68].

Broadly speaking, batching is orchestrated by a *broker* as follows [26].[3] Over a small window of time, the broker collects multiple client-issued messages in a batch, which it disseminates to the servers; the broker then submits to an underlying instance of Atomic Broadcast a cryptographic hash of the batch it collected; upon delivering the hash of a batch from Atomic Broadcast, a server retrieves the batch, and delivers to the application all the messages it contains. Because the size of a hash is constant, the cost of ordering a batch does not depend on its size: as batches become larger, the cost of ordering each message goes to zero. In practice, batching can effectively eliminate the cost of ordering in any real-world implementation of Atomic Broadcast.

Cost of integrity and no duplication. Batching does not efficiently uphold integrity and no duplication. Regardless of how many messages are batched together, the cost of classic authentication and sequencing stays constant: one public key, one signature and one sequence number for each message.

In practice, these costs dominate the computation and communication budget of a batched Atomic Broadcast system (see §3.2). On the one hand, signatures are among the most CPU-intensive items in the standard cryptographic toolbox, dwarfing in particular symmetric primitives such as hashes and ciphers. On the other, public keys, signatures and sequence numbers can easily account for the majority of a batch's size.

To illustrate these costs, consider the example of a payment system. A payment operation requires three fields: sender, recipient, and amount. Sender and recipient fit in 4 B each if the system serves less than 4 billion users. Amount needs 4 B for payments between 1 cent and 40 millions. Hence, a payment can be encoded in just 12 B. Using public keys to identify sender and recipient (2×32 B using Ed25519 [8, 40]) and attaching a signature (64 B) and a sequence number (8 B) to each message inflates payloads to 140 B. For payments, *91% of the bandwidth is spent on integrity and no duplication*.

2.2 Existing Mitigations

Chop Chop integrates the two following techniques to reduce the bandwidth and CPU cost of authentication.

Short identifiers. Repeated public keys consume a significant slice of a server's communication budget. A workaround is to have servers store public keys in an indexed *directory* [2]. Upon first joining the system, a client announces its public key via Atomic Broadcast to *sign up*. Upon delivering a sign-up message, a server appends the new public key to its directory. The same public key appears at the same position in the directory of all correct servers thanks to Atomic Broadcast's agreement. Having signed up, a client uses its position in the directory as identifier instead of its public key.

In the previous example of a payment system, using such identifiers reduces a payment size by 40%, from 140 B to 84 B. However, a signature per payment must still be transmitted.

Pooled signature verification. Authenticating a batch by verifying its signatures is a computationally intensive task for a server [18, 71]. However, Red Belly [23] and Mir [71] showed that not all servers need to authenticate all batches. Indeed, assuming at most f faulty servers, a broker optimistically asks only $f+1$ servers to authenticate a batch to be certain to reach at least one correct server. If $f+1$ servers do not reply by a timeout, the broker extends its request to f additional servers, thus reaching at least $f+1$ correct servers.

A correct server that authenticates a batch sends back to the broker a *witness shard*, i.e., a signed statement that the batch is correctly signed. The broker aggregates $f+1$ identical shards into a *witness*, which it sends to the other $2f$ servers. Because every witness contains at least one correct shard, the servers can trust the witness instead of verifying the batch.

Assuming $3f+1$ servers, this technique shaves up to two-thirds off the system's authentication complexity.

3 Distilled Batches

Chop Chop's main contribution is *distillation*, a set of techniques aimed at extending the amortizing properties of batches to authentication and sequencing.

[2] Byzantine Atomic Broadcast among n participants cannot be achieved with a bit complexity smaller than $\Theta(n^2)$ [29].

[3] In the literature, servers usually play the role of brokers. As we discuss in §4, however, Chop Chop minimizes its load on the servers by offloading brokerage to a separate, trustless set of processes.

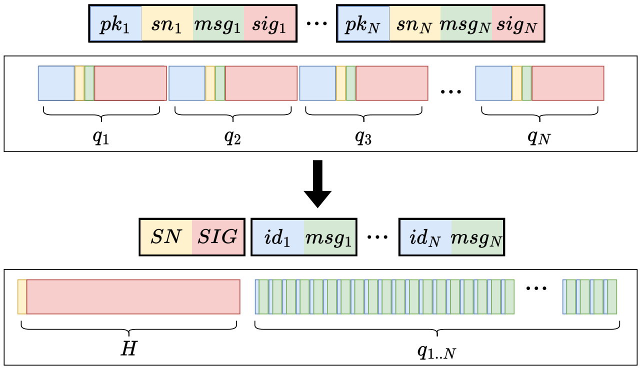

Figure 2: **Full distillation in action.** With classic authentication and sequencing, each payload q_i contains a public key pk_i, a sequence number sn_i, a message msg_i and a signature sig_i. In the fully distilled case, each q_i reduces to just id_i and msg_i: one header H, composed of one aggregate sequence number SN and one aggregate signature SIG, is sufficient for the entire batch. Bars are to scale if small messages are broadcast using Ed25519 for signatures and BLS12-381 for uncompressed multi-signatures: sn_i and SN are 8 B, msg_i is 8 B, pk_i is 32 B, sig_i is 64 B, SIG is 192 B.

Background: multi-signatures. Chop Chop makes use of multi-signature schemes [39] to authenticate batches. Secret keys produce signatures that can be verified against the corresponding public keys. Public keys and signatures, however, can be *aggregated*. Let $(p_1, r_1), \ldots, (p_n, r_n)$ be distinct key pairs, and $s_1, \ldots, s_n$ be signatures produced by $r_1, \ldots, r_n$ on the *same* message m: $p_1, \ldots, p_n$ (resp., $s_1, \ldots, s_n$) can be aggregated into a constant-sized aggregate public key p (resp., aggregate signature s).

Remarkably, s can be verified in constant time against p and m [10, 57]. Chop Chop uses BLS multi-signatures [10] which can be aggregated cheaply and non-interactively: even a non-signing process can compute p (resp., s) once provided with $p_1, \ldots, p_n$ (resp., $s_1, \ldots, s_n$) by computing a single multiplication over an elliptic curve.

3.1 Distillation at a Glance

In brief, distillation aims to produce *distilled batches*. A distilled batch has some of its signatures (resp., sequence numbers) replaced by an *aggregate signature* (resp., *aggregate sequence number*). When maximally successful, distillation produces a *fully distilled batch*, where all signatures (resp., sequence numbers) have been replaced by a *single* aggregate signature (resp., sequence number). As we discuss below, distilled batches are vastly cheaper for servers to receive and process. Fig. 2 depicts the effect of distillation on a batch.

Full distillation (failure-free). For pedagogical purposes, we introduce distillation under the assumption that all processes are correct. We detail Chop Chop's fault-tolerant distillation techniques in §4.2, optimized and adapted to the Byzantine setting. As in the classic batching case, a set $\chi_1, \ldots, \chi_b$ of clients submit their messages $m_1, \ldots, m_b$ to a broker β. Each χ_i selects for its message m_i a sequence number k_i (greater than any sequence number it previously used), then sends (k_i, m_i) to β. Upon receiving all (k_i, m_i)-s, β computes the aggregate sequence number

$$k = \max_i k_i$$

then builds the *batch proposal*

$$B = [(x_1, k, m_1), \ldots, (x_b, k, m_b)]$$

where x_i is χ_i's numerical identifier in the system (see §2.2). β then sends B back to every χ_i. Upon receiving B, χ_i produces a multi-signature s_i for the hash $H(B)$ of B, which it sends back to β. Having collected all multi-signatures, β computes the aggregate signature

$$s = \prod_i s_i$$

In doing so, β obtains the fully distilled batch

$$\tilde{B} = [s, k, ((x_1, m_1), \ldots, (x_b, m_b))]$$

Upon receiving $\tilde{B}$, any server now can: compute B by inserting k between each (x_i, m_i); compute $H(B)$; use each x_i to retrieve χ_i's public key p_i from its directory; compute the aggregate public key

$$p = \prod_i p_i$$

and finally verify s against p and $H(B)$.

Distillation outcome. Having engaged with β to distill the batch, every χ_i multi-signs the *same* message $H(B)$ and updates its sequence number to the *same* k. This allows β to authenticate and sequence all of $\tilde{B}$ using s and k only.

Distillation safety. The proposed distillation protocol has no safety drawback. First, because (x_i, k, m_i) appears in B, χ_i still gets to authenticate m_i. Intuitively, χ_i's multi-signature on $H(B)$ publicly authenticates *whatever message in B is attributed to* χ_i, m_i in this case. Second, because $k \geq k_i$, k is still a valid sequence number for m_i. Sequence number distillation might cause χ_i to skip some sequence numbers whenever any χ_j issues some $k_j > k_i$. Contiguity of sequence numbers, however, is not a requirement for deduplication. As with classic sequencing, χ_i produces—and servers deliver—messages with strictly increasing sequence numbers; servers disregard all other messages as replays.

3.2 Distillation Microbenchmark

Having discussed how distilled batches are produced, we now estimate the significance of their effect by means of a back-of-the-envelope calculation and a simple microbenchmark on AWS. Consider a setting where 100 million clients broadcast 8-byte messages, e.g., to issue payments (see § 2.1). We compare *classic authentication and sequencing*, where clients are identified by their public keys, messages are individually signed and sequenced, against *fully distilled batches* where

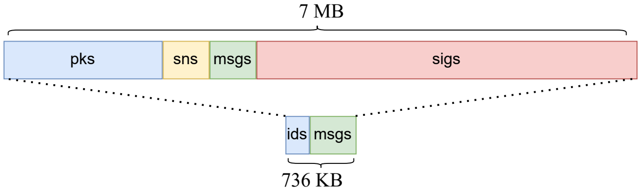

Figure 3: **Full distillation of a batch of 65,536 payloads (sizes to scale).** The aggregate signature and aggregate sequence number do not appear as a result of their small size.

clients are identified by a numerical identifier and each batch contains only one aggregated signature and sequence number. We use Ed25519 [40] for signatures (32 B public keys, 64 B signatures) and BLS12-381 [12] for multi-signatures (192 B uncompressed signatures). We use uncompressed BLS multi-signatures to save computation time at the cost of storage space (96 B compressed vs. 192 B uncompressed).

Communication complexity. Payloads are 112 B per message in the classic case (32 B of public key, 8 B of sequence number, 8 B of message, 64 B of signature) vs. 11.5 B in the fully distilled case (28 bits = 3.5 B of identifier to represent 257M clients, 8 B of message). Assuming batches of 65,536 messages (Fig. 3), classic batches are exactly 7 MB long, while fully distilled batches are 736 KB long including aggregate signature and sequence number.

Computation complexity. Running at maximum load, an Amazon EC2 c6i.8xlarge instance authenticates 16.2 ± 0.4 classic batches per second using Ed25519's batch verification for 65,536 signatures. The same machine authenticates 457.1 ± 0.3 fully distilled batches per second: each authentication requires the aggregation of 65,536 BLS12-381 public keys and the verification of one BLS12-381 multi-signature.

Summary. By the order-of-magnitude calculations above, fully distilled batches hold the promise to reduce the costs of authentication and sequencing by a factor 9.7 for network bandwidth, and 28.2 for CPU. Chop Chop aims to deliver on that promise for a real-world fault-tolerant system.

4 Chop Chop

This section overviews Chop Chop's architecture, Chop Chop's protocol, and provides arguments for its correctness.

Overview. Chop Chop involves three types of processes (Fig. 4): broadcasting clients, delivering servers and a layer of broadcast-facilitating brokers between them. Servers run an Atomic Broadcast instance among themselves, to which brokers submit messages. Chop Chop is agnostic to the implementation of Atomic Broadcast used by the servers. On top of the provided broker-to-server Atomic Broadcast, Chop Chop implements a much faster client-to-server Atomic Broadcast: clients submit messages to the servers, aided by brokers.

Chop Chop's protocol unfolds in two phases: *distillation* (§4.2) and *submission* (§4.3). In the distillation phase, clients interact with a broker to gather their messages in a distilled batch (see §3). In the submission phase, the broker disseminates the distilled batch to the servers and submits the batch's hash to the server-run instance of Atomic Broadcast. Upon delivering its hash from Atomic Broadcast, servers retrieve the batch and deliver its messages. Chop Chop's contributions mainly focus on the distillation phase. Chop Chop's submission strategy closely resembles prior batch-based Atomic Broadcast implementations [26, 34, 69].

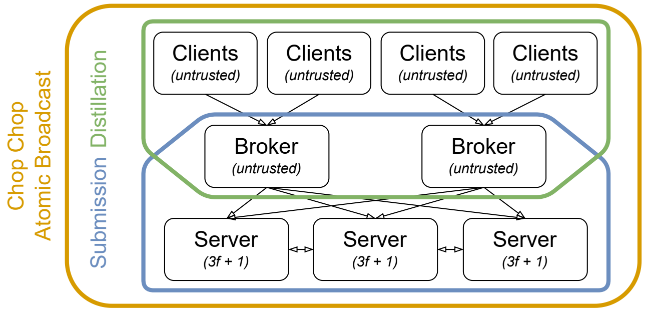

Figure 4: **Chop Chop architecture.**

4.1 Architecture and Model

Chop Chop augments the architecture of a classic Atomic Broadcast, as described in §2, with novel brokers.

Clients and servers. *Clients* broadcast messages to a (distinct) set of *servers*. We assume that less than one third of servers can be faulty and behave in an arbitrary manner, i.e., be Byzantine [50], while all clients can be faulty. For simplicity, servers form a fixed set that is known by all correct processes at system startup. Chop Chop can be extended for reconfiguration thanks to its modular use of Atomic Broadcast [9, 49] (Fig. 4). Clients issue messages after broadcasting their public keys to the system (see §2.2).

Brokers. We discussed in §3 how both classic and distilled batches are assembled by a broker. The role of brokers is traditionally taken by servers. Given the additional strain put on brokers by Chop Chop's interactive distillation protocol, however, having servers be brokers would result in a waste of scarce, trusted resources. Importantly, however, distillation is *trustless*. On the one hand, agreement rests entirely on Chop Chop's underlying Atomic Broadcast instance, for which brokers are only clients. On the other hand, as we argue in §§4.2 and 4.4.1, a faulty broker cannot compromise integrity or no duplication: distilled batches are publicly authenticated, and correct clients cannot be tricked into using stale sequence numbers. Hence, *brokers need no trust*: a broker either does its job correctly or produces distilled batches that are visibly malformed, and easily discarded by all correct servers.

This observation is of paramount importance to the performance of Chop Chop: *because distillation is heavy but trustless, brokers should be distinct from servers.* Along with clients and servers, we thus assume a third, *independent set of brokers*, sitting between clients and servers, to accelerate Atomic Broadcast by assembling client messages in distilled batches. We assume that at least one broker is correct; the system loses liveness but not safety if all brokers are faulty.

Network. Chop Chop guarantees that the batches collected and submitted to servers by correct brokers are well-formed even in asynchrony, but achieves full distillation when the network is synchronous (see §4.2). Chop Chop inherits the network requirements of its underlying Atomic Broadcast.

4.2 Distillation Phase

We introduced in §3 a simplified, failure-free distillation protocol. This section describes how Chop Chop renders distillation tolerant to arbitrary failures and improves its performance via a sequence of improvements, each addressing a shortcoming of the simplified protocol. The complete fault-tolerant protocol of Chop Chop is depicted in Fig. 5.

In the failure-free distillation protocol: clients $\chi_1, \ldots, \chi_b$ send their messages $m_1, \ldots, m_b$, with sequence numbers $k_1, \ldots, k_b$ (#2) to a broker β (Fig. 5, #1); β identifies the maximum submitted sequence number k and builds a batch proposal $B = [(x_1, k, m_1), \ldots, (x_b, k, m_b)]$ (#3); β disseminates B to $\chi_1, \ldots, \chi_b$ (#4); each χ_i produces a multi-signature s_i on $H(B)$ (#5), which it sends to back β (#6); β aggregates $s_1, \ldots, s_n$ into an aggregate s, thus producing a fully distilled batch $\tilde{B} = [s, k, ((x_1, m_1), \ldots, (x_b, m_b))]$ (#7).

Background: Merkle trees. Chop Chop uses Merkle trees [59] to hash batches. An l-element vector $z_1, \ldots, z_l$ is hashed into a *root* r, used as commitment. For each i, z_i's value can be proved by means of a proof of inclusion p_i, verifiable against r and z_i. Proofs of inclusions are $O(\log l)$ in size and are verified in $O(\log l)$ time.

What if a broker forges messages? A faulty β could try to falsely attribute to some χ_i a message $m'_i \neq m_i$. β could do so by replacing m_i with m'_i in B, then having χ_i sign $H(B)$, thus implicitly authenticating m'_i. This is easily fixed by having χ_i check that m_i correctly appears in B before signing $H(B)$.

Can a broker avoid sending the entire batch? A clear inefficiency of the simplified protocol is that β has to convey all of B back to each χ_i. This is fixed using Merkle trees. Upon assembling B, β computes the Merkle root r of B, along with the Merkle proof p_i for each (x_i, k, m_i) in B. Instead of sending B to all clients, β just sends r, k and p_i to each χ_i. Upon receiving r, k and p_i, χ_i checks p_i against r and (x_i, k, m_i), producing s_i on r only if the check succeeds. If χ_i signs r, then (x_i, k, m_i) is necessarily an element of B. Importantly, however, β could inject $(x_i, k, m'_i \neq m_i)$ somewhere else in B, while still providing χ_i only with the proof for (x_i, k, m_i). This is solved by having servers ignore every distilled batch where two or more messages are attributed to the same client. This way, if χ_i signs r, then either m_i is the only message in B attributed to χ_i, or $\tilde{B}$ is rejected by all servers as malformed: either way, integrity is upheld.

What if a client does not multi-sign? Under the assumption that $\chi_1, \ldots, \chi_b$ are correct, β can safely wait until it collects all $s_1, \ldots, s_b$. This policy is clearly flawed in the Byzantine setting: a single crashed client can prevent β from ever aggregating s. Furthermore, lacking an assumption of synchrony, β cannot exclude from $\tilde{B}$ those clients that do not sign r by some timeout: consistently slow clients would always be excluded, and validity would be lost. This issue is fixed by the fallback mechanism introduced in the following.

Fault-tolerant distillation. Upon first sending (k_i, m_i) to β (#2), χ_i also sends an individual, non-aggregable signature t_i for (x_i, k_i, m_i), which β stores. β then waits for s_i-s on r until either all s_i-s are collected, or a timeout expires. For every s_i that ends up missing, due to χ_i being crashed or delayed, β attaches (k_i, t_i) to $\tilde{B}$. Upon receiving $\tilde{B}$, a server first checks each individual signature t_i against the corresponding (x_i, k_i, m_i). The server then checks s against the public keys of the clients for which an individual signature t_i was not given, i.e., the public keys of all clients that signed r in time.

In summary: fast, correct clients who successfully produce their s_i-s in time authenticate their message by multi-signing r; slow or crashed clients still get their messages through, individually authenticated by the t_i-s that they originally produced. Full distillation is achieved whenever the network is synchronous and all clients are correct, which we argue is the case in practice for the majority of a system's lifetime. When the network is asynchronous, however, a fraction of clients might fail to produce their s_i in time, resulting in a *partially distilled batch*. At the limit where all clients fail to sign r in time, $\tilde{B}$ reduces to a classic batch, degrading server-side performance to pre-distillation levels. We underline that safety and liveness are preserved regardless of synchrony.

What if a broker replays messages? A problem introduced by the last fix is that χ_i authenticates both k_i and k as sequence numbers for m_i, allowing a faulty β to play m_i twice, hence breaking Atomic Broadcast's no duplication. This is fixed by having each client engage in the broadcast of only one message at a time. This way, while β can indeed replay m_i, it can only do so consecutively: all sequence numbers χ_i authenticates for m_i belong to a range that does not contain sequence numbers for any other message $m_{i' \neq i}$ issued by χ_i.

This observation is key to the following fix: along with the last sequence number $\bar{k}_\chi$ each client χ used, a correct server σ stores the last message $\bar{m}_\chi$ that χ broadcast; upon ordering a message m with sequence number k from χ, σ delivers m if and only if $k > \bar{k}_\chi$ and $m \neq \bar{m}_\chi$. In doing so, σ discards all consecutive replays of $\bar{m}_\chi$, thus preventing replays in general.

What if a client broadcasts too frequently? The last fix relies on clients broadcasting one message at a time. Depending on latency, a client broadcasting too frequently might

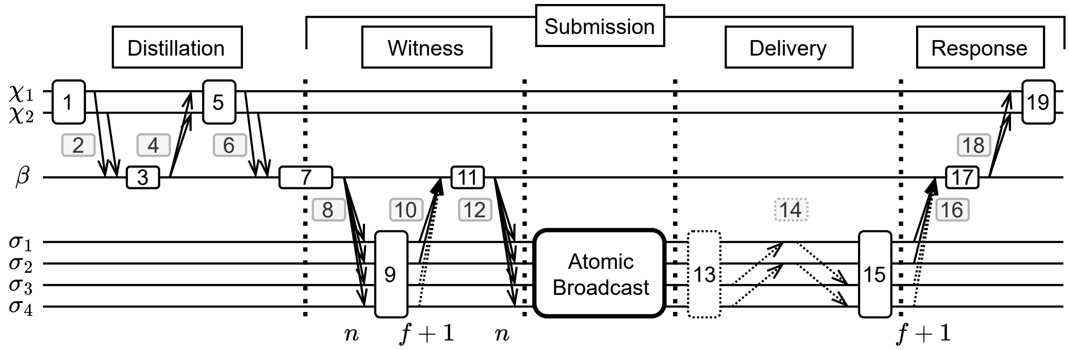

Figure 5: **Overview of the Chop Chop protocol between two clients (χ_1, χ_2), a broker (β) and four servers (σ_1–σ_4).** The protocol is comprised of 19 steps (#1–#19) and of an underlying instance of Atomic Broadcast such as BFT-SMaRt or HotStuff.

accrue an ever-growing queue of pending messages. This issue is fixed by flushing application messages in bursts, akin to Nagle's buffering algorithm for TCP.

What if a client uses the largest possible sequence number? Assuming that a finite number of bits (e.g., 64) are allocated to representing sequence numbers, a faulty client χ_m could set its k_m to the largest possible sequence number k_{max} (e.g., $2^{64}-1$). In doing so, χ_m would force all other χ_i-s to update their sequence number to k_{max}. Since correct clients only use strictly increasing sequence numbers, no χ_i could ever broadcast again: sequence numbers would run out. Proving the *legitimacy* of sequence numbers fixes this issue.

Legitimate sequence numbers. By the rule that we established, no more than one message from the same client can appear in the same batch. Moreover, correct clients always tag their messages with the smallest sequence number they have not yet used, i.e., the largest they have used plus one. By induction, we then have that unless some client misbehaves, no client ever needs to use a sequence number larger than the number of batches ever delivered by the servers: the largest sequence number any client submits to the very first batch is 0, therefore no client submits a sequence number larger than 1 to the second batch, and so on. This observation allows us to define as *legitimate* any sequence number smaller than the number of batches servers have delivered at any given time.

Legitimacy proofs. This definition of legitimacy allows for the generation of *legitimacy proofs*: upon delivering the n-th batch, a server publicly states so with a signature. By collecting $f+1$ server signatures stating that the n-th batch was delivered into a certificate l_n, any process can publicly prove that any sequence number smaller than n is legitimate.

Upon initially submitting k_i (#2), χ_i also sends to β a certificate l_n, for any $n > k_i$; β ignores client submissions that lack such certificate, except when $k_i = 0$ since no certificate is needed. Upon sending k back to all χ_i-s (#4), β attaches the highest $l_{\hat{n}}$ it collected: $l_{\hat{n}}$ proves that k is legitimate since $\hat{n} > k$. χ_i signs r (#5) only if k is proved legitimate by $l_{\hat{n}}$.

This technique ensures correct clients always use legitimate sequence numbers. Since legitimate sequence numbers grow only with the number of delivered batches, no correct client is forced to skip too far ahead, compromising its own liveness.

What if a broker crashes? If β fails to engage in the protocol, each χ_i can submit its message to any other broker.

4.3 Submission Phase

The submission phase ensures that all servers efficiently deliver a distilled batch, and that all broadcasting clients receive a proof that their messages were delivered.

Witness. Having gathered a distilled batch $\tilde{B}$ (#7), β moves on to have $f+1$ servers signs a *witness shard* for $\tilde{B}$. In signing a witness shard for $\tilde{B}$, a server σ simultaneously makes two statements. First, $\tilde{B}$ is *well-formed*: σ successfully verified $\tilde{B}$'s signatures and found all messages in $\tilde{B}$ to have a different sender. Second, $\tilde{B}$ is *retrievable*: σ stores $\tilde{B}$ and makes it available for retrieval, should any other server need it. We call a *witness* for $\tilde{B}$ the aggregation of $f+1$ witness shards for $\tilde{B}$. Because any set of $f+1$ processes includes a correct process, when presented with a witness for $\tilde{B}$ any server can trust $\tilde{B}$ to be well-formed and retrievable.

As discussed in §2.2, witnesses optimize server-side computation. Only $f+1$ servers need to engage in the expensive checks required to safely witness $\tilde{B}$. All other servers can trust $\tilde{B}$'s witness, saving trusted CPU resources.

In order to collect a witness for $\tilde{B}$, β sends $\tilde{B}$ to all servers (#8). Optimistically, β asks only $f+1$ servers to sign a witness shard for $\tilde{B}$, progressively extending its request to $2f+1$ servers upon expiration of suitable timeouts. Upon receiving $\tilde{B}$ (#9), a correct server σ stores $\tilde{B}$. If asked to witness $\tilde{B}$, σ checks that $\tilde{B}$ is well-formed and sends back to β its witness shard for $\tilde{B}$ (#10). β collects and aggregates $f+1$ shards into a witness for $\tilde{B}$ (#11), then submits $\tilde{B}$'s hash and witness to the server-run Atomic Broadcast (#12).

Delivery. Upon delivering $\tilde{B}$'s hash and witness from Atomic Broadcast (#13), a correct server σ retrieves $\tilde{B}$, either from its local storage (if it directly received $\tilde{B}$ from β at #8) or from another server (#14). Because $\tilde{B}$ is retrievable, σ

is guaranteed to eventually find a server to pull $\tilde{B}$ from. Having retrieved $\tilde{B}$ (#15), σ delivers all non-duplicate messages in $\tilde{B}$ (see §4.2 for how σ detects duplicates).

Response. Finally, σ signs a *delivery certificate*, listing the messages in $\tilde{B}$ that σ delivered. σ sends its signature back to β (#16). By agreement of Atomic Broadcast, all correct servers deliver the same subset of messages in $\tilde{B}$. As such, β is guaranteed to eventually collect $f+1$ signatures on the same delivery certificate (#17). Upon doing so, β distributes a copy of $\tilde{B}$'s delivery certificate to $\chi_1, \ldots, \chi_b$ (#18). Armed with $\tilde{B}$'s delivery certificate, a correct χ_i can publicly prove the delivery of m_i (#19) and safely broadcast its next message.

4.4 Correctness

This section summarizes Chop Chop's correctness analysis. We prove Chop Chop's correctness to the fullest extent of formal detail in an extended document available online [15].

4.4.1 Safety

The safety of Chop Chop is given by its agreement, integrity and no duplication properties (see §2).

Agreement. Chop Chop inherits agreement from its underlying, server-run instance of Atomic Broadcast. A correct server delivers messages only upon delivering the hash of a batch from the server-run Atomic Broadcast. Upon doing so, a correct server retrieves the full batch, checks its hash, and delivers all its messages in order of appearance. All correct servers deliver the same messages in the same order assuming cryptographic hashes are collision-resistant.

Integrity. A correct server only delivers messages included in a batch witnessed by $f+1$ servers, i.e., by at least one correct server. A correct server witnesses a batch only if: no more than one message in the batch is attributed to the same client; every client in the batch authenticates its message with a signature or the root of the batch's Merkle tree with a multi-signature. A correct client multi-signs the root of a batch's Merkle tree only upon receiving a proof of the inclusion of its message in the batch. As such, if a correct client multi-signs the root of a batch's Merkle tree, either the batch contains only the client's intended message or it is not witnessed. In summary, a correct server delivers a message m from a correct client χ only if χ broadcast m.

No duplication. A correct client only broadcasts one message at a time. As such, while the client might attach multiple sequence numbers to the same message (different brokers may propose different aggregate sequence numbers for the client to authenticate) the sequence numbers the client attaches to each message belong to distinct ranges. A correct server delivers client messages only in increasing order of sequence number, and ignores repeated messages. This means that a correct server delivers at most one message from each sequence number range. In summary, no server delivers a correct client's message more than once.

4.4.2 Liveness

The liveness of Chop Chop is given by its validity property.

Validity. If a correct client submits its message to a correct broker, the message is guaranteed to eventually be delivered by all correct servers: even if the client fails to engage in distillation in a timely manner, its message is still included in a batch which gets disseminated, witnessed and delivered by all correct servers. Faulty brokers can clearly refuse to service (specific) clients. Upon expiration of a suitable timeout, however, a correct client submits its message to a different broker. As we assume that at least one broker is correct, all correct clients are eventually guaranteed to find a correct broker and get their messages delivered by all correct servers.

4.4.3 Other Attacks

As we outlined in §§4.4.1 and 4.4.2, Chop Chop satisfies all properties of Atomic Broadcast. In this section, we consider other attacks an adversary might deal to impair Atomic Broadcast's performance and fairness [43] in Chop Chop.

Denial of service. A faulty broker may refuse to service clients, thus forcing them to fall back on other brokers, increasing latency. A faulty broker may also submit deliberately non-distilled batches to servers to force them to waste trusted resources to receive and verify individual signatures. While handling DoS is beyond the scope of this paper, Chop Chop is amenable to accountability mechanisms [36]. Brokers could be asked to stake resource to join the system. Correct, high-performance brokers could be rewarded, akin to gas fees in Ethereum [78]. Brokers that accrue a reputation of misbehavior or slowness could be banned and lose their initial stake.

Front-running. A faulty broker might impact fairness by front-running messages of interest [25, 83]. While front-running resistance is beyond the scope of this paper, Chop Chop is compatible as-is with existing mechanisms to mitigate or prevent front-running, most notably schemes that have clients submit encrypted messages whose content is revealed only after delivery [60, 81]. Importantly, these encrypt-order-reveal schemes could be selectively employed only for those messages that are vulnerable to front-runs, e.g., messages used for stock trading [65]. Maintaining Chop Chop's throughput while providing quorum-enforced fairness for every message [82] opens a valuable future avenue of research.

5 Implementation Details

A straightforward implementation of the protocol we presented in §4 would not achieve the throughput and latency we observe in §6. In this section, we discuss some of the techniques and optimizations required on the way to practically achieving Chop Chop's full potential. (Many optimizations are however left out due to space constraints).

Code. Chop Chop is implemented in Rust, totaling 8,900 lines of code. The main libraries Chop Chop depends on are: tokio 1.12 for an asynchronous, event-based runtime; rayon 1.5 for worker-based parallel computation; serde 1.0 for serialization and deserialization; blake3 1.0 for cryptographic hashes; ed25519-dalek 1.2 for EdDSA signatures on Curve25519 [40]; blst 0.3.5 for multi-signatures on the BLS12-381 curve [12]. Chop Chop also depends on in-house libraries: talk (9,800 lines of code) for basic distributed computing and high-level networking and cryptography; zebra (7,100 lines of code) for Merkle-tree based data structures.

5.1 Broker

The goal of a Chop Chop broker is to produce batches as distilled as possible (to minimize server load), as large as possible (to amortize ordering), and as quickly as possible (to minimize latency). Our target is for a broker to assemble one fully distilled batch of 65,536 messages ($\sim$ 736 KB, see Fig. 3) per second, with a 1 second distillation timeout.

Reliable UDP. Short-lived TCP connections between broker and clients are easier to work with, but unfeasible for the broker to handle. Assuming an end-to-end broadcast time of up to 10 seconds, the broker would need to maintain upwards of 600,000 simultaneous TCP connections, which preliminary tests immediately proved unfeasible on the hardware we have access to. This makes UDP the only option for client-broker communication. However, UDP lacks the reliability properties of TCP, and tests showed non-negligible packet loss even within the same AWS EC2 availability zone. As we discussed in §4.2, message loss immediately translates to partial distillation. We address this issue by means of an in-house, ACK-based, message retransmission protocol based on UDP that also smoothens the rate of outgoing packets.

EdDSA batch verification. To avoid spoofing, all client messages are authenticated with signatures. At the target rate, however, individually verifying each signature is unfeasible for a broker. Luckily, ed25519-dalek allows for more efficient batched verification. A broker buffers the client messages it receives and authenticates them in batches.

Tree-search invalid multi-signatures. Clients contributing to the same batch produce matching multi-signatures for the batch's root. At the target rate the broker cannot independently verify each multi-signature. We tackle this problem by gathering multiple matching multi-signatures on the leaves of a binary tree: internal nodes aggregate their children. For each tree, the broker verifies the root multi-signature, recurring only on the children of an invalid parent. This allows to identify invalid multi-signatures in logarithmic time while enabling batched verification in the good case.

Caching legitimacy proofs. Clients justify their sequence numbers with legitimacy proofs. Again, the broker cannot verify each proof in time. We address this problem by having the broker verify a legitimacy proof only if higher than the highest it previously observed. As a result, a faulty client might get away with submitting an invalid legitimacy proof but, importantly, not an illegitimate sequence number.

5.2 Server

The goal of a Chop Chop server is to process distilled batches as quickly as possible without overflowing its memory.

Batch garbage collection. Servers update each other on which batches they delivered. A server garbage-collects a batch, both messages and metadata, as soon as it is delivered by all other servers. We underline that, even if a single server fails to deliver a batch, the others cannot garbage-collect it as the slow server might be correct. This is an inherent limitation of Atomic Broadcast: agreement without synchrony can be ensured only in the infinite-memory model.

Identifier-sorted batching. No two messages from the same client must appear in the same batch. To simplify processing, brokers sort the messages in a batch by client identifier. Servers reject batches whose identifiers are not strictly increasing, thus verifying that all identifiers are distinct in constant size and in linear time. Sorting messages by identifier also enables parallel deduplication: messages are split by identifier range, chunks are deduplicated independently.

6 Evaluation

We evaluate Chop Chop focusing on the following research questions (RQs): What workload can Chop Chop sustain (§ 6.3)? What are the benefits of Chop Chop's distillation (§6.4)? How does Chop Chop scale to different numbers of servers (§6.5)? How efficiently does Chop Chop use resources overall (§6.6)? How does Chop Chop perform under adverse conditions, such as server failures (§6.7)? What performance can applications achieve using Chop Chop (§6.8)?

6.1 Baselines

We compare Chop Chop against four baselines:

- HotStuff [80]: an Atomic Broadcast protocol designed for high-throughput (written in C++);
- BFT-SMaRt [9]: an Atomic Broadcast protocol, similar to PBFT [18], designed for low-latency (written in Java);
- Narwhal-Bullshark: the DAG-based Atomic Broadcast protocol Bullshark [69] with the state-of-the-art high-throughput mempool Narwhal [26] (written in Rust);
- Narwhal-Bullshark-sig: akin to Narwhal-Bullshark but with Narwhal modified to authenticate messages, thus matching Chop Chop's guarantees.

We deploy Chop Chop with two distinct underlying Atomic Broadcast protocols (Fig. 5): HotStuff and BFT-SMaRt.

HotStuff and BFT-SMaRt. Evaluating HotStuff and BFT-SMaRt allows us to assess the base performance of an Atomic Broadcast protocol and determine how much acceleration Chop Chop provides. We evaluate Chop Chop on top of the same implementations of HotStuff [22] and BFT-SMaRt [21] we benchmark against. These implementations

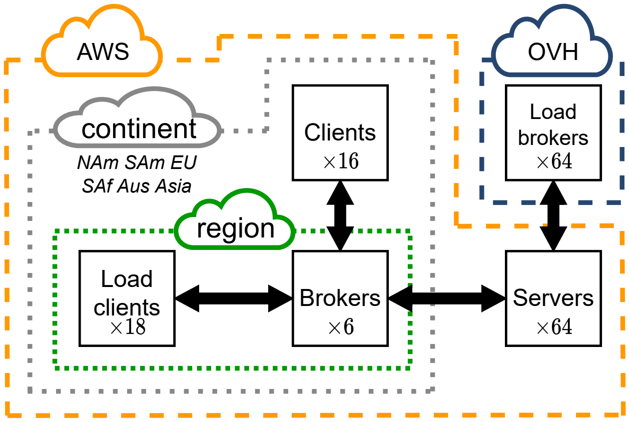

Figure 6: **Cross-cloud deployment summary.**

are production-ready and do not use state-of-the-art mempool protocols, only some basic form of batching. When evaluated stand-alone, each message in these systems includes 80 B of header composed of a client identifier (8 B), a sequence number (8 B), and a signature (64 B) verified by the servers. Both systems use batches of 400 messages, i.e., of 34.4 KB.

Narwhal-Bullshark. As a state-of-the-art mempool, Narwhal is a close point of comparison for Chop Chop. Servers in Narwhal scale out following a primary-workers model: each server is paired with one or several workers into a server group. Similarly to Chop Chop, Narwhal greatly accelerates its underlying Atomic Broadcast (here, Bullshark). Unlike Chop Chop, however, Narwhal leaves the responsibility of authenticating and deduplicating messages to the application.

Narwhal-Bullshark-sig. For a better comparison, we also benchmark Narwhal-Bullshark-sig: Narwhal-Bullshark where messages are authenticated by Narwhal in a state-of-the-art way, i.e., using batched, multi-core Ed25519 signature verification. Each message includes an 80 B header as for HotStuff and BFT-SMaRt. As for Narwhal-Bullshark, the remaining parameters are the default ones, e.g., 500 KB batches.

6.2 Setup

Unless otherwise specified—in §§ 6.5 and 6.6—the Chop Chop benchmarks involve 64 c6i.8xlarge AWS servers, of 32 Intel vCPUs each, geo-distributed across 14 regions. Brokers assemble, and servers process, batches of 65,536 messages. Each message is 8 B in length, resulting in 736 KB batches (Fig. 3). Baselines always use the same set of server machines as their Chop Chop counterpart. All experiments run with maximum resilience, e.g., the system survives 21 faulty servers out of 64. Fig. 6 overviews the used deployment.

Matching trusted and total resources. Unlike its baselines, Chop Chop leverages *untrusted* resources, brokers, to boost its performance. Lacking a well-defined conversion between trusted and untrusted resources, two extremes can be taken to compare Chop Chop with its baselines: we can either match trusted resources, e.g., same number of Chop Chop servers as Narwhal workers, or match total resources, e.g., same number of servers and brokers in Chop Chop as workers in Narwhal.

Intuitively, the first approach considers untrusted resources to be free while the second considers untrusted resources to be as costly as trusted resources. We use the first approach in §§6.3 to 6.5, 6.7 and 6.8 to stress Chop Chop, provisioning the system with enough brokers to bottleneck servers. We use the second approach in §6.6 to assess how efficiently Chop Chop uses its hardware resources, trusted or not.

Load clients and load brokers. We show in §6.3 that Chop Chop servers handle up to 43.6 million operations per second with an average latency of 3.6 seconds. To produce this level of workload, a real-world deployment would require over 700 brokers, each handling around 200,000 clients broadcasting back-to-back thus totaling hundreds of millions of machines. As we cannot experiment at such a scale, we introduce two new actors: *load clients* and *load brokers*. (In the rest of this section, “brokers” and “clients” denote real brokers and real clients; the term “load” is always used explicitly.)

Load clients connect to brokers and simulate thousands of concurrent client requests. Most system evaluation typically use this approach to stress the system and measure latency. However, we explicitly separate clients from load clients in this evaluation. Clients run on very small machines—less powerful than most smartphones—to provide more accurate end-to-end latency measurements. We similarly split clients from load clients in all baseline runs.

Load brokers are unique to Chop Chop. Even using load clients, we could not deploy enough brokers to bottleneck Chop Chop’s servers. Load brokers work around this limitation, submitting batches of pre-generated messages directly to the servers. Free from interactions with clients and expensive cryptography, a load broker puts on the servers a load equivalent to that of tens of brokers working at full capacity.

Using load clients and load brokers, we manage to show that brokers can quickly generate large batches of messages, and servers can process large numbers of batches.

Cross-cloud deployment. All servers are deployed on AWS, balanced across 14 regions: Cape Town, São Paulo, Bahrain, Canada, Frankfurt, Northern Virginia, Northern California, Stockholm, Ohio, Milan, Oregon, Ireland, London, and Paris. For system sizes of 8 in §6.5, we distribute servers across the first 8 regions from the list, which constitute the most adversarial setup with the highest pairwise latency.

Load brokers are placed in a separate cloud provider, OVH, for two purposes. First, it provides a better representation of Internet load than a single-cloud deployment. AWS operates under its own AS so any AS peering bottlenecks would be bypassed by an AWS-only deployment. Second, OVH is one of the few cloud providers with enough peering with AWS to stress Chop Chop without charging for egress bandwidth, saving us from using AWS' costly bandwidth. The final cost amounted to 25,000 USD in AWS credits. Using OVH saved us more than 70,000 USD since each of Chop Chop's data point on a figure would have cost 1,700 USD in AWS egress bandwidth—21 TB at 0.08 USD per GB ≈ 1,700 USD.

For all experiments, we deploy one broker in each continent (Cape Town, São Paulo, Tokyo, Sydney, Frankfurt, and Northern Virginia) and one client in each of the 14 regions above, plus Tokyo and Sydney. Clients connect to their nearest broker. We configure the network for geo-distribution and high load, e.g., TCP buffer sizes [37] and UDP parameters.

All baselines run on the same parameters. For Narwhal-Bullshark, we collocate each server with one of the workers in its server group. We reproduced Narwhal-Bullshark's original experiments [69] and matched the results.

Hardware. All servers, brokers and load clients run on c6i.8xlarge machines with an Intel Xeon Platinum 8375C (32 virtual CPUs, 16 physical cores, 2.9 GHz baseline, 3.5 GHz turbo), 64 GB of memory and 12.5 Gb/s of bandwidth. We selected these machines since they provide good performance and are in the same "commodity" price range as those chosen initially for Chop Chop's main baseline: Narwhal-Bullshark. Clients run on t3.small machines: 2 vCPUs, 1 physical core, 2 GB of memory, and up to 5 Gb/s bandwidth—of which they use less than 1 KB/s. All machines run Linux Ubuntu 20.04 LTS on the AWS patched version of the Linux kernel 5.15.0, except for the load brokers on OVH which run on Linux kernel 5.4.0—the same kernel was not available.

Challenges. The most significant evaluation challenges arose from the scale of the targeted deployment. The setup and orchestration alone required simultaneous handling of up to 320 machines across two different cloud providers and 25 regions, as well as transferring 13TB of files—mostly public keys and pre-generated batches—for each of the 12 setups. To handle this, we developed a new command-line tool to efficiently deploy distributed systems: `silk`. Among other things, we use `silk` for peer-to-peer-style file transfer over aggregated TCP connections, as well as for grouped process control. With `silk`, transferring all files from a single machine takes around 30 minutes, compared to 68 hours with `scp`. The code for `silk` can be found at [*anonymized*].

Additional challenges came from the real-world nature of the targeted deployment. First, the connection between OVH and AWS's Asia and Pacific regions was particularly unstable at certain times of day especially when close to saturation. For example, Tokyo's connection was frequently degraded between 3pm and 5pm UTC. Second, the performance of some machines sometimes deviated from their specifications. As an example, in a setup size of 64, we observed around 2 machines operating with a 10% lower CPU turbo clock rate than specified. Considering these variations, we increased the number of servers a broker initially asks for witness shards (see §4.3) by a margin, e.g., $f+5$ instead of $f+1$. This improves system stability—i.e., lower latency variability—while slightly reducing maximum throughput. Unless otherwise specified, we set the margin to 4 in all experiments, i.e., $f+5$.

Plots. Every data point is the mean of 5 runs of 2 minutes each (after excluding warmup and cooldown, the relevant cross-section is at least 1 minute). All plots further depict one standard deviation from the mean using either colored shaded areas or black error bars (which may be too small to notice). Experimental data can be found at [*anonymized*].

6.3 RQ1 – Load Handling

Fig. 7 shows the latency and throughput of Chop Chop and all its baselines for various input rates of 8 B messages. The variability is represented using shaded areas.

Baselines. Both BFT-SMaRt and HotStuff showcase stable performances under low loads, respectively achieving around 1,400 and 1,600 operations per second. BFT-SMaRt's latency is consistently better than HotStuff's up to its inflection point (0.45–0.53 s vs. 1.2–1.6 s). We measure up to 3.8M op/s for Narwhal-Bullshark and up to 382k op/s for Narwhal-Bullshark-sig. The difference in respective throughputs highlights the cost of authentication for servers: verifying signatures reduces the throughput of Narwhal-Bullshark by one order of magnitude. We observe a latency of around 3.6 s for both Narwhal-Bullshark and Narwhal-Bullshark-sig.

Chop Chop. Chop Chop achieves close to 44M op/s while running on top of both HotStuff and BFT-SMaRt. Chop Chop's latency range is 3.0–3.6 s with BFT-SMaRt and 5.8–6.5 s with HotStuff. Notably, the latency of Chop Chop-HotStuff decreases under high load. This is due to the internal batching mechanism of the HotStuff implementation: buffers fill faster under higher load, thus avoiding timeouts. This has an immediate impact on Chop Chop, which feeds HotStuff at a low rate: HotStuff alone accounts for over 60% of Chop Chop-HotStuff's overall latency. BFT-SMaRt makes a better fit for Chop Chop, as its throughput is sufficient for Chop Chop's needs, and its latency is lower than HotStuff's.

Mempools' trade-off. In comparison to BFT-SMaRt and HotStuff, Chop Chop trades latency in favor of throughput. This trade-off is mostly explained by batching and distillation. When assembling a batch, a broker has to wait twice: once to collect enough messages to fill a batch, and once to collect all multi-signatures from clients engaging in distillation. We set both waits' timeout to 1 second. Notably, Narwhal-Bullshark seems to incur a similar latency cost, as Chop Chop's latency approximately matches that of Narwhal-Bullshark, even though Chop Chop needs an extra round trip between clients and broker (Fig. 5, #4–#6).

6.4 RQ2 – Distillation Benefits

We showcase the benefits of distillation by: evaluating throughput with and without distillation, evaluating distilla-

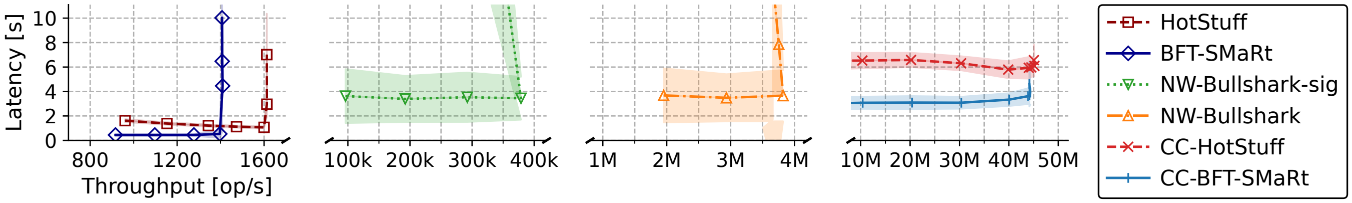

Figure 7: **Throughput-latency of Chop Chop and of notable Atomic Broadcast systems under various input rates.**

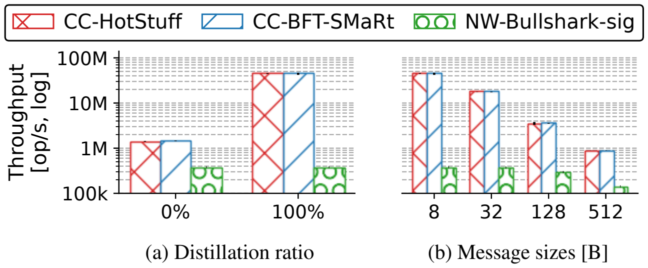

(a) Distillation ratio

(b) Message sizes [B]

Figure 8: **Throughput of Chop Chop and authenticated Narwhal with Bullshark (log scale) when (a) Chop Chop has no distillation and with (b) varying message size.**

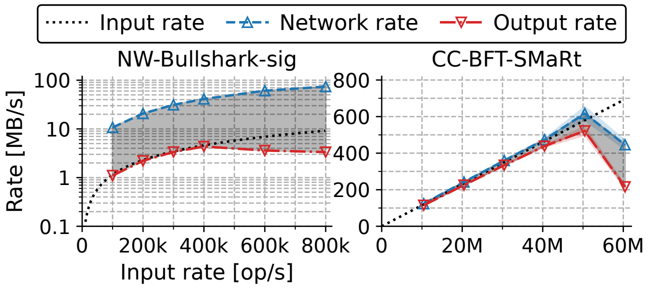

Figure 9: **Throughput efficiency of authenticated Narwhal with Bullshark (left, log scale) and Chop Chop with BFT-SMaRt (right, linear scale) with various input rates.**

tion for messages of different sizes, and observing the impact of distillation on network bandwidth to achieve line rate.

Distillation vs. mitigations. Along with distillation, Chop Chop makes use of two techniques available in the literature to mitigate the cost of Atomic Broadcast's authentication: short identifiers and pooled signature verification (see §2.2).

Fig. 8a breaks down Chop Chop's throughput, measuring how significantly distillation alone contributes to Chop Chop's performance. When no message is distilled, Chop Chop's servers bottleneck at 1.5M op/s, 3.9× higher than Narwhal-Bullshark-sig. This result is in line with both systems bottlenecking on server CPU, as the technique employed by Chop Chop to mitigate authentication complexity has only one third of the servers verify each client signature. (We conjecture that the additional 1.3 factor may be owed to engineering differences.) When batches are fully distilled, Chop Chop's throughput grows to 44M op/s, accounting for the additional 29-fold boost to Chop Chop's performance.

Distillation for larger messages. Fig. 8b illustrates Chop Chop's maximum throughput for message sizes of 8 B to 512 B which may be relevant to applications that cannot work around smaller message sizes, e.g., many smart contracts. Chop Chop's throughput is similar with BFT-SMaRt and HotStuff, decreasing at an approximately 1-to-1 ratio as the message size increases: 44.3M op/s for 8 B, 17.6M op/s for 32 B, 3.5M op/s for 128 B and 890k op/s for 512 B.

This is in line with expectations. As we discuss in §3.2, a server should receive $\sim b$ bytes in order to deliver a b-bytes message in a large, fully distilled batch, as full distillation amortizes to zero the communication cost of authenticating and sequencing each message. For 8 B messages, servers encounter a CPU bottleneck slightly before the link between load brokers and servers is saturated. This explains why the throughput decreases only 2.52× when messages grow to 32 B: all remaining server-bound bandwidth is used to convey messages (as messages are larger) while the load on server CPUs is reduced (as less messages are delivered overall). The system remains communication-bottlenecked as the size of the messages increases, and throughput starts decreasing linearly with message size, e.g., Chop Chop's throughput for 512 B messages is 4.00× smaller than for 128 B.

By contrast, Narwhal-Bullshark-sig bottlenecks on server CPUs longer, due to signature verification, maintaining a stable throughput until 512 B messages finally fill server links. Overall, Narwhal-Bullshark-sig's throughput only decreases from 382k op/s for 8 B messages to 142k op/s for 512 B messages, which matches their non-authenticated evaluation with 512 B messages. The gap between Chop Chop and Narwhal-Bullshark-sig at 512 B messages can be mostly attributed to Chop Chop's more efficient use of server bandwidth: unlike Narwhal, Chop Chop offloads the dissemination of batches to external brokers. Narwhal's use of worker-to-worker communication in its common path also makes it more prone to be affected by AWS's various upload limitations, e.g., AWS upload bandwidth is half the stated download bandwidth, and there are network credit limits for "burst" uploading.

Line rate. Fig. 9 illustrates Chop Chop's near line-rate network use by depicting its input, network and output rates:

- Input rate measures the total bytes of useful information—i.e., client identifiers and messages—that clients, load clients and load brokers all broadcast per time unit;

- Network rate measures the ingress bandwidth of servers at their network interface, i.e., useful information captured by the input rate as well as the Atomic Broadcast's overhead for ordering, authentication and deduplication;
- Output rate, or "goodput", measures the total bytes of useful information that each server delivers per time unit.

A system with perfect line rate would match all three rates: input rate would match output rate as messages can be delivered in a timely fashion with no backlogging, and output rate would match network rate as a server would only receive useful information, with no overhead due to Atomic Broadcast. The gray-shaded areas in Fig. 9 highlight this overhead, i.e., the difference between network and input rates. Network and output rates are averaged over all servers.

In this experiment, each of the 257M simulated clients broadcast 8 B messages. This results in 11.5 B of useful information per broadcast as 28 bits = 3.5 B are sufficient to represent every identifier. This conversion is captured by the dotted line which converts the input rate from op/s, represented on the x-axis, to B/s, represented on the y-axis.

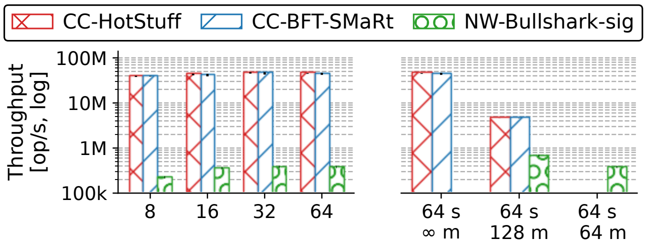
For authenticated Narwhal-Bullshark, the output rate closely matches the input rate until signature verification becomes the bottleneck at 378k op/s, shown by the plateauing output rate. The gap between Narwhal-Bullshark-sig's network and input rates is evident, differing by one order of magnitude (notably in line with our back-of-the-envelope calculation in §3.2). In contrast, thanks to distillation, Chop Chop practically achieves line-rate up to its maximum throughput. Before its inflection point at 40M op/s, the overhead of Chop Chop is less than 8%. The drop in output and network rates at 60M op/s is due to servers surpassing their computational capacity: broadcasts stall, server witness verification gets backlogged and brokers, suspecting server faults, ask for more batch witnesses, further stressing servers' CPUs.

6.5 RQ3 – Number of Servers

Fig. 10a illustrates the maximum throughput for systems of 8 ($f = 2$), 16 ($f = 5$), 32 ($f = 10$) and 64 ($f = 21$) servers. For Chop Chop, we adjust the witnessing margin as the system grows by 0, 1, 2, and 4 for 8, 16, 32 and 64 servers respectively (see § 6.2). Both Chop Chop and authenticated Narwhal-Bullshark scale well to 64 servers. Note that, unless trust assumptions are modified, Narwhal-Bullshark-sig only scales vertically: if a Narwhal server or any of its workers are faulty, the entire server group is compromised. Chop Chop, instead, scales horizontally with the number of brokers.

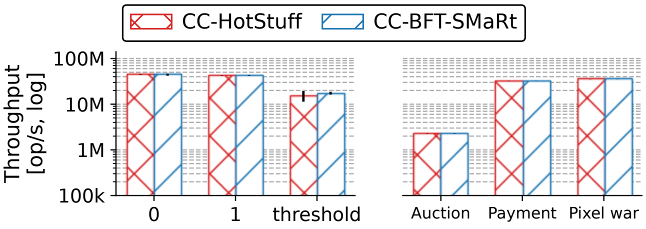
6.6 RQ4 – Overall Efficiency

The center cluster of bars in Fig. 10b compares Chop Chop's throughput with that of authenticated Narwhal-Bullshark when overall hardware resources are matched. In this setting, both systems have 128 machines at their disposal. Chop Chop is provided with 64 servers, 64 brokers and 0 load brokers. Since a load broker uses pre-generated synthetic data to simulate tens of brokers (see §6.2), involving load brokers in this experiment would give an unfair advantage to Chop Chop. Narwhal-Bullshark-sig is provided with 128 workers, to match Chop Chop's total machines, balanced across 64 server groups, to match Chop Chop's servers. The left and right clusters of bars depict Chop Chop using load brokers and Narwhal-Bullshark-sig with 64 server groups containing 1 worker each, respectively, as in the other experiments.



(a) System sizes (b) Matching resources

Figure 10: **Throughput of Chop Chop and authenticated Narwhal with Bullshark (log scale) when (a) varying system size, and when (b) varying the number of overall machines ("m") with 64 servers ("s").** Load brokers in Chop Chop simulate tens of brokers, hence are noted "∞ m".



(a) Server failures (b) Applications

Figure 11: **Throughput of Chop Chop (log scale) with (a) various server failures and for (b) different applications.**

We observe 4.6M op/s for Chop Chop, with servers reporting around 5% CPU usage. We observe 679k op/s for Narwhal-Bullshark-sig. Chop Chop's higher throughput is in line with expectations. In Narwhal-Bullshark-sig, workers are trusted, and as such a worker can only contribute to its own server group. Instead, since Chop Chop brokers are untrusted, a broker's work is useful to all servers.

6.7 RQ5 – Chop Chop Under Failures

Fig. 11a depicts Chop Chop's throughput when some servers crash 30 seconds into the run. Performance drops marginally (from 44M op/s to 43M op/s) with one crash and by 66% (down to 15M op/s) when one-third of the servers crash, resulting in less CPU globally available to witness batches.

Fig. 8a captures Chop Chop's performance hit when clients fail to engage in distillation. This could be caused by clients being slow or crashed, or brokers being malicious. Under the most extreme conditions, where no client engages in distillation, the throughput drops from 44M op/s to 1.5M op/s.

6.8 RQ6 – Application Use Cases

Fig. 11b depicts the maximal stable throughput for various application use cases. In the Auction app, a client can bid an amount on a token it does not own, or take the highest offer it received for an item it owns. The highest amount bid on each token is locked and cannot be used to bid elsewhere. Money bid is transferred when the owner of the token takes the offer, or refunded when the bid is raised by another client. The Auction app is single-threaded and many clients bid on the same token to approximate a real auction. In the Payments app, clients choose a recipient and an amount to transfer. In Pixel war, clients choose a pixel and an RGB color to paint on a 2,048 by 2,048 board. Operations are generated at random.

We observe 2.3M op/s for the Auction, 32M op/s for Payments and 35M op/s for Pixel war. The bottleneck is the application in all cases, thus Chop Chop has sufficient capacity for high, single-application throughput. Chop Chop can also support many separate high-throughput applications simultaneously, making it a fitting Atomic Broadcast candidate to power a universal SMR system, i.e., an Internet computer.

7 Related Work

We overview below the state-of-the-art most relevant to Chop Chop, namely Atomic Broadcast systems with high-throughput and efficient signature aggregation schemes.

High-throughput Atomic Broadcast. Narwhal [26] is a mempool protocol that separates the reliable distribution of payloads from the communication-expensive ordering in order to accelerate DAG-based Atomic Broadcast [33, 42, 69]. Narwhal utilizes trusted workers to increase throughput while Chop Chop relies on *trustless* brokers, for the same effect, and scales out more efficiently. To circumvent the bottleneck associated with the broadcast leader, approaches using multiple leaders have been developed—both for crash [31, 61] and arbitrary [3, 6, 70, 71] faults—to scale the broadcast throughput linearly with the number of leaders. Dissemination trees [44, 63] have also been employed to reduce communication cost and maximize network bandwidth utility, while sharded [46, 76] and federated [54] approaches reduce communication cost by promoting local communication in geo-distributed setups. In comparison, Chop Chop shows that an optimal distillation mechanism for batches achieves better performances without adding complexity to the Atomic Broadcast protocol itself.

Other approaches have shown that the underlying hardware of servers can also be exploited for higher throughput, such as FPGA [38, 41] and Intel SGX enclaves [7]. In comparison, Chop Chop uniquely boosts throughput by exploiting *trustless hardware* via brokers. Atomic Broadcast can also be accelerated in data centers by using the topology of the network [51, 64] or even by running within the network itself using P4-programmable switches [27, 45]. In such low latency environments, the processing overhead incurred by the operating system kernel can be bypassed to further increase the throughput of Atomic Broadcast [1, 45, 75].

Signature aggregation. Aggregate signatures were first proposed to save space by compacting a large number of signatures into just one [11, 67]. Up until recently, aggregation could also save verification time but only in certain cases: either when the signatures are generated by the same signer [17, §5.1], or when the signatures are on the same message, i.e., multi-signatures [39]. In the latter case, aggregation mechanisms have been proposed to achieve constant-time verification of aggregated multi-signatures for both BLS [10] and Schnorr [57] signature schemes. In particular, multi-signatures are used in cryptocurrencies to have many servers sign the same batch of payloads [30, 44]. Servers in Chop Chop use rapidly-verifiable BLS multi-signatures [10] for that very purpose. In addition to aggregating server signatures on batches, Chop Chop's distillation mechanism also aggregates all client signatures in a batch in a way that provides constant-time verification. The theoretical scheme Draft [16] proposed signature aggregation with similar verification performances but is tailored to Reliable Broadcast. It is however unclear how Draft could be implemented as a real-world system without compromising liveness. Indeed, Draft assumes infinite memory to prevent message replay attacks which would rapidly exhaust servers' memory if deployed to match Chop Chop's maximum throughput (see §6.2). Chop Chop also aggregates client sequence numbers to significantly reduce bandwidth consumption when small messages are broadcast (Fig. 2). Chop Chop aggregates sequence numbers thanks to the ordering of and thanks to novel legitimacy proofs (see §4.2).

8 Concluding Remarks

Chop Chop's performance comes with two limitations. First, Chop Chop's high throughput makes memory management a challenge: servers fill their memory quickly if unable to garbage-collect under heavy load. Second, all servers in Chop Chop are known at startup and it is unclear if its performance would be maintained when deployed on thousands of servers. Interesting avenues of future research include sharding to achieve even higher throughput by running multiple, independent, coordinated instances of Chop Chop, and offloading more tasks to the brokers, such as public key aggregation.

A Artifact Appendix

Abstract

This artifact is a full implementation of Chop Chop, an end-to-end client-server Byzantine Atomic Broadcast system leveraging a third-party—brokers—to optimize network usage and vastly reduce the computational load of authenticating client requests on the server-side while preserving safety.

Scope

This artifact can be used to validate the following claims (*provided the setup is the same*):

- End-to-end performance (Figs. 7 and 10).
- Distillation benefits (Fig. 8) and throughput efficiency (Fig. 9).
- Performance under faults (Fig. 11).

Note that reproducing the same plots (including error bands) can be prohibitively costly given the scale of the evaluation (number and hourly price of machines, see §6.2).

Contents

The artifact contains all the source code used to implement Chop Chop. We provide a docker file to set up experiments. We also provide automated scripts to extract and interpret the data as well as generate plots. Please refer to the README.md file in the repository for more details.

Hosting

The repository can be accessed through GitHub[4] (see the instructions on the README.md file).

Requirements

There are no special hardware or software requirements beyond a recent enough version of Rust (§5) and the desired network layout to evaluate. If you wish to reproduce our results exactly, please see §6.2 for the setup used.

Abstract

Obtaining high-performance tensor programs with high efficiency continues to be a substantial challenge. Approaches that favor efficiency typically limit their exploration space through heuristic constraints, which often lack generalizability. Conversely, approaches targeting high performance tend to create an expansive exploration space but employ ineffective exploration strategies.

We propose a tensor program generation framework for deep learning applications. Its core idea involves maintaining an expansive space to ensure high performance while performing powerful exploration with the help of language models to generate tensor programs efficiently. We thus transform the tensor program exploration task into a language model generation task. To facilitate this, we explicitly design the language model-friendly tensor language that records decision information to represent tensor programs. During the compilation of target workloads, the tensor language model (TLM) combines knowledge from offline learning and previously made decisions to **probabilistically sample** the best decision in the current decision space. This approach allows more informed space exploration than **random sampling** commonly used in previously proposed approaches.

Experimental results indicate that TLM excels in delivering both efficiency and performance. Compared to fully tuned Ansor/MetaSchedule, TLM matches their performance with a compilation speedup of 61×. Furthermore, when evaluated against Roller, with the same compilation time, TLM improves the performance by 2.25×. Code available at https://github.com/zhaiyi000/tlm.

1 Introduction

As deep learning rapidly grows in both scale and complexity, the gap between the computational needs of deep learning workloads and the capabilities of existing computing platforms is widening. This gap underscores the imperative for low-latency execution of deep learning workloads. Solutions for low-latency execution primarily include kernel libraries provided by vendors (e.g., cuDNN [1], oneDNN [2]) and search-based tensor compilers (e.g., TVM [3], Halide [4], Tensor comprehensions [5], Flextensor [6], NeoCPU [7]). Existing deep learning frameworks (e.g., TensorFlow [8], PyTorch [9], and MXNet [10]) map the operators (e.g., convolution, matrix multiplication) in deep learning workloads to vendor-provided kernel libraries to optimize performance. Given the high development costs of vendor-provided kernel libraries, developers are increasingly turning to tensor compilers to auto-explore for tensor programs, i.e., optimized, low-level implementations of operators.

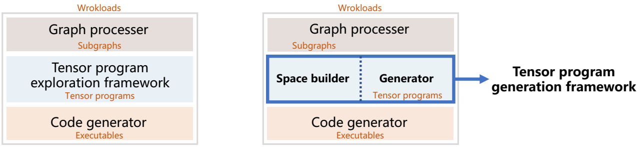

Figure 1: The left shows the architecture of common tensor compilers, while the right illustrates the structure incorporating our tensor program generation framework.

The left of Figure 1 shows that a tensor compiler can be divided into three parts: a graph processor (e.g., Relay [11], HLO), a tensor program exploration framework (e.g., AutoTVM [12], Ansor [13], MetaSchedule [14], AKG [15]), and a code generator (e.g., LLVM [16], NVCC [17]). The graph processor is responsible for converting various deep learning workloads of different formats (e.g., ONNX [18], TensorFlow PB) into a unified graph representation, performing graph optimizations, and splitting the workloads into subgraphs. Then, the tensor program exploration framework takes subgraphs as inputs, which, after scheduling, are lowered into tensor programs. Finally, a code generator is invoked to produce executables explicitly tailored for the target hardware.

The tensor program exploration framework, in lowering subgraphs to tensor programs, is tasked with making a series of critical decisions. These include determining the tiling

[*] Corresponding authors.

sizes of loop axes, setting unroll steps, choosing computation locations for operators, strategizing on parallelization and vectorization, and, particularly on GPUs, deciding thread bindings. The options for each decision create a decision space, and all decision combinations form the exploration space. The primary objective of this exploration framework is to find a decision combination that minimizes the execution latency of the resulting tensor program.

Previous work either introduces heuristic constraints to define or prune the exploration space, resulting in limited performance or constructs an expansive exploration space but employs less effective exploration strategies – for instance, the random sampling used by Ansor [13] and MetaSchedule [14]. For a detailed literature review, please refer to section §2.1.

To address this challenge, we propose an approach to maintain an expansive exploration space while conducting more powerful exploration – i.e., enabling language models to assist in generating high-performance tensor programs. Specifically, we present a *generation-based* tensor program exploration framework, i.e., a tensor program generation framework, for deep learning applications. The proposed framework consists of two components, a space builder and a generator, as shown in the right of Figure 1. The space builder is dedicated to building an expansive tensor program exploration space, ensuring high performance; meanwhile, the generator focuses on efficiently generating high-performance tensor programs, regardless of the exploration space's magnitude. They function independently without mutual constraints, each focusing solely on ensuring high performance and high efficiency.

Generating tensor program source code with language models naturally presents challenges. The length of tensor program source codes often exceeds ten thousand tokens, and these programs must adhere to strict syntactic rules. Crafting such lengthy and syntactically valid tensor program source codes is nearly unfeasible. Therefore, instead of aiming for direct end-to-end generation source code, we utilize tensor compilers for constructing tensor programs and leverage language models to assist in decision-making. To facilitate this, we explicitly design the language model-friendly tensor language to represent tensor programs. A tensor language sentence (abbreviated as tensor sentence) uniquely corresponds to a tensor program by recording the input subgraph, hardware specifications, and decision information of the tensor program. Compared to tensor program source code, a tensor sentence conveys the same semantics (i.e., both represent a tensor program) but in a far more concise manner, capped at no more than 1024 tokens. Building on the tensor language, we draw on the training methods of ChatGPT [19] to develop a language model, the tensor language model (TLM). We utilize millions of tensor sentences and a select few demonstration sentences (corresponding to high-performance tensor programs) to pre-train and fine-tune TLM in a supervised manner. After that, during the compilation of target workloads, TLM combines knowledge from offline learning and previous decisions to make probabilistic predictions for the current decision space, resulting in more effective exploration than random sampling.

It is noteworthy that, in contrast to methods like Ansor/MetaSchedule that depend exclusively on online data, TLM requires about 300K pieces of offline labeled data (i.e., tensor programs with measured execution latency) to select demonstration sentences, requiring tens of hours to collect. However, the labeled data for TLM is still significantly less than that for TenSet [20] or TLP [21], which amounts to 8.6 million and requires several weeks to collect.

In this paper, we also refer to our proposed tensor program generation framework as the TLM framework. The primary innovations of the TLM framework focus on the tensor language and tensor language model. The supported decision spaces are adapted from previous frameworks, which is largely an engineering effort. The space builder currently supports decision spaces adapted from several previous search frameworks, including Ansor, MetaSchedule, AKG, and AKG-MLIR.

We conducted extensive experiments to validate the high efficiency and performance of the TLM framework, examining scenarios with various exploration budget points. Under a limited budget, TLM's performance matches that of Ansor/MetaSchedule yet compiles 61× faster. While its compilation time aligns with Roller, its performance is 2.25× better. In ample exploration times, TLM's compilation duration is consistent with Ansor and MetaSchedule, delivering a performance boost of 1.08× and 1.04×, respectively.

In summary, this paper makes the following contributions:

- We design the language model-friendly tensor language to represent tensor programs, bridging the gap between tensor programs and language models.
- We develop a tensor language model that combines knowledge from offline learning and previously made decisions to probabilistically sample the best decision in the current decision space, enabling more effective space exploration.
- Experimental results show that TLM excels in delivering both high efficiency and performance.

2 Background

2.1 Tensor Program Exploration Framework

In the development of tensor program exploration frameworks, previous studies mainly employ search algorithms to locate optimal tensor programs automatically. As a result, the search-based tensor program exploration framework often gets dubbed as the tensor program search framework, with its exploration space used as the search space.

Earlier, the Halide auto-scheduler [4] aggressively prunes the search space by evaluating incomplete programs; AutoTVM and FlexTensor [6] employ predefined, manually written templates to define their search space. These methodologies introduce constraints that limit the search space, thereby missing out on many potent decision combinations and leading to suboptimal performance.

Subsequently, Ansor [13] and MetaSchedule [14] utilize derivation rules to build an expansive search space, pushing performance to state-of-the-art levels. However, this came with a notably vexing issue — excessive compilation time. In our experience, using Ansor to bring a BERT-base workload to convergence takes 21.6 hours on the NVIDIA V100 GPU; on the Intel i7-10510U CPU, it requires 13.1 hours. The reason behind this is that Ansor/MetaSchedule utilizes a strategy of random sampling followed by evaluation using a learnable cost model. Until completing the random sampling of all decision spaces, Ansor/MetaSchedule lowers subgraphs to tensor programs and then extracts statistical features, including computation, memory access, and arithmetic strength for performance evaluation with the learnable cost model. However, this strategy has three main issues:

- Random sampling represents a form of inefficient exploration, with equal probabilities of sampling optimal or suboptimal decisions.
- The evaluation demonstrates hysteresis. Decisions made during the initial sampling might lead to poor performance but can only be ascertained when evaluating.
- The inadequacy of training data and the small parameter size of the cost model weaken the model's learning ability, limiting its effectiveness in guiding the search algorithm. Ansor/MetaSchedule relies exclusively on minimal online data to train cost models. Moreover, their models are primarily based on low-parameter machine learning or deep learning models (e.g., XGBoost [22], MLP, LSTM).

More recent studies, Roller [23], TenSet [20], and TLP [21], were proposed to address the issue of slow compilation. Roller speeds up the compilation by aligning tensor shapes with the properties of the hardware. However, in doing so, Roller experiences a declining performance (§6.4.2), still due to the generalizability of the heuristic constraint. TenSet and TLP collect offline datasets before compiling the target workloads to build a stronger cost model. While these approaches expedite compilation, they exhibit two key shortcomings. Firstly, they adopt the Ansor/MetaSchedule strategy of conducting random sampling followed by evaluating with a cost model. Moreover, they rely on 8.6 million pieces of labeled data.

An example. We illustrate an example to analyze the differences between heuristic compilers, exemplified by Roller, search-based frameworks like Ansor/MetaSchedule, and our generation-based TLM framework from a probabilistic perspective. Consider a decision space, D_i, with four valid decisions. The optimal decision is d_3, as depicted in Figure 2.

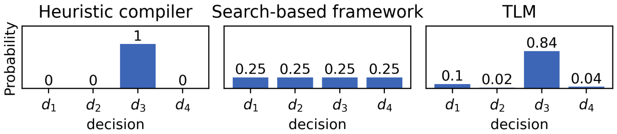

Figure 2: Example of probability distributions in a decision space for several different methods.

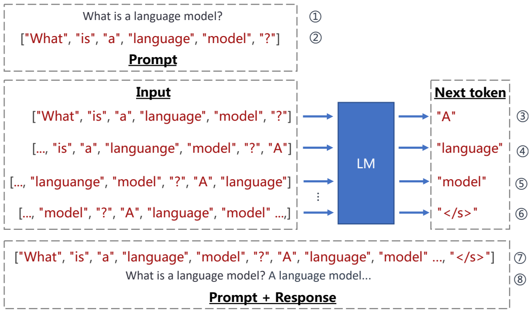
Heuristic compilers use heuristic constraints to eliminate d_1, d_2, and d_4. After this pruning, d_3 has a 100% chance of being sampled, reducing the search space and speeding up the compilation. However, such heuristics aren't always accurate and can sometimes degrade performance. In contrast, search-based frameworks keep all decision options and sample one decision randomly. Here, d_3 has a 25% sampling probability. Until all decision spaces are sampled, a learnable cost model evaluates the results. After sufficient searching, search-based frameworks can always approximate the optimal solution, making them performance-oriented but inefficient methods. Unlike search-based frameworks, TLM combines the knowledge learned offline with the decisions already made to make probabilistic predictions about the best decision in the current decision space.

2.2 Language Model

Deep learning language models mainly fall into two categories: the Masked Language Model (MLM) and the Causal Language Model (CLM), with CLM also known as the Autoregressive Language Model. Notable examples of CLM include the GPT series, such as GPT-2 [24] and GPT-3 [25]. CLMs, recognized for their natural text generation method, often excel in tasks that need coherent text creation, like writing or chatbot conversations. In this paper, a language model refers specifically to a CLM.

Before training a language model, a vocabulary is created through tokenization. Tokenization typically refers to fragmenting an input sentence into its constituent tokens for subsequent language analysis or as input to a model, with all such tokens collectively forming a vocabulary. The steps ①② and ⑦⑧ in Figure 3 represent the processes of tokenizing a sentence into tokens and converting tokens back into a sentence, respectively. For simplicity in description, here we tokenize by words (in practice, the process is more complex). The only thing language models perform is to combine the learned knowledge with the given input to predict the probability distribution of the next token being a specific one from the vocabulary. The initial input is referred to as a prompt. During the training of a language model, natural language sentences are utilized as input. Through the backpropagation algorithm [26], the language model's parameters are iteratively updated to maximize the probability that the next token generated aligns with the corresponding token within the natural language.

Employing the language model for inference, take a real-life instance as an example: we ask a language model, "What



What is a language model?

Figure 3: Employing a language model to generate a natural language sentence.

is a language model?" and it responds, "A language model is a type of artificial intelligence that is trained to understand, generate, and respond to human language...". The generation process is illustrated in Figure 3. In step ③, the language model uses the prompt as input to predict a probability for each token in the vocabulary. This probability signifies the likelihood of each token logically following the input. The next token is then sampled based on these probabilities. Step ④ involves using the prompt and the token generated in step ③ as input to sample the next token probabilistically, continuing this process until the "</s>" token is generated. The ending "</s>" signifies the end of a sentence.

2.3 ChatGPT/InstructGPT

ChatGPT [19] and InstructGPT [27] employ a similar training methodology that encompasses: pre-training, SFT, and RLHF (RM + RL). TLM partially adopts these training approaches. The training process for InstructGPT includes:
Pre-training GPT-3. InstructGPT is based on GPT-3, which boasts 175 billion parameters, leverages approximately 45TB of Internet text for training, and necessitates a significant amount of hardware resources throughout its training process, with the aim of enabling GPT-3 to learn the fundamental structures and semantics of language.
Supervised fine-tuning (SFT). Training a supervised policy by collecting demonstration data (around 14K entries) to fine-tune GPT-3 through supervised learning, with the demonstration data provided by humans representing the desired output behavior corresponding to a prompt.
Reward modeling (RM). Training a reward model by collecting comparison data (around 51K entries), wherein the comparison data, also provided by humans, offers a ranking of model outputs from best to worst.
Reinforcement learning (RL). Optimizing a policy against the reward model using the PPO [28] reinforcement learning algorithm, with rewards determined by the preceding reward model, this step will be iterated multiple times.

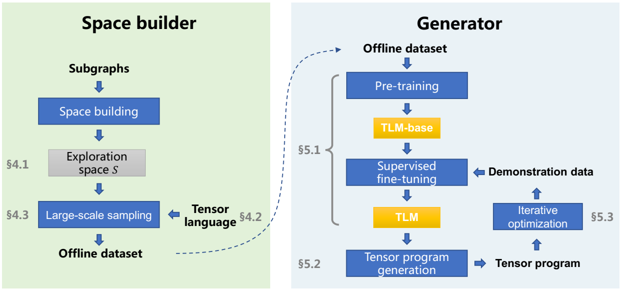

Figure 4: System overview of the TLM framework.

3 System Overview

The TLM framework is a tensor program generation framework designed to generate high-performance tensor programs efficiently. Maintaining a large exploration space can ensure that high-performance tensor programs are not eliminated by heuristic constraints. However, this requires stronger exploration capabilities. Utilizing deep learning models to glean knowledge from offline data for aiding online tensor program exploration presents a promising strategy. Given the current learning capabilities, language models are the most powerful method available. Hence, we propose to leverage the language model to assist in generating high-performance tensor programs, transforming the tensor program exploration task into a language model generation task.

Figure 4 shows the system overview and marks the corresponding subsections that detail each system component. Section 4 centers on collecting a large-scale offline dataset necessary for the pre-training of TLM. Section 4.1 details the exploration space for data sampling and its build process, providing a theoretical foundation for tensor language design through formalization of the exploration space. Section 4.2 discusses tensor language design, emphasizing its role in preserving tensor programs sampled from the exploration space in a format more amenable to language models. Following the discussion of the sampling space and preservation methods, Section 4.3 introduces large-scale sampling, where extensive random sampling achieves an unbiased estimation of the exploration space.

Section 5 focuses on the development of a tensor language model. Initially, Section 5.1 addresses the model architecture, training methods, and the training process of TLM, encompassing both pre-training and supervised fine-tuning. Upon completing pre-training, TLM should be able to generate any valid tensor program within the exploration space. Section 5.2 then details how the TLM framework generates tensor programs with decision-making support from TLM. For generating high-performance tensor programs, we employ demonstration data (corresponding to high-performance tensor programs) to fine-tune TLM through supervised learning, aligning the tensor sentences it generates with our anticipated

demonstration sentences. Section 5.3 discusses obtaining this demonstration data via iterative algorithms.

4 Space Builder

The function of a space builder is to create a large exploration space to ensure high performance. This exploration space consists of all possible tensor programs. Regarding the idea that a large exploration space can guarantee high performance, two aspects need to be discussed. First, a larger space implies that, in comparison to a smaller one, it is constructed with fewer constraints, thus enabling the generation of more tensor programs. To some extent, it can be said that the large space includes the smaller space. Second, ensuring high performance means maintaining the potential for high-performance tensor programs to exist within the exploration space. The larger the space, the less likely it is to be pruned by constraints, but this also demands greater exploration capabilities.

4.1 Exploration Space

In this section, we introduce two primary topics. The first is about building the exploration space. The second involves formalizing the tensor program generation process, providing a theoretical basis for designing the tensor language.

Tensor compilers customarily extract two intermediate representations (IRs) for optimization purposes, i.e., the graph layer and the tensor layer, which are specifically tailored for hardware-independent and hardware-dependent enhancements, respectively. As depicted in Figure 5, the graph layer ingests a workload, optimizing with several passes and employing algorithms for operator fusion and partitioning. Then, it produces subgraphs, each consisting of one or more operators. A subgraph describes the expected computational results, whereas the tensor program exploration framework transforms this subgraph into a tensor program, providing a detailed computational implementation. The collective of all possible tensor programs forms the exploration space S of the tensor layer. Previous exploration frameworks utilize expert knowledge, including templates (AutoTVM), the polyhedral model (AKG), and derivation rules (Ansor, MetaSchedule), to map subgraphs into tensor programs. For areas where expert knowledge falls short, these frameworks use tunable parameters (AutoTVM, AKG), annotations (Ansor), or random variables (MetaSchedule) to create a decision space D_i and then employ search algorithms, such as simulated annealing [29] and genetic algorithm [30], to locate the optimal solution.

The decision spaces chiefly involve determining tiling sizes for loop axes, setting unroll steps, selecting computation locations for operators, strategizing parallelization and vectorization, and on GPUs, specifically determining thread bindings.

From the analysis above, tensor programs result from optimizing input subgraphs through a series of decisions. We formalize the tensor layer's exploration space as follows:

$$S = \left\{ s^{(n)} \;\middle|\; \begin{array}{l} s^{(i)} = \text{apply}\left(s^{(i-1)}, d_i\right), \\ \forall d_i \in D_i,\ 1 \le i \le n \end{array} \right\}$$

where $s^{(0)}$ denotes the initial program of the input subgraph, and d_i represents a random sample from the set D_i. Thus, the size of the exploration space aligns with the number of decision combinations. We have:

$$|S| = |D_1| \times |D_2| \times \ldots \times |D_n|.$$

This work discusses only the exploration space of the tensor layer. On a CPU, the exploration space size corresponding to a subgraph is roughly 10^6; on a GPU, it approximates 10^9.

We reuse the decision space from previous work (e.g., Ansor, MetaSchedule), as we think that this space is already sufficiently large to yield high-performance tensor programs. Expanding the exploration space of tensor layers to larger is a considerable challenge. In future endeavors, we advocate exploring larger spaces mainly by integrating the decision space of the graph layer. Certainly, the TLM framework supports exploration spaces of varying sizes since they all integrate with TLM in the same manner.

4.2 Tensor Language

In this section, we focus on how to store tensor programs sampled from the exploration space.

Recall that our objective is to teach language models of these tensor programs, enabling them to aid in generating high-performance tensor programs during target workload compilation. Tensor program source codes often exceed ten thousand tokens, posing a challenge for language models to generate such lengthy, coherent, and valid source codes. Therefore, we do not pursue the end-to-end generation of tensor program source codes. Instead, we utilize language models to assist in decision-making. To facilitate this, we explicitly design the language model-friendly tensor language that records decision information to represent tensor programs.

As understood from Section 4.1, a tensor program $s^{(n)}$ pertains exclusively to the initial program $s^{(0)}$ of the input subgraph and decisions $d_1, d_2, \ldots, d_n$. Each decision d_i is randomly sampled from decision space D_i, the design of which

Algorithm 1: Sampling tensor sentences from decision spaces.

```
Func GenerateSampleData(subgraph, hardware):
    tokens = []
    ExtractTokensFromSubgraph(subgraph, tokens)
    ExtractTokensFromHardware(hardware, tokens)
    decision_spaces = DetermineDecisionSpaces(subgraph,
      hardware)
    foreach space in decision_spaces do
        switch space.type do
            case "tile_size" do
                HandleTileSizeSpace(space, tokens)
            case "unroll" do
                HandleParallelSpace(space, tokens)
            // Additional space types
            case ... do
                ...
    return tokens
Func HandleTileSizeSpace(space, tokens):
    tokens.append("split")
    tokens.extend(Serialize(space.operator))
    tokens.extend(Serialize(space.axis))
    tiles = RandomSample(space)
    tokens.extend(Serialize(tiles))
    // Other properties
```

hinges on the hardware platform. Consequently, to ensure that a tensor language sentence uniquely corresponds to a tensor program, a tensor sentence must encapsulate the input subgraph, hardware specifications, and decisions. We utilize Algorithm 1 to sample data from the exploration spaces. Each sentence extracts information from the input subgraph, encompassing the type and shape information of each operator within the subgraph. Furthermore, it retrieves hardware details, including the number of processing cores and the supported vector instructions. Successively extracting information from each decision space, Algorithm 1 demonstrates how to extract tokens from the tile size decision space, conserving details such as the corresponding operator, axis, decision space type, sampled decisions from the space, and other pivotal information. A similar method is applied to other decision spaces as well.

Tensor language is a form of natural language, not a programming language, and thus does not strictly follow the Backus-Naur Form [31]. Its primary intent is to represent a tensor program using a single sentence, emphasizing its role in recording rather than programming. This recording process offers significant **flexibility**, with only one constraint being the **consistency** between tensor sentences collected offline and generated online. Such consistency is essential for deep learning models to ensure that training and testing data are independently and identically distributed.

Given the flexibility of tensor language, there are no strict guidelines on the exact details that need to be recorded about input subgraphs, hardware specifications, and decision information. Under the premise of maintaining consistency, these details can be dynamically adjusted in conjunction with specific engineering projects. Figure 6 showcases tensor sentence samples tailored for Ansor (top) and MetaSchedule (bottom).

4.3 Large-scale Sampling Tensor Sentences

This section introduces employing the sampling algorithm to create a large-scale offline dataset.

Large-scale sampling serves two main purposes. Firstly, it is to create an unbiased estimation of the exploration space S through widespread random sampling, which allows TLM to learn the basic structures and semantics of tensor language, enabling TLM to generate any tensor sentence within space S. Secondly, it is to build as large a vocabulary (§2.2) as possible, where all decision options like "i.0=16" and "i.0=32" are tokenized into discrete tokens. If a decision, such as "i.0=17", is not in the vocabulary, it will never be generated.

The workload dataset configured for TLM takes cues from TenSet. The workloads are derived from PyTorch's Vision Model Zoo and Huggingface's Transformer Model Zoo, encompassing tasks emblematic of both computer vision (CV) and natural language process (NLP). We adjust the input shape to generate a variety of subgraphs. Note that we focus on small batch sizes in this dataset because tensor compilers are mainly used for optimizing trained models for inference. Altogether, the dataset consists of 138 workloads, with 12 held out for testing; from the remaining approximately 3K subgraphs are extracted.

We collect 2 million tensor sentences for 3K subgraphs to pre-train TLM. It is worth noting that the 2 million data entries are distinct from the 8.6 million used in TenSet/TLP. The data here is unlabelled, i.e., it does not require measuring execution latency; measurement is typically the most time-consuming part. On a 96-core server, it takes about 2 hours to collect 2 million CPU data entries, and around 10 hours for the GPU. This longer duration for GPU data is due to additional checks, such as ensuring thread binding meets hardware constraints.

5 Tensor Language Model

5.1 Model Details

Model architecture. Taking into account both learning capacity and resource overhead, TLM adopts the architecture of GPT-2 Small, which encompasses approximately 100 million parameters. TLM is composed of 12 Transformer layers, each featuring 12 attention heads and 768 hidden units.

Training methodology. The TLM training is partially inspired by the training procedure utilized by ChatGPT, as introduced in §2.3. To put it succinctly, we modify the formula from $1 \times \text{pre-training} + 1 \times \text{SFT} + n \times (\text{RM} + \text{RL})$ to $1 \times \text{pre-training} + n \times (\text{measurement} + \text{SFT})$.

We substitute reward model (RM) with measurement. RM allocates a reward value to the model output and evaluates its quality. Here, tensor language has a natural advantage. A tensor sentence can be converted into a tensor program (§5.2), allowing its execution latency to be directly measured on hardware, with a lower latency suggesting a better tensor sentence. While ChatGPT only performs supervised fine-tuning (SFT) once, we conduct it multiple times. The input for SFT is demonstration data, provided by humans, symbolizing the desired output behavior corresponding to a prompt. In the NLP field, it's hard to say which demonstration data is the "best" for a prompt, but this is achievable in tensor language. That is, the sentence with the lowest execution latency is the "best" for its prompt. Performing measurement and SFT multiple times is consistently seeking the best tensor sentences (§5.3). We abstained from using reinforcement learning (RL) mainly because it requires adjusting various hyperparameters and presents a training challenge to convergence, and we find the performance was sufficiently good after performing SFT multiple times.

Training details. The model resulting from pre-training is termed TLM-base, and TLM is derived by performing SFT on TLM-base. We pre-train TLM-base using the offline dataset gathered in §4.3 in the same manner as pre-training other language models. It is noteworthy that TLM-base converges within just 2 epochs. This quicker convergence is due to the more pronounced regularity in tensor language compared to the broad diversity in natural languages. Among the 2 million data entries, the input subgraph types, hardware types, and decision types are all limited. Pre-training TLM-base for 2 epochs takes about 10 hours using 4 NVIDIA V100s.

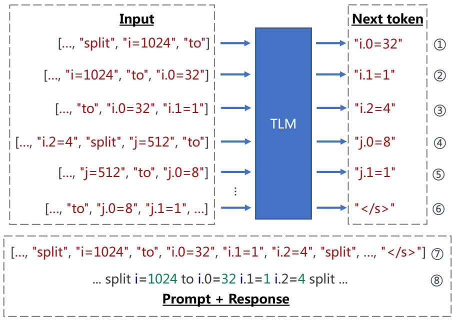
Following its pre-training, TLM-base possesses the ability to generate valid tensor sentences. Furthermore, for the input subgraphs, we expect that TLM-base can aid in generating high-performance tensor programs. To this end, we employ demonstration data to fine-tune TLM-base through supervised learning. Demonstration data refers to the tensor sentences corresponding to a small subset of tensor programs with the lowest execution latency for a given input subgraph. **The purpose of SFT of a language model with demonstration data is to achieve that the model's responses to prompts align with the human intentions reflected in the demonstration data.** Similarly, we apply demonstration data to TLM, aiming to empower it to generate high-performance outputs, in response to prompts. Performing SFT on TLM-base requires a small batch (about 3K, selecting the best one for each subgraph) of demonstration data. We employ iterative optimization (§5.3) to continuously optimize these demonstration entries. With 3K demonstration data, using 4 NVIDIA V100s to perform SFT on TLM-base once takes approximately 10 minutes.

Algorithm 2: Generating tensor programs aided by TLM in decision-making.

```
Func GenerateTensorProgram(subgraph, hardware):
    tokens = []
    ExtractTokensFromSubgraph(subgraph, tokens)
    ExtractTokensFromHardware(hardware, tokens)
    program = GetInitProgram(subgraph, hardware)
    decision_spaces = DetermineDecisionSpaces(subgraph,
      hardware)
    foreach space in decision_spaces do
        switch space.type do
            case "tile_size" do
                ApplyTileSize(space, tokens, program)
            case "unroll" do
                ApplyParallel(space, tokens, program)
            // Additional space types
            case ... do
                ...
    return program
Func ApplyTileSize(space, tokens, program):
    tokens.append("split")
    tokens.extend(Serialize(space.operator))
    tokens.extend(Serialize(space.axis))
    response_tokens = TLM(tokens)
    tiles = ConvertTokensToTiles(response_tokens)
    if not CheckValidTiles(space, tiles) then
        raise Exception("Invalid Tensor Program")
    tokens.extend(Serialize(tiles))
    program.apply(space.operator, space.axis, tiles)
    // Other properties
```

5.2 Tensor Program Generation

The TLM framework utilizes TLM for decision-making during the tensor program generation process, as detailed in Algorithm 2. The steps in Algorithm 2 align with those in Algorithm 1, adhering to the consistency required for generating tensor sentences. After TLM generates a decision, the framework checks its validity within the decision space. If the decision is invalid, the framework discards the tensor program and initiates regeneration. Since the decision is obtained through sampling, the next generation might sample a different decision, preventing continuous failure in regeneration. Fortunately, following pre-training and fine-tuning,



Input

Prompt + Response

Figure 7: Generating a tensor sentence for a matrix multiplication operator with dimensions $m = 1024$, $n = 512$, and $k = 1024$, with the tiling size component depicted therein.

we observe that invalid decisions are exceedingly rare. On average, generating a valid tensor program necessitates no more than 1.1 calls to Algorithm 2.

Figure 7 illustrates the process of *response_tokens* = `TLM`(*tokens*) in Algorithm 2 for a matrix multiplication operator with dimensions $m = 1024$, $n = 512$, and $k = 1024$, with the tiling size component depicted therein. This tensor sentence matches the one at the top of Figure 6 and is presented here (with the operator's index omitted) in a more human-readable format. In Step ①, known information—including input subgraph, hardware specifications, and "split i=1024 to" (corresponds to $m = 1024$) — serves as the input prompt to TLM. TLM then predicts the probability distribution of the next token based on this prompt, subsequently choosing a token, assumably "i.0=32", via probabilistic sampling from the distribution. In Step ②, the prompt and the predicted next token from Step ① are combined to formulate a new input for TLM to forecast the next token. Steps ③ replicates Step ②. After completing the three steps, TLM finalizes tile sizes for the *i*-axis and returns to Algorithm 2. When necessary to generate tile sizes for the *j*-axis, TLM will be invoked again. In Step ④, the input from Step ③, its predicted next token, and "split j=512 to" (corresponding to $n = 512$) are merged into a new input, which is then input into TLM to predict the next token. TLM can but does not employ the input graph and hardware specifications as a prompt to generate all decision information in one go. Instead, the framework repeatedly invokes TLM within Algorithm 2, generating only a subset of decisions each time. This granular approach efficiently filters out invalid data, enhancing TLM availability and stability.

5.3 Iterative Optimization

Fine-tuning TLM-base using demonstration sentences is crucial for its operation. This section focuses on the methods for acquiring a batch of demonstration data.

Throughout acquiring demonstration data, measurement is the most time-consuming step and lies on the critical path, acting as the bottleneck of the process. To address this, we develop a pipeline system that executes the iterative optimization algorithm for collecting demonstration data. This system maximizes the utilization of the measurement hardware by employing two separate processes: one for executing SFT and another for measurement, with the former's execution time controlled to be shorter than the latter, ensuring continuous measurement. When operating on GPUs, these processes operate on separate GPU cards.

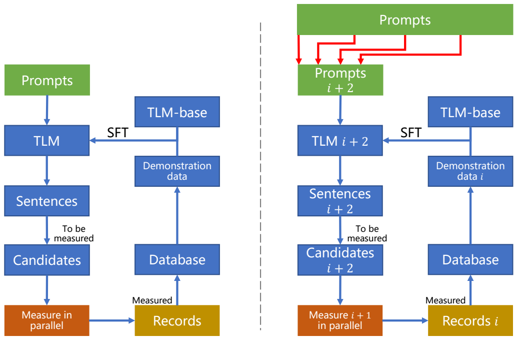

Figure 8: Flowchart of the iterative optimization process.

Figure 8 shows a flowchart of the iterative optimization on the left and a flowchart incorporating a pipeline on the right. We split (the text color matching that in Figure 8) all subgraphs (with each subgraph corresponding to one prompt) in the workload dataset into k_b (e.g., 4) batches and then cyclically select each batch. Upon the completion of the measurement of batch *i* (referred to as records *i*), the optimal batch of data is extracted from the database, noted as demonstration data *i*, and employed to fine-tune TLM-base, yielding TLM $i+2$. Subsequently, TLM $i+2$ is used to produce sentences $i+2$ (one prompt produces k_p (e.g., 16 or 32) sentences). TLM 0 and TLM 1 are replaced by TLM-base.

There are several details worth noting:

- When splitting subgraphs, we **sort them by subgraph type** (e.g., fused_nn_dense_add, fused_nn_conv2d_add_nn_relu, and fused_nn_adaptive_avg_pool2d), selecting one every k_b, based on the rationale that a superior decision often also has a certain optimizing effect on subgraphs of the same type.
- Only when TLM can generate superior tensor sentences can this iterative optimization algorithm operate normally. **So why can TLM generate more optimal data?** From a genetic perspective, when generating a sentence for a subgraph, TLM has already learned the demonstration data corresponding to the current subgraph, as well as demonstration data from other subgraphs, thereby inheriting the advantages of both itself and other subgraphs. When producing the next token for a prompt, probability sampling is used, which, owing to its stochastic nature, provides additional exploration and thus may introduce mutations. The combination of inheritance and mutation may potentially

generate higher quality data, aligning with the design philosophy of genetic algorithms.

- Demonstration refers to low execution latency. The total execution latency of all subgraphs can be expressed as $latency_{\text{total}} = \sum_{s_i \in \text{subgraphs}} \min(\text{all record latencies of } s_i)$. The latency of the demonstration data will not rise since it always selects the best from all measurements, so it decreases monotonically. Furthermore, the best latency of the demonstration data cannot be lower than its physical limit, so it is bounded. **Mathematically speaking, a monotonic and bounded limit results in convergence.** Section 6.2 of the evaluation discusses how much data needs to be measured for convergence.
- TLM is designed to assist in making decisions within a decision space, trained by a gradient descent strategy. TLM i may perform worse than TLM $i-1$ because gradient descent does not guarantee that TLM can always be trained to its optimal state. However, since TLM i is always trained from TLM-base, it remains unaffected by TLM $i-1$ and does not influence TLM $i+1$. Hence, **TLM i does not likely exhibit cumulative errors**, and the final TLM is only related to TLM-base and the final demonstration data.
- The demonstration data in Figure 8 is obtained through iterative optimization from scratch. Similarly, **there are also other methods to obtain a batch of demonstration data**. For instance, it can be obtained using other search algorithms; if there is a batch of demonstration data on Hardware A, it can be transferred to Hardware B through transfer learning; the data can be directly written using expert knowledge. The good news is that this demonstration data can still continue to use iterative optimization algorithms until convergence.
- **The iterative optimization algorithm can also be viewed as a tuning system, particularly suitable for situations where multiple workloads need to be tuned at once.** For instance, in dynamic shape scenarios, the target workload with different shapes need to be tuned simultaneously.

6 Evaluation

6.1 Experimental Settings

TLM supports several decision spaces, including those adapted from Ansor (V0.12), MetaSchedule (V0.12), AKG (V2.1), and AKG-MLIR (V0.1). In subsequent sections, these TLMs are referred to as TLM-Ansor, TLM-Meta, TLM-AKG, and TLM-AKG-MLIR. In the evaluation, we focus only on TLM-Ansor and TLM-Meta, which together are implemented in Python and C++ with about 10K lines of code.

The dataset we configured for TLM consists of 138 workloads. We hold out a test set that consists of 12 workloads, as shown in Table 1.

For the CPU experiments, we use a notebook equipped with a 4-core Intel(R) Core(TM) i7-10510U CPU supporting the AVX2 instruction set, 16GB memory, and running on Ubuntu 20.04. For the GPU experiments, we utilize a server outfitted with a 48-core Intel(R) Xeon(R) Gold 6226 CPU, 376GB memory, and four 32GB NVIDIA Tesla V100 GPUs. It runs on Ubuntu 20.04 with CUDA 11.6 and cuDNN 8.4.0.

Table 1: Workloads in the TLM test set.

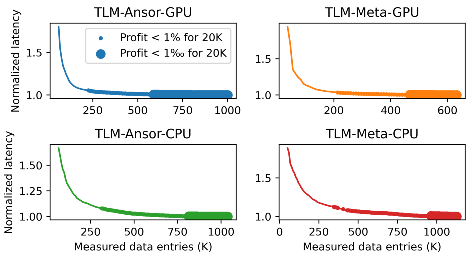

Figure 9: Demonstration data convergence curves of TLM-Ansor and TLM-Meta on the GPU and the CPU.

6.2 Convergence Behavior of Demonstration Data

This section discusses the convergence behavior of obtaining demonstration data through the iterative algorithm, which is the slowest phase of the entire pipeline. Figure 9 displays four curves corresponding to the convergence of TLM-Ansor and TLM-Meta on both the GPU and the CPU, respectively labeled as TLM-Ansor-GPU, TLM-Meta-GPU, TLM-Ansor-CPU, and TLM-Meta-CPU. These four scenarios utilize 2169, 3120, 2169, and 2657 subgraphs (extracted from 126 workloads). The horizontal axis denotes measured data entries (across all subgraphs), while the vertical axis indicates normalized total latency. We define "convergence" as the point at which 20K measurements (across all subgraphs) result in a performance improvement of less than one percent, denoted in the graph as "Profit < 1% for 20K." We also mark the instance where 20K measurements (across all subgraphs) yield a performance gain of less than one per thousand, corresponding to "Profit < 1‰ for 20K".

To reach the convergence state, an average of 104, 69, 145, and 130 measurements per subgraph are required, corresponding to overall totals of 225K, 213K, 314K, and 344K measurements, respectively, for all subgraphs. In other words, inducing convergence across all 126 workloads utilizing TLM calls for approximately 200K tensor program measurements on the GPU and about 300K on the CPU. TLM involves a data volume an order of magnitude smaller compared to TenSet and TLP, which utilize approximately 8.6 million measurements. Furthermore, for a performance gain of less than 1‰, individ-

Table 2: The overall speedup for the 23 TLM-Ansor subgraphs. The higher the overall speedup, the better. In the table, "Times" represents the measurement times for each subgraph.

		Ansor			TLM-Ansor
	Times	64	1K	10K	10K
TLM-Ansor	1	1.26	0.98	0.92	0.85
	10	1.40	1.08	1.03	0.95
	16	1.43	1.10	1.04	0.96
	32	1.45	1.12	1.06	0.98
	64	1.45	1.12	1.06	0.98
	1K	1.46	1.13	1.07	0.99
	10K	1.48	1.14	1.08	1.00
Ansor	10K	1.37	1.06	1.00	0.92

Table 3: The overall speedup for the 40 TLM-Meta subgraphs.

		MetaSchedule			TLM-Meta
	Times	64	1K	10K	1K
TLM-Meta	1	1.00	0.69	0.68	0.67
	10	1.41	0.96	0.95	0.94
	16	1.45	1.00	0.99	0.97
	32	1.46	1.01	1.00	0.97
	64	1.49	1.02	1.01	0.99
	1K	1.50	1.02	1.01	1.00
MetaSchedule	10K	1.48	1.01	1.00	0.99

ual subgraphs require 272, 150, 375, and 363 measurements each, which also translates to a cumulative total of 588K, 467K, 813K, and 963K measurements for all subgraphs. The TLM used in the experiments of the subsequent sections has been fine-tuned using about 300K labelled data.

6.3 Subgraph Benchmark

After SFT, we conduct subgraph experiments on the NVIDIA V100. The TLM test set comprises 12 workloads, yielding 232 and 364 subgraphs for TLM-Ansor and TLM-Meta, respectively. These subgraphs fall into 23 and 40 categories, and we select one representative subgraph from each category for the experiments. Two comparisons are established: TLM-Ansor vs. Ansor and TLM-Meta vs. MetaSchedule, with measurement times set at 10K, 10K, 1K, and 10K for each subgraph, respectively. The latency of a subgraph is defined as the lowest value among its measurements. The latency comparison curves are presented in Figures 14 and 15 in the Appendix B, while here, we focus on critical data highlights in Tables 2 and 3.

We define Framework$_k$ as follows:

$$\text{Framework}_k = \sum_{s_i \in \text{subgraphs}} \min\left(\begin{array}{c} \text{Framework's } k \\ \text{record latencies of } s_i \end{array} \right),$$

where Framework can be TLM-Ansor, TLM-Meta, Ansor, or MetaSchedule, and k represents the measurement times. Each speedup in Table 2 represents the overall speedup for the 23 subgraphs of Framework1$_{k_1}$ in the first two columns compard to Framework2$_{k_2}$ in the first two rows. Table 3 is similar to Table 2.

In Tables 2 and 3, TLM-Ansor$_{1K}$ achieves 99% (the text color matching that in the tables) of the performance of TLM-Ansor$_{10K}$, while TLM-Meta$_{64}$ attains 99% of the performance of TLM-Meta$_{1K}$. Furthermore, MetaSchedule$_{10K}$ shows a speedup of 1.01× compared to MetaSchedule$_{1K}$. We observe that a tenfold increase in the number of measurements results in a performance gain of no more than one percent. Achieving further acceleration in the **current** exploration space is challenging, and a better approach to gain additional speedup is to explore a larger space.

The primary goal of the TLM framework is to generate high-performance tensor programs efficiently. Notably, even with 10 measurements, TLM can achieve 103% and 95% of the performance of Ansor and MetaSchedule after 10K measurements, respectively. Additionally, TLM-Ansor$_{32}$ achieves a 1.06× speedup over Ansor$_{10K}$, while TLM-Meta$_{32}$ reaches a 1.00× speedup compared to MetaSchedule$_{10K}$. It is evident that TLM's performance, with 32 measurements, has already exceeded that of both Ansor and MetaSchedule.

TLM-Ansor$_{1K}$ achieves a 1.13× speedup over Ansor$_{1K}$, TLM-Ansor$_{10K}$ reaches a 1.08× speedup compared to Ansor$_{10K}$, and TLM-Meta$_{1K}$ attains a 1.02× speedup over MetaSchedule$_{1K}$. These ratios demonstrate that TLM consistently achieves acceleration relative to Ansor and MetaSchedule with equal measurement times. To attain a higher acceleration ratio, building a larger exploration space might be necessary.

6.4 End-to-End Workload Benchmark

6.4.1 Comparison with Ansor/MetaSchedule

For both GPU and CPU, we set up four experiments: 1) Tuning with Ansor (V0.12) and conducting 20K measurements; 2) Tuning with MetaSchedule (V0.12) and conducting 20K measurements; 3) Generating tensor programs using TLM-Ansor, carrying out 20K measurements, and reporting end-to-end performance for $1 \times g$, $10 \times g$, and $32 \times g$ measurements, where g indicates the number of subgraphs partitioned from the test workload[1]; 4) Generating tensor programs using TLM-Meta, with the same settings as in 3.

GPU results. Initially focusing on the last four columns of each workload in Figure 10, TLM-Ansor-20K shows a speedup of 0.99-1.38× compared to Ansor-20K across 12 test workloads, with the average speedup being 1.08. Similarly, TLM-Meta-20K achieves a speedup of 0.98-1.14× relative to MetaSchedule-20K, with the average speedup being 1.04. These results align with those from the subgraph benchmark, indicating that TLM offers acceleration over Ansor/MetaSchedule.

The primary goal of the TLM framework is to efficiently generate high-performance tensor programs. We now turn our attention to the first six columns in Figure 10. For Ansor-20K,

[1] For instance, TLM-Ansor can partition 9 subgraphs from BERT-base; thus, $1 \times g$ represents 9 measurements, $10 \times g$ represents 90, and $32 \times g$ represents 288.

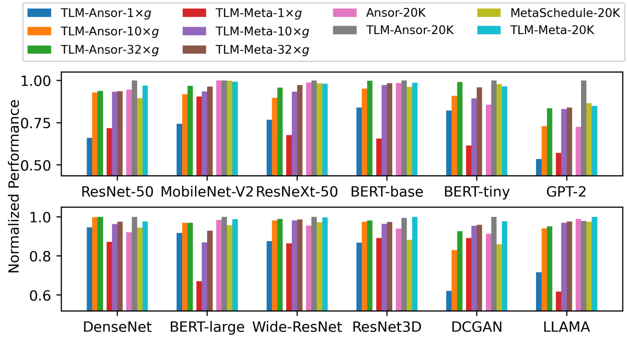

Figure 10: Workload inference performance comparison with Ansor/MetaSchedule on V100.

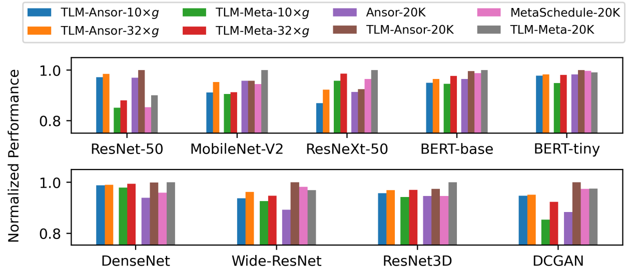

Figure 11: Workload inference performance comparison with Ansor/MetaSchedule on the Intel CPU.

TLM-Ansor-1×g achieves a 0.68-1.03 speedup, with an average speedup of 0.83; TLM-Ansor-10×g offers a 0.91-1.08 speedup, averaging at 0.99; and TLM-Ansor-32×g speeds up by 0.96-1.16, with an average speedup of 1.03. Regarding MetaSchedule-20K, TLM-Meta-1×g can accelerate by 0.63-1.04, with an average speedup of 0.80; TLM-Meta-10×g achieves a 0.91-1.11 speedup, averaging at 1.00; and TLM-Meta-32×g offers a 0.96-1.12 speedup, with an average speedup of 1.02.

To summarize, TLM can reach 80% of Ansor/MetaSchedule's performance by conducting only 1×g measurements, as opposed to the 20K measurements required by Ansor/MetaSchedule. With 10×g measurements, TLM's performance aligns with that of Ansor/MetaSchedule. Notably, the purpose of measurement is to identify the tensor program with the lowest execution latency. The fact that only one measurement is needed implies no necessity for measurement, indicating that TLM can reach 83% of Ansor/MetaSchedule's performance without any measurement. This indicates the feasibility of applying the TLM strategy within deep learning training frameworks (e.g., PyTorch, TensorFlow, MindSpore [41]).

CPU results. The CPU results (excluding BERT-large, GPT-2, and LLAMA, which will trigger the OOM error), depicted in Figure 11, align with the GPU outcomes. Here, we simply present the average speedup. Relative to Ansor-20K, TLM-Ansor-10×g achieves a 1.01× speedup, while TLM-Ansor-32×g accomplishes a 1.03× speedup. Compared to MetaSchedule-20K, TLM-Meta-10×g attains a 0.97× speedup, and TLM-Meta-32×g achieves a 1.00× speedup.

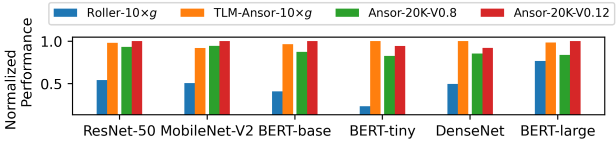

Figure 12: Workload inference performance comparison with Roller on V100.

Compilation time. This paper uses the measurement times to calculate the speedup of compilation time, the justification for which is discussed in the Appendix A. Simply put, the time allocated to measurement predominates the entire compilation time and remains unaffected by the system's load, establishing it as a stable metric for the issue.

In the TLM-Ansor test set, the 12 workloads comprise 5-72 subgraphs, averaging 20.9 subgraphs. As a result, TLM-Ansor-10×g, compared to Ansor-20K, can deliver the same performance level while accelerating compilation by 95×. Similarly, TLM-Meta-10×g can speed up compilation by 61× relative to MetaSchedule-20K.

Summary. In subgraph and end-to-end benchmarks, we primarily analyze from a statistical perspective rather than investigating why certain subgraphs or workloads surpass the baseline. This is due to the inherent randomness of the probabilistic/random sampling, which results in a lack of clear patterns in speedup. What becomes apparent, however, is that across nearly all subgraphs and workloads, TLM matches the baseline results with significantly fewer measurements. This indicates a general improvement in exploration capabilities.

6.4.2 Comparison with Roller on V100

Roller is implemented on top of TVM (V0.8) and Rammer [42]. We utilize the Docker image provided by Roller for experiments, which runs on Ubuntu 16.04 with CUDA 10.2 and cuDNN 7.6.5; it lacks maintenance to utilize the latest CUDA. To observe the impact of software versions on performance, we present the performance of Ansor, integrated within TVM (V0.8), as a bridge for comparing TLM and Roller; the performance of Ansor is measured in the same execution environment as Roller. Compiling workloads with Roller requires carefully configured, workload-specific script files; we offer script files for six workloads.

We set up four experiments: 1) Compiling with Roller and performing 10×g measurements; 2) Adopting TLM-Ansor-10×g from §6.4.1; 3) Tuning with Ansor (V0.8) and executing 20K measurements; 4) Adopting Ansor-20K from §6.4.1, designated as Ansor-20K-V0.12.

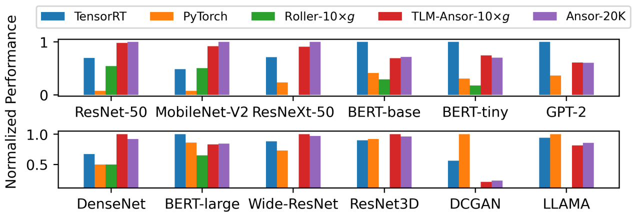

Figure 13: Workload inference performance comparison with TensorRT/PyTorch on V100.

Figure 12 illustrates that in the same execution environment, Ansor-20K-V0.8 outperforms Roller-10$\times g$. Additionally, TLM-Ansor-10$\times g$ and Ansor-20K-V0.12 have comparable performance levels, slightly better than Ansor-20K-V0.8. Therefore, it is evident that TLM-10$\times g$ surpasses Roller-10$\times g$ when the influence of software versions is excluded. In a direct comparison, TLM-Ansor-10$\times g$ achieves a speedup of 1.28-4.23× compared to Roller-10$\times g$, with the average speedup being 2.25. The reason is that, in pursuit of high efficiency, Roller significantly prunes the exploration space by aligning tensor shapes with the key features of the hardware, as discussed earlier.

6.4.3 Comparison with TensorRT/PyTorch on V100

In this section, we conduct a performance comparison against TensorRT [43] (V8.6) and PyTorch (V1.13.1) on V100. Both TensorRT and PyTorch are backed by static kernel libraries.

We set up five experiments: 1, 2) Performing inference using TensorRT and PyTorch; 3) Adopting Roller-10$\times g$ from §6.4.2; 4, 5) Adopting TLM-Ansor-10$\times g$ and Ansor-20K from §6.4.1.

Figure 13 illustrates that relative to TensorRT, TLM-Anosr-10$\times g$ achieves a 0.38-1.89× speedup, averaging at 1.04; compared to PyTorch, TLM-Anosr-10$\times g$ sees a 0.21-12.92× increase in performance, with an average speedup of 3.42. TensorRT outperforms TLM-Anosr-10$\times g$ in BERT-tiny, BERT-base, BERT-large, GPT-2, LLAMA, and DCGAN workloads, while PyTorch excels over TLM-Anosr-10$\times g$ in BERT-large, LLAMA, and DCGAN. The primary components of BERT and LLAMA are batch matmul operators, GPT-2 mainly involves matmul operators, and DCGAN primarily uses transposed 2D convolution operators. The speedup achieved by TensorRT/PyTorch is attributed to the deep optimization of batch matmul, matmul, and transposed 2D convolution operators in recent kernel libraries, as well as the utilization of hardware computing units. Overall, tensor compilers excel in supporting a wide range of operators, while static kernel libraries are more adept at deeply optimizing commonly used operators.

7 Related Work

Halide [44] introduces the concept of separating compute and schedule, employing a domain specific language (DSL) to define computations and scheduling primitives to abstract hardware characteristics, enhanced by an auto scheduler [4,45,46] for optimal primitive combination. TVM [3], inheriting the philosophy of Halide, utilizes scheduling primitives for operator implementation. It currently boasts three generations of tensor program search frameworks: The first generation maps subgraphs to tensor programs using templates and optimizes them through AutoTVM [12]. The second generation, Ansor [13], addresses the limitations of template-based exploration spaces by constructing tensor programs with derivation rules and searching for efficient programs using the genetic algorithm. The third generation, which includes TensorIR [47] and MetaSchedule [14], tackles the challenges of supporting TensorCore, introducing a block abstraction that isolates tensorized computations for mapping to tensor computing units. TenSet [20] and TLP [21] propose using offline datasets to address the issue of extended search times brought by Ansor/MetaSchedule. Roller [23] introduces a tile abstraction that encapsulates tensor shapes, aligning them with the key features of the underlying accelerator to limit shape choices. FlexTensor [6] is a schedule exploration and optimization framework proposing automatically general templates to map the tensor algorithms onto low-level implementations for different hardware platforms.

Tiramisu [48], AKG [15], and Tensor Comprehensions [5] apply polyhedral-based techniques, formulating the optimization of programs as an Integer Linear Programming (ILP) problem. Triton [49] introduces a tile-based template representation where programmers can specify block sizes and manage their scheduling for effective program optimization. CUTLASS [50] is a collection of template abstractions for implementing high-performance matrix-matrix multiplication and related computations within CUDA at all levels and scales. MLIR [51] builds reusable and extensible compiler infrastructure to address software fragmentation and improve compilation for heterogeneous hardware.

8 Discussion

Limitation. 1) At its core, TLM is a deep learning model that leverages offline data to guide exploration. The data distributions of the target and training scenarios need to be aligned. To achieve optimal performance in scenarios with significant discrepancy, it might be necessary to incorporate additional training data. 2) TLM's design philosophy is trading compile time for pre-compile time. The overhead of training TLM, which could span tens of hours, should not be overlooked. If the intent is solely to compile one or just a handful of models, TLM might not be the most economical choice. Instead, TLM is better suited for compiling a vast array of models.

Future Work. 1) With 100M parameters, TLM's time and hardware overhead for training and inference should be noticed. It may be worthwhile to explore substantial reductions in parameter size while ensuring TLM's performance remains robust. 2) In contrast, with just 100M parameters, there is an opportunity to substantially expand TLM's parameter size and the training data. These improvements could lead to remarkable generalization capabilities. Examples include compiling directly from TLM-generated results without measurement or achieving strong generalization across various hardware platforms. 3) Delve into a more expansive exploration space. Equipped with TLM's potent exploration capabilities, it's feasible to navigate vast territories without being constrained by exploration costs.

9 Conclusion

We introduce the TLM framework, a novel tensor program generation framework that consists of two decoupled components: a space builder and a generator. The TLM framework is pioneering in its integration of language models into the tensor program domain. Owing to TLM's dual strengths of adeptly learning from offline data and effectively capturing context, it demonstrates formidable generative capabilities. Experimental results show that TLM consistently delivers both high efficiency and high performance.

A Compilation Speedup Metrics

In this section, we discuss the rationality of using measurement times to calculate the speedup of compilation time.

$$
\begin{aligned}
T_{total} &= T_{exploration} + T_{post\ exploration\ compilation} \\
&= \sum_k \left(c \times T_{sample} + T_{measurement}\right) \\
&\quad + T_{post\ exploration\ compilation} \\
&= \sum_k \left(c \times T_{sample} + (T_{compilation} + T_{execution})\right) \\
&\quad + T_{post\ exploration\ compilation}
\end{aligned}
$$

The total time for compiling a workload (T_{total}), as indicated in the formula above, consists of two main components: the time spent exploration to identify high-performance tensor programs ($T_{exploration}$), and the time for the final compilation of the workload ($T_{post\ exploration\ compilation}$). The exploration process involves sampling c tensor programs ($c \times T_{sample}$) and then measuring the execution latency of one of these programs ($T_{measurement}$). In Ansor/MetaSchedule, the purpose of sampling multiple tensor programs is to use a cost model to select the most promising tensor program; if a program sampled by TLM is found to be invalid, it will be resampled. The sampling coefficients c_{Ansor} and $c_{MetaSchedule}$ are approximately 128, while c_{TLM} does not exceed 1.1. Measuring a tensor program includes both its compilation ($T_{compilation}$) and execution ($T_{exection}$).

$$
\begin{aligned}
T_{total} &= T_{exploration} + T_{post\ exploration\ compilation} \\
&\approx T_{exploration} \quad \text{if } k \geq k_0 \\
&= \sum_k \left(c \times T_{sample} + T_{measurement}\right) \\
&= \sum_k T_{measurement} \quad \text{if } T_{measurement} \text{ hides } c \times T_{sample} \\
&= \sum_k \left(T_{compilation} + T_{execution}\right)
\end{aligned}
$$

When measurement times k exceeds a certain threshold k_0 (e.g., 100), $T_{exploration}$ becomes the dominant factor in T_{total}, making $T_{post\ exploration\ compilation}$ negligible. Sampling and measurement processes can be optimized using a pipeline approach for parallel execution. Overall, measurement is a critical part of the entire compilation process, and reducing measurement times requires methodological innovation rather than just engineering efforts.

TLP uses the speedup on T_{total} to calculate the acceleration of compilation time, while Roller uses $\sum_k T_{compilation}$ to calculate the acceleration of compilation time. Although they indeed reflect the speedup of compilation time to some extent, these metrics are unstable due to the influence of system load. In this paper, we use measurement times k to calculate the speedup of compilation time.

B Subgraph Performance

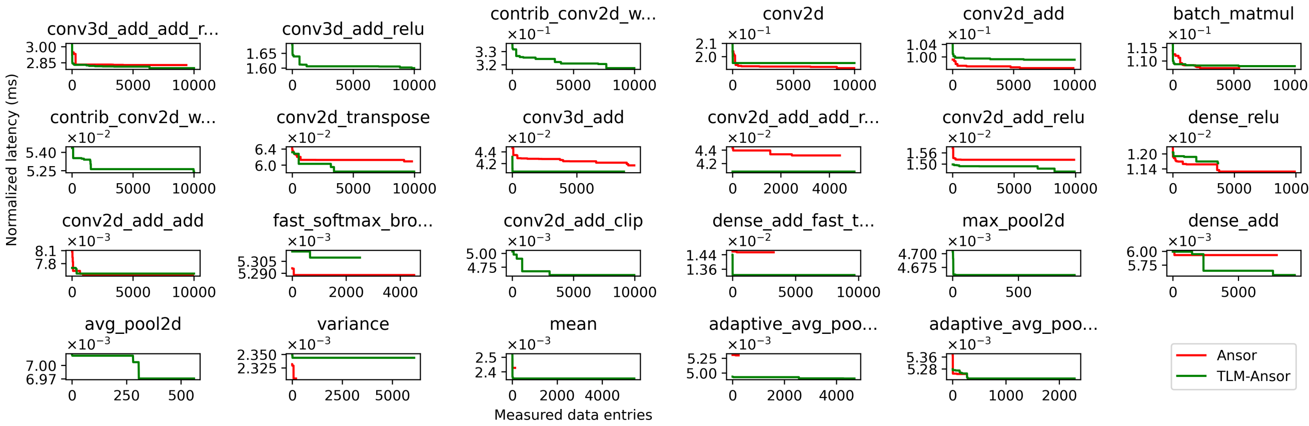

Figure 14: Subgraph latency comparison curves for TLM-Ansor vs. Ansor. To enhance the comparison of subtle details, the curve only includes latencies that do not exceed 1.1 times the lowest latency of either TLM-Ansor or Ansor. In the figure, if one is not visible throughout, it indicates that its lowest latency exceeds that of the other by 10%.

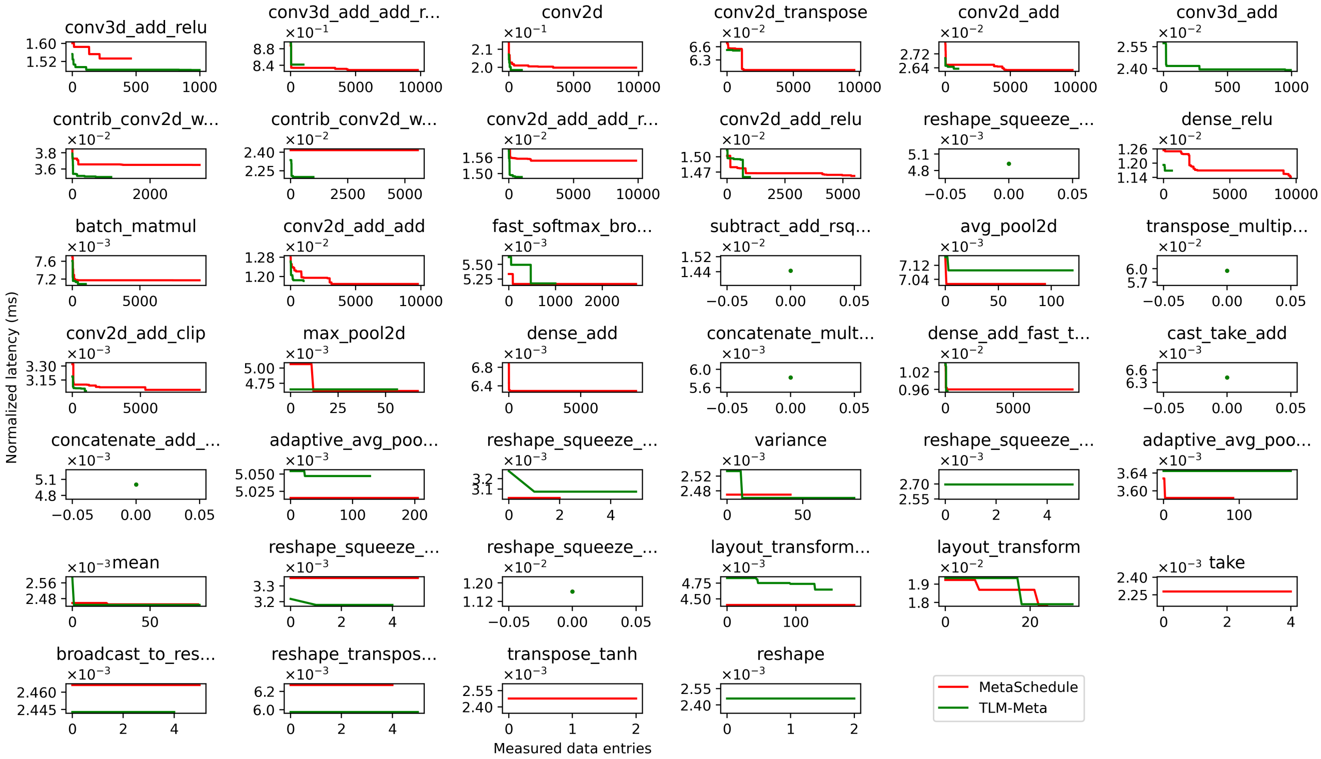

Figure 15: Subgraph latency comparison curves for TLM-Meta vs. MetaSchedule. To enhance the comparison of subtle details, the curve only includes latencies that do not exceed 1.1 times the lowest latency of either TLM-Meta or MetaSchedule. In the figure, if one is not visible throughout, it indicates that its lowest latency exceeds that of the other by 10%.

Abstract

The increasing demand for improving deep learning model performance has led to a paradigm shift in supporting low-precision computation to harness the robustness of deep learning to errors. Despite the emergence of new low-precision data types and optimization approaches, existing hardware and software have insufficient and inefficient support for those evolving data types, making it challenging to achieve real performance gains through low-precision computing.

This paper introduces LADDER, a novel compiler designed to bridge the gap between evolving custom data types and the fixed precision formats supported by current hardware. Leveraging a general type system, *t*Type, and an extended tensor expression, LADDER transforms deep neural network (DNN) computations into optimized computing pipelines with custom data types as the first-class citizen, exposing an optimization space for efficiently handling data storage, accesses, and type conversions. LADDER employs a new set of tensor scheduling primitives and a hardware-aware optimization policy to navigate the complex transformation space, ensuring optimal performance across different memory layers and DNN operators. Our evaluation demonstrates LADDER's capability to systematically support a wide array of low-bit precision custom data types, significantly enhancing the performance of DNN computations on modern accelerators without necessitating hardware modifications. This innovation empowers model designers with the ability to explore data type optimizations and offers hardware vendors a flexible solution to expand their support for diverse precision formats.

1 Introduction

Building on the recent advancements in scaling up deep learning models [11, 17, 26], there's a growing demand for more powerful computing performance in hardware accelerators like GPUs. The inherent robustness of deep learning to errors enables the use of lower precision arithmetic, setting it apart from traditional workload like scientific computing, which necessitate high precision like float64. In line with this trend, cutting-edge accelerators are increasingly integrating more low-precision computational units, such as 32-bit, 16-bit, and even 8-bit floating-point operations, into their new generations. At the same time, model developers are vigorously investigating various custom low-precision data types, such as mixed precision formats, to strike an optimal balance between model accuracy and training efficiency. Moreover, during the model deployment phase, computations can be converted to even more compact data representations to achieve extreme efficiency, such as 2 bits fixed-point precision in LLM [12] or group-based types where multiple values share the same scaling factor [41].

However, hardware accelerators are challenging in keeping pace with the diverse and rapidly evolving requirements for supporting various data precision formats, i.e., custom data types. This difficulty arises because each accelerator can only integrate a few types of computing units for standard data types, given the limited chip area and high hardware cost. Even for those recently supported low-precision data types, such as those under 16 bits in width, existing software is generally inefficient due to the complexity of aligning fine-grained low-bit data access with the coarse-grained memory system. For instance, NVIDIA GPU's shared memory bank size is 4 bytes in width, and simply loading or storing 8-bit data elements can easily lead to bandwidth waste. This often necessitates non-trivial optimizations, such as packing multiple data values together to align with the features of different memory hierarchies. Consequently, optimizing kernel libraries for all these new data types, combined with different operators and shapes, becomes a challenging task. For instance, the highly-optimized cutlass library for NVIDIA GPUs only achieves 422 tflops (68% utilization) on INT8 matrix multiplication. The inadequacy and inefficiency in supporting these new custom data types significantly hinder the innovation for both models and accelerators.

To address these challenges, we make the following observations: First, despite hardware accelerators lacking comput-

[*] Work is done during the internship at Microsoft Research.

ing instructions for those custom data types, their memory system can be utilized to store arbitrary data types by casting them into an opaque data chunk with a fixed bit width. Second, most custom data type can be losslessly converted to a wider-bits standard data type supported by the computing units in existing hardware. For example, NF4 tensors can be computed with an FP16 or FP32 operation by converting their data types. These observations inspire us a general approach to support all custom data types by separating data storage and computation. That is, store and transmit tensors in custom data types and compute in standard data types through type conversion. Given that modern DNN models tend to be memory-intensive and the latest hardware faces the memory wall issue [43], such an approach is increasingly critical as it can effectively exploit the performance benefits of low-bits data types by saving memory traffic and footprint.

However, efficiently supporting such computing pipeline for general custom data types on existing accelerators is non-trivial. A typical tensor computation pipeline involves loading data from multiple layers of memory hierarchy, such as DRAM, L2 cache, shared memory, register, etc. First, converting tensor data types in different layers could significantly impact the performance factors like memory footprint, data access traffic, hardware cost, etc., which is complex to optimize. For example, converting a low-bit data chunk to a higher-bit type in a register could lead to register spill, causing a dramatic performance drop. Second, pipelines involving different data types usually require different data layout optimization to align with memory system, e.g., align with memory bank, to maximize the data access throughput. Existing optimizations like swizzling memory accesses [6] are mostly designed for a few specific data types, which is hard to be generalized.

To address these challenges, we present LADDER, a compiler for efficient deep learning computation on general custom data types. To facilitate the implementation of quickly-evolving custom data types, such as block-wise data types like MXFP, LADDER first introduces a general type system called *t*Type. *t*Type is inherently a tile-wise data type, which can define all common custom types by explicitly specifying type width, element shape, and the type-converting functions. Based on *t*Type, LADDER extends the existing tensor expression, used to express a DNN operator, to natively support annotating *t*Type for each tensor. This way, LADDER can systematically translate a DNN computation with custom data types into a standard computation pipeline.

To optimize the computation pipeline involving custom data storage, access, and type conversions, we observe that tensor storage and access in a pipeline can be transformed into various logically equivalent formats, each with dramatically different performance impacts. For instance, a sub-tensor can be stored in row-major, column-major, block-wise, or even custom-defined layouts, padded to a certain shape to match computing instructions, and accessed in different granularities (e.g., different tile shapes) by the upper-layer memory. All these factors significantly affect overall performance. To facilitate such transformations, LADDER introduces a set of tensor scheduling primitives, including *slice*, *map*, *pad*, and *convert*, that can be used to transform a default computing pipeline into optimized ones.

Deriving optimal tensor transformations for a specific computing pipeline requires holistic consideration of inter-memory layer and inter-operator optimizations. For example, a specific data layout can be propagated to adjacent operators to avoid explicit layout conversation costs. Moreover, the data layout in a specific memory layer needs to consider both the memory feature and upper-layer access pattern. Both cross-layer or cross-operator optimizations form a vast optimization space. LADDER optimizes such transformation space through a layer-wise hardware-aware optimization policy: a lower-layer memory provides the preferred data access granularity as a hint, and the upper layer decides the optimal compute granularity by aligning with the data access granularity. Thus, LADDER first models a DNN computation into a tile-level data flow graph and then optimizes the transformation scheduling using a granularity-aware scheduling policy.

LADDER is implemented on top of TVM [13], Roller [57] and Welder [43]. We have open-sourced LADDER [1]. Furthermore, the DNN operation compilation in LADDER has also been released as BitBLAS [2], a library that can be integrated into existing DNN and LLM frameworks to empower efficient low-precision computing in existing deep learning ecosystem. Our evaluation of DNN inference on NVIDIA A100, NVIDIA V100, NVIDIA RTX A6000 and AMD Instinct MI250 GPUs shows that LADDER outperforms state-of-the-art DNN compilers on native-supported data types, while efficiently supports custom data types that GPUs do not support with up to 14.6× speedup. As a result, LADDER is the first system to systematically support general low-bit precision represented by custom data types for DNN computation on modern hardware accelerators. It opens the door for both model designers to explore more flexible data type optimization with real performance feedback and hardware vendors to support a large range of types without hardware modification.

2 Background and Motivation

2.1 Precision Requirements in Deep Learning

The increasing demand to scale deep learning models to larger sizes, such as Large Language Models (LLM), enhances the requirement of computing in lower bits and mixed precision to increase computation efficiency and save memory. This section introduces some new data type requirements in deep learning.

[1] https://github.com/microsoft/BitBLAS/tree/osdi24_ladder_artifact

[2] https://github.com/microsoft/BitBLAS

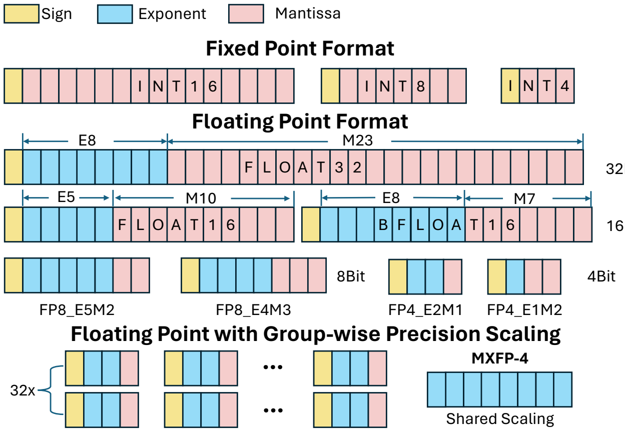

Figure 1: Diverse narrow-precision data types in deep learning training and inference.

Lower-bit numeric precision. FP32 (32-bit float) has been the go-to choice for data representation in deep learning models. However, recent practices suggest that the high precision of FP32 isn't always necessary. Lower precision can deliver the same level of effectiveness while simultaneously reducing costs. A pivotal example of this precision shift is the FP16/BF16 computation in Automatic Mixed Precision (AMP) training [36]. More aggressively, systems like *Transformer Engine* [37] and *MS-AMP* [39] have begun to employ FP8 for weight, gradient, and even optimizer tensors, pushing the boundaries of precision reduction in deep learning. During inference, models are frequently quantized to significantly lower precision, typically down to 8 or 4 bits [14,22,48]. Contemporary cutting-edge research is challenging these limits further, aiming to decrease weight quantization to a remarkable 2 or even 1 bit [12, 46]. This is primarily due to the redundancy inherent in pretrained weights and the fact that computations are mostly forward passes. Figure 1 highlights various data formats used in deep learning models, marking the notable shift from high-precision formats to low-bit alternatives.

Group-wise precision scaling. To improve the accuracy and robustness of low-precision deep learning models, a common approach is to use a scaling factor to rescale the values for a more accurate representation of the data distribution. Traditional methods typically employ a tensor-wise or channel-wise scaling factor. However, group-wise scaling, by virtue of its finer granularity, can better capture the distribution of sub-tensors or groups, leading to improved performance. For instance, in Post-training Quantization (PTQ) [22], group sizes of 128 and 64 are typically preferred, with each group scaled using FP16. In OCP-MXFP [41], an 8-bit shared scale is applied to a group of 32 elements.

Mixed-precision operations. Mixed-precision operations emerge in data quantization due to the varying sensitivity of different tensors to lower bit quantization. For example, mixed-precision training employs a combination of higher and lower bit tensors, such as FP32, FP16, and FP8. This strategic utilization of precision levels strikes a balance between computational efficiency and precision, thereby optimizing performance. Similarly, in Large Language Model (LLM) quantization, weights that are more receptive to quantization can be represented using lower bits. On the other hand, activations, which pose more substantial quantization challenges, require higher bit representations. This divergence leads to mixed-precision operations, including W4A16 (i.e., weight values are represented in 4-bit data types, and activations are represented in 16-bit data types), W2A16, W1A8, and others [12,22,46].

Data Type	$W_{FP16}A_{FP16}$			$W_{INT8}A_{INT8}$			$W_{FP8}A_{FP8}$	$W_{NF4}A_{FP16}$
GPU	V100	A100	MI250	V100	A100	MI250	V100/A100/MI250	
cuBLAS	78%	87%	X	X	68%	X	X	X
rocBLAS	X	X	46%	X	X	75%	X	X

Roller	50%	70%	29%	X	X	X	X	X

Table 1: MatMul [M,N]=[M,K]x[N,K] where M,N,K=16384. "X" indicates not supported in tensor core or matrix core.

2.2 Insufficient Precision Supports in GPUs

Hardware accelerators like GPUs are constantly adapting to the evolving data type requirements in deep learning. Early generations of GPUs, such as NVIDIA's Fermi, supported standard data types like FP32 and FP64. As deep learning workloads gained relevance, lower precision formats like FP16 were introduced in the Pascal architecture. The Turing architecture further expanded support by introducing INT4 and INT8 for inference workloads. The Ampere architecture later introduced BF16, striking a balance between performance benefits and numerical range for machine learning applications. The latest architecture, NVIDIA's Hopper, extends this trend by supporting FP8, showcasing the ongoing pursuit of efficiency by adjusting the precision-performance trade-off. This evolution highlights the increasing versatility of GPUs in handling diverse computing workloads.

However, hardware typically lags behind the requirements of algorithms or models. When encountering unsupported data types, we must convert or simulate them in higher-precision supported data types. This could lead to significant performance issues and inefficiencies.

2.3 Inefficiency of Low-precision Computing

Low-precision computing is particularly challenging to optimize due to the fine-grained data access granularity and special hardware units, such as TensorCore. We tested the performance of a standard matrix multiplication benchmark with different precisions, using the latest software libraries and compilers on three of the latest GPUs: NVIDIA V100 and A100, and AMD MI250, as shown in Table 1. We make the following observations. First, the hardware utilization of low-precision computing is generally low, i.e., less than 60% on

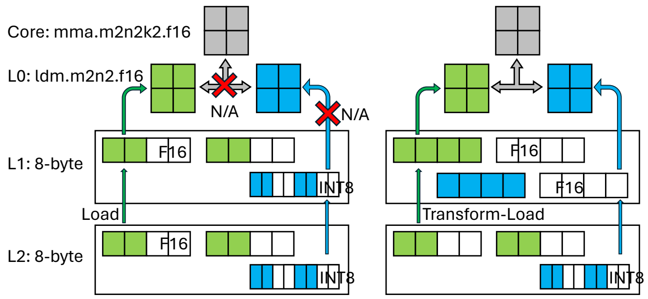

Figure 2: MatMul: $C_{FP16}[2,2]=A_{FP16}[2,4]\times B_{INT8}[2,4]$

average. Even for the most dominant precision in today's deep learning workload, like FP16, the average utilization is around 60%. Second, some hardware-supported precisions are not well supported by the software. For example, while INT8 is supported in both A100 and MI250, most existing deep learning compilers do not support INT8 computing on these GPUs. Third, meeting new precision requirements is challenging for hardware to support in a timely manner. For instance, FP8 is only available in the next generation of NVIDIA Hopper architectures. Mixed precision computing, such as F16 × NF4, is not supported by all the latest GPUs.

2.4 Our Insights

We use mixed-precision matrix multiplication, specifically FP16×INT8, as an example to illustrate our key insights, as shown in Figure 2. A DNN operation is often implemented as a computing pipeline, which continuously loads small data tiles from input tensors across multiple layers of memory hierarchy to compute in the top-level cores. Each memory layer usually has its preferred minimum access granularity, such as an 8-byte transaction length in the L1 layer. Some of the latest GPUs even introduce built-in instructions for highly efficient data loading, which load a two-dimensional data tile at a time—for instance, the *ldmatrix.2x2.f16* loads a 2x2 tile. Given that a data tile is typically stored in a strided memory space, data access often becomes unaligned with the transaction length or instruction shape, potentially leading to low bandwidth utilization. For example, the left figure illustrates that each memory access from L1 only achieves half utilization for both tensors. Furthermore, due to the absence of computing instructions for FP16×INT8, the operation cannot be supported, even if we manage to load the corresponding data into the register.

To address these issues, we observe that the alignment issue can be circumvented by transforming the tensor layout into a well-optimized one based on the data type width, memory transaction length, and instruction shape. For instance, in the right figure, we store each 2x2 tile in contiguous memory space in the L1 layer so that the load instructions at the upper layer can fully utilize the bandwidth. Moreover, given that the computing instruction only supports the FP16 data format, we can convert the second tensor from INT8 to FP16 during the data loading from the L2 to the L1 memory layer. Consequently, the data loading from L2 to L1 efficiently leverages the low traffic due to the low-bit data type, the data loading from L1 to L0 fully utilizes the memory bandwidth through transaction alignment, and the computation is ultimately accelerated in the hardware computing unit by type conversion. This example demonstrates that a DNN computation on a custom data type not supported by hardware can still be scheduled and optimized through a well-designed tensor transformation on its layout and data types.

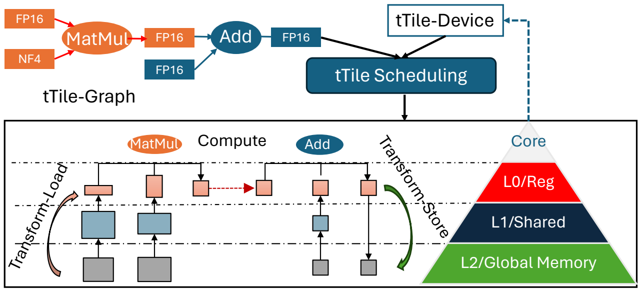

Figure 3: The system overview of LADDER

3 LADDER Design

The observations in §2 motivate LADDER, a DNN compiler that treats data type as a first-class citizen and introduces tensor transformations to support efficient DNN computation on custom data types. Figure 3 shows the system architecture.

The core of LADDER is the *TypedTile* (*t*Tile) abstraction, which augments the tile-based tensor abstraction with data type (i.e., *t*Type, §3.1). Specifically, the algorithm designer can use commonly-used data type (e.g., FP16) or define a custom data type (e.g., MXFP8, NF4) as a *t*Type, and define the DNN computation at this data type. Then, LADDER takes the DNN model as input and converts it into a *t*Tile-based data-flow graph (i.e., *tTile-graph*) where operators are defined as *t*Tile-based computing tasks (i.e., *tTile-operator*) (§3.1).

Besides, LADDER abstracts a hardware accelerator as a multi-layer hierarchy where the requirement of each layer is represented as a *t*Tile (*t*Tile-device, §3.1). *t*Tile-device explicitly describes the requirements of each layer, e.g., supported data type, transaction size, etc. By aligning *t*Tiles in the *t*Tile-graph with the *t*Tile-device, the *t*Tile-graph represented DNN computation can be executed on the hardware accelerator.

Given the initial *t*Tile-graph and the hardware specifications, LADDER will compile the DNN model into an efficient execution plan on the accelerator. To schedule the *t*Tile-graph on the *t*Tile-device and satisfy the requirements of the hardware hierarchy, LADDER separates the scheduling mechanism from its policy. On the mechanism side, LADDER proposes four *t*Tile transformation primitives: *slice*, *map*, *pad*, and *convert*, enabling the transformation from a *t*Tile to an equivalent *t*Tile (§3.2).

Then, the scheduler will schedule the initial *t*Tile-graph

```
class tType {
 TileShape shape;
 size_t nElemBits;
 struct metadata;
 map<TileType, c_func> c_tTypes;
};
```

(a)

```
class tTile {
 TileShape shape;
 tType type;

 struct metadata;
};
```

(b)

```
class tTile-Operator {
 TensorExpr expr;
 TileShape shape;
 vector<tTile> get_input_tTiles();
 vector<tTile> get_output_tTiles();
 void compute();
};
```

(c)

Figure 4: The definition of *t*Type, *t*Tile and *t*Tile-operator

into a *t*Tile-graph of fine-grained control over *t*Tile configurations, transformations and *t*Tile placement on the hardware hierarchy. The *t*Tile abstraction enlarges the scheduling space for DNN computation and opens a new trade-off between memory footprint efficiency and latency efficiency. On the policy side, LADDER plays heuristics based on observations and provides a hardware-aware layer-wise policy optimizing for latency efficiency (§3.3).

Finally, the compiled plan represented as a *t*Tile-graph is then generated as an executable code for the given hardware accelerator.

3.1 The *t*Tile Abstraction

***t*Type** According to the observations in §2, data types in DNN computation are usually defined at either element-wise granularity or block-wise granularity. To express these data types, LADDER introduces the concept of *t*Type (Figure 4(a)). Specifically, the *t*Type represents a data type that consists of a group of homogeneous elements. The layout of these elements is a n-dimensional array `shape`. Each element shares the same type with `nElemBits` bits to store an element. This group of elements also share the same `metadata`. As described in §2, data types usually can be losslessly represented by some higher-bit data types. The `c_tTypes` represents a *t*Type can be losslessly converted to another *t*Type with the `c_func` function.

Both existing commonly-used data types and new customized data types can be represented with *t*Type. For example, the FP16 type can be expressed as a *t*Type of `shape=[1]` with `nElemBits=16`. The element-wise granulated NF4 type can be expressed as a *t*Type of `shape=[1]` with `nElemBits=4` and the shared value map in `metadata`. The NF4 type can be losslessly represented as FP16, and therefore there could be a `<FP16, NF4_to_FP16_func>` entry in `c_tTypes`. The block-wise granulated OCP-MXFP8 type can be expressed as a *t*Type of `shape=[32]` with `nElemBits=8` and the shared scaling factor in `metadata`.

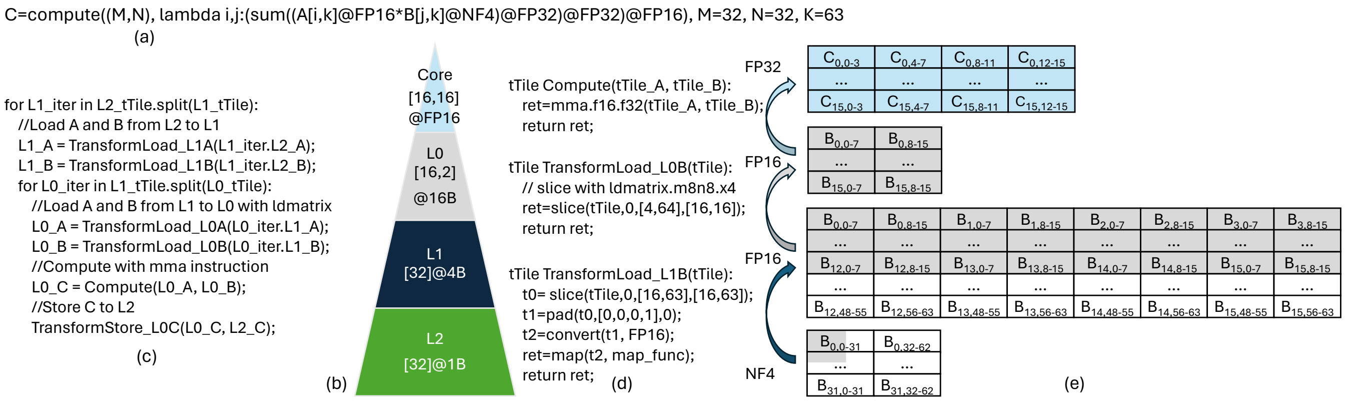
***t*Tile** Based on the *t*Type that represents a data type, LADDER proposes *t*Tile to represent a tensor of a specific data type at the fine-grained tiles. Specifically, as shown in Figure 4(b), a *t*Tile is defined as a group of homogeneous elements with the same data type `dtype` and a layout of a n-dimensional array `shape`. Elements in a *t*Tile share a `metadata`. Besides, elements in a *t*Tile are stored as row-major.

***t*Tile-Operator** A DNN operator (e.g., MatMul) are commonly implemented as a group of independent and homogeneous tasks, where each task processes a tile of the input tensor and outputs a tile of the output tensor. With the *t*Tile abstraction, a tensor of a specific data type is represented at the fine-grained tile granularity. Therefore, LADDER can leverage *t*Tile to representent a DNN operator of custom data types as a group of independent and homogeneous fine-grained tasks, i.e., *t*Tile-operator. Specifically, as Figure 4(c) shown, a *t*Tile-operator explicitly represents the tensor computation task over elements of `shape`. `get_input_tTiles()` and `get_output_tTiles()` return the input and output *t*Tiles of this computation task. `compute()` executes the computation defined in the tensor expression `expr` for the input and output *t*Tiles.

The computation of a *t*Tile-operator is defined as an index-based lambda expression `expr` [13,40,57]. However, the tensor expression in existing tensor compilers [13,21,52,56,57] focuses on describing the index and the shape and cannot flexibly indicate the data type during computation. For example, it cannot express a tensor in FP16 multiples a tensor in FP16 with FP32 as the accumulation. To support expressing computation over mix-ed data types, it requires the expression of data types during computation. Therefore, LADDER introduces the *t*Type annotation in tensor expression to explicitly indicate the data type during computation, including inputs, outputs and intermediate data, to represent computation over mix-ed data types. For example, a tensor A[M,K] of FP16 type multiplies a tensor B[N,K] of NF4 type with FP32 as the accumulation and outputs a tensor C[M,N] of FP16 type can be expressed as Figure 5(a). With the *t*Type-annotated tensor expression, given the `shape`, LADDER can infer the corresponding input and output *t*Tiles.

With the *t*Tile-based fine-grained representation for DNN operators, a DNN model can be represented as a fine-grained ***t*Tile-graph**, where each node is a *t*Tile-operator and each edge represents the dependency of two *t*Tile-operators.

***t*Tile-based Hardware Abstraction** Modern hardware accelerators usually have a hardware hierarchy, including memory layers (e.g., DRAM, register) and computing units. Each layer in the hardware hierarchy has its preference for data accessing. Specifically, a memory layer usually requires accesses via transactions where a transaction is a sequential or a shape of data at a granularity. For example, the shared memory of NVIDIA GPUs requires a transaction of 32 4-byte banks. A compute unit also usually requires processing a shape of data at a granularity. For example, the `hfma2` instruction in NVIDIA GPUs processes at the granularity of two FP16 value.



```
C=compute((M,N), lambda i,j:(sum((A[i,k]@FP16*B[j,k]@NF4)@FP32)@FP32)@FP16), M=32, N=32, K=63
```

```
for L1_iter in L2_tTile.split(L1_tTile):
  //Load A and B from L2 to L1
  L1_A = TransformLoad_L1A(L1_iter.L2_A);
  L1_B = TransformLoad_L1B(L1_iter.L2_B);
  for L0_iter in L1_tTile.split(L0_tTile):
    //Load A and B from L1 to L0 with ldmatrix
    L0_A = TransformLoad_L0A(L0_iter.L1_A);
    L0_B = TransformLoad_L0B(L0_iter.L1_B);
    //Compute with mma instruction
    L0_C = Compute(L0_A, L0_B);
    //Store C to L2
    TransformStore_L0C(L0_C, L2_C);
```

```
tTile Compute(tTile_A, tTile_B):
  ret=mma.f16.f32(tTile_A, tTile_B);
  return ret;

tTile TransformLoad_L0B(tTile):
  // slice with ldmatrix.m8n8.x4
  ret=slice(tTile,0,[4,64],[16,16]);
  return ret;

tTile TransformLoad_L1B(tTile):
  t0= slice(tTile,0,[16,63],[16,63]);
  t1=pad(t0,[0,0,0,1],0);
  t2=convert(t1, FP16);
  ret=map(t2, map_func);
  return ret;
```

Figure 5: MatMul of FP16 tensor A and NF4 tensor B: (a) *t*Type-annotated tensor expression, (b) *t*Tile-device for NVIDIA A100, (c) Pseudo code of computing pipeline, (d) `Tramsform-Load` with *t*Tile transformation primitives, (e) Tensor B transformations

These requirements can be described as *t*Tiles.

Therefore, LADDER abstracts a hardware accelerator as a hierarchy of multiple layers described as *t*Tiles, i.e., ***t*Tile-device**. Each layer is a memory layer or the compute unit, whose requirement represented as a shape on a granularity is described as a *t*Tile and the granularity is described as *t*Type.

Figure 5(b) shows the *t*Tile-device for the NVIDIA A100 GPU with the FP16 tensor cores. The FP16 tensor core MMA instruction [3] requires processing at a granularity of [16,16] and [8, 16] for two inputs, respectively. This can be expressed as a *t*Tile of `shape[16,16]` with the `dtype=FP16`. The FP16 tensor core data loading instruction [4] requires loading [16,2] data at a granularity of `half8` (i.e., 8 FP16 value), and can be expressed as a *t*Tile of `shape[16,2]` with the `dtype=16B`. Besides, the requirement of fully utilizing the shared memory can be expressed as a *t*Tile of `shape[32]` with the `dtype=4B`. The 32-byte transaction requirement of the global memory can be expresses as a *t*Tile of `shape[32]` with the `dtype=1B`.

3.2 *t*Tile Transformation

*t*Tile explicitly describes the fine-grained tensor storage and the requirements of the hardware hierarchy. The *t*Tile-represented DNN computation in the *t*Tile-graph should align with the *t*Tile-device for efficient execution. Fortunately, according to our observations in §2, the tensor storage and access in a pipeline can be transformed into logically equivalent formats, where each has different performance impacts in the hardware hierarchy. Therefore, LADDER proposes *t*Tile transformation mechanism to enable transforming the layout or the *t*Type of a *t*Tile to an equivalent *t*Tile. Specifically, LADDER augments the computation pipeline of a *t*Tile-operator as three stages on the hardware hierarchy: `Transform-Load`, `Compute`, and `Transform-Store`. `Transform-Load` loads the *t*Tiles from the lower memory layer to a higher memory layer with *t*Tile transformations. `Compute` executes the computation task of the *t*Tile-operator on the compute units. `Transform-Store` stores the *t*Tiles from the higher memory layer to a lower memory layer with *t*Tile transformations.

```
tTile slice(tTile_input, index, shape, out_shape);
tTile map(tTile_input, map_func);
tTile pad(tTile_input, pad_shape, pad_value);
tTile convert(tTile_input, new_tType);
```

Figure 6: *t*Tile transformation primitives

LADDER provides four primitives to transform a *t*Tile to an equivalent *t*Tile, as shown in Figure 6.

Slice The `slice` primitive slices a group elements of `shape` from the address `index` of the `tTile_input` and returns them as a new *t*Tile of `out_shape`. The `slice` primitive is usually used to represent the data tiling.

Map The `map` primitive modifies the layout of the elements in a *t*Tile. Given the `map_func`, the `map` primitive maps the address of each element to the expected address. For example, in Figure 5(d), the `TransformLoad_L1B` from the L2 memory layer to the L1 memory layer leverages the `map` primitive to modify the elements' addresses with the `map_func`.

Pad The `pad` primitive pads the `tTile_input` with the `pad_value` on each border given in `pad_shape`. The length of the `pad_shape` is 2 times of that of the `tTile_input`'s `shape`, and describes the left and the right borders of each dimension, respectively.

Convert The `convert` primitive converts the *t*Type of the `tTile_input` to the given `new_tType`. The given `new_tType` should be in the `c_tTypes` of the `tTile_input`'s *t*Type. `convert` will call the corresponding `c_func` of the given `new_tType` on each element in the `tTile_input`, and return the expected *t*Tile of `new_tType`. For example, in Figure 5(d), the `TransformLoad_L1B` converts the *t*Type from NF4 to FP16 with the `convert` primitive to satisfy the cores' FP16 *t*Type requirement.

With the above four primitives, a *t*Tile can be transformed to another equivalent *t*Tile by changing the `shape` with `slice` and `pad`, modifying the elements' layout with `map`, or con-

[3] mma.sync.aligned.m16n8k16.row.col.f16.f16.f32.f32

[4] ldmatrix.sync.aligned.m8n8.x4.shared.b16

verting the *t*Type with `convert`. This enables transforming the *t*Tiles of a *t*Tile-operator to align with the *t*Tile-device, so that these *t*Tiles can be efficiently processed in the hardware hierarchy.

Figure 5 shows an example that a FP16 tensor A[32,63] multiplies a NF4 tensor B[32,63] with FP32 as the accumulation and outputs a FP16 tensor C[32,32] (Figure 5(a)) on a four-layered *t*Tile-device (i.e., from L2 to core, Figure 5(b)). Specifically, Figure 5(c) shows the pseudo code of the execution. *t*Tiles of A and B are transformed and loaded from L2 to L1 as FP16 type. Then, the *t*Tiles are loaded to L0 with `ldmatrix` and processed by the `mma` instruction which accumulates intermediates as FP32 in L0. Finally, the *t*Tiles of C in L0 are transformed and stored to L2 as FP16. Figure 5(d)(e) shows the detailed transformations of the NF4 tensor B to align with the *t*Tile-device, while the transformations of tensor A are similar. Specifically, the `mma` and `ldmatrix` instructions require the FP16 data type in L1. Each layer also has its transaction requirement shown as Figure 5(b). Therefore, `TransformLoad_L1B` `slices` [16,63] and `pads` it to [16,64], which aligns with the L2's transaction requirement. Then, `TransformLoad_L1B` `converts` it to FP16 and `maps` it to another elements layout to align with the transaction requirements of L1 and L0. We get the FP16 `L1_B`[16,64] in L1. Then, `TransformLoad_L0B` leverages the `ldmatrix` to `slice` the `L1_B` and gets the FP16 `L0_B`[16,16] on L0, which aligns with the requirements of L1, L0 and the `mma` core.

3.3 Hardware-Aware *t*Tile-Graph Scheduling

Given the DNN computation represented as a *t*Tile-graph, to schedule it to a *t*Tile-device, we can map each *t*Tile-operator's computation pipeline for *t*Tiles (i.e., `Transform-Load`, `Compute`, and `Transform-Store`) to the *t*Tile-device. Specifically, we can partition each *t*Tile-operator into multiple *t*Tiles to fit the capacity of each memory layer, schedule *t*Tile transformations to align the *t*Tiles with the requirements of hardware layers, and coordinate inter-operator *t*Tile configurations and transformations for holistic optimizations. Finally, the entire *t*Tile-graph is scheduled as a data pipeline where *t*Tiles of a *t*Tile-operator node move up and down on the hardware hierarchy and are passed cross the edge to the successor *t*Tile-operator node.

The scheduling space of the *t*Tile-graph becomes much larger because *t*Tile opens another dimension (i.e., tensor transformation) in DNN computation scheduling. Furthermore, the *t*Tile transformations introduce a new trade-off between memory footprint efficiency and latency efficiency, which brings more complexities and challenges in scheduling. Take the MatMul of a FP16 tensor and a NF4 tensor on NVIDIA GPU as an example, it requires to `convert` the NF4 type to FP16 due to the hardware support limitation. This conversion should be finished before the `Transform-Load` from L1 to L0, and therefore can be scheduled to either L2 or L1. When the conversion is on L2, it will take more memory on L2 and L1, but it will not occupy the compute unit in later *t*Tile movement from L2 to L1 and to L0. When the conversion is on L1, it will save memory on L2 and save the memory bandwidth of L2, but it will occupy the compute unit for the type conversion. When the operator is bounded by the compute unit, the previous option can achieve lower latency but more memory footprint. When the operator is bounded by the memory IO, the latter one can achieve better performance on both latency and memory footprint. Additionally, as the `convert` is only required to be finished before the `Transform-Load` from L1 to L0, this `convert` can be fused into the previous operator for execution to achieve better end-to-end performance.

Given such a large scheduling space, LADDER provides a latency-oriented policy that targets at minimizing the end-to-end latency. Specifically, LADDER proposes a layer-wise scheduling policy based on hardware-awareness: a lower-layer memory provides the preferred data access granularity as a hint represented as a *t*Tile, and the upper layer decides

Algorithm 1: Hint-based layer-wise scheduling

```
Data: g: tTile-graph; D: tTile-device
Result: $g_{ret}$: scheduled tTile-graph
Function GetDeviceHint(g, D):
    D = SelectDeviceConfig(g, D);
    HintShape = None, HintGranularity = None;
    for layer ∈ D.layers do
        HintGranularity = LCM(HintGranularity, layer.tTile.type);
    for layer ∈ D.layers do
        layer.tTile = convert(layer.tTile, HintGranularity);
        HintShape = LCM(HintShape, layer.tTile.shape);
    for layer ∈ D.layers do
        layer.tTile.shape = HintShape;
    return D;
Function ScheduleTransform(op,D,$l_{id}$):
    $tTile_h$ = op.tTile[$l_{id}$-1];
    $tTile_l$ = op.tTile[$l_{id}$];
    ScheduleSlice($tTile_l$, $tTile_h$);
    if LCM($tTile_l$.shape, $tTile_h$.shape) $\neq$ $tTile_l$.shape then
        SchedulePad($tTile_l$, $tTile_h$, D);
    if $tTile_l$.type $\neq$ $tTile_h$.type then
        ScheduleConvert($tTile_l$, $tTile_h$, D);
    if nBits($tTile_h$.shape[-1]) $\neq$ nBits(D.layers[$l_{id}$].shape[-1]) then
        ScheduleMap($tTile_l$, $tTile_h$, D);
    return op.transform[$l_{id}$-1];
Function ScheduleConnectedGraph(g, D):
    D = GetDeviceHint(g, D);
    for $l_{id}$ in length(D.layers) do
        for op ∈ g[$l_{id}$] do
            op.tTile[$l_{id}$] = ScheduleTiling(op,D,$l_{id}$);
            if $l_{id}$ > 0 then
                op.transform[$l_{id}$] = ScheduleTransform(op,D,$l_{id}$);
    g = ProfileAndSelect(g);
    return g;
Function Schedule(g,D):
    g = ExtractConnectedGraph(g, D);
    for $g_{conn}$ ∈ g do
        $g_{conn}$ = ScheduleConnectedGraph($g_{conn}$, D);
    return g;
```

the optimal compute granularity by aligning with this *t*Tile represented granularity with transformations. To reduce the large scheduling space and schedule a proper plan within reasonable time, LADDER plays heuristics based on our observations.

Scheduling policy. Algorithm 1 describes the hint-based layer-wise scheduling policy. It takes a DNN model `g` represented as a *t*Tile-graph and the hardware specifications represented as a *t*Tile-device `D`, and returns the scheduled *t*Tile-graph $\mathtt{g}_{ret}$. Initially, this policy schedules the graph into sub-graphs (line 33). Each sub-graph represents as a computation pipeline that loads *t*Tiles from the lowest memory layer to the core and then stores the results to the lowest memory layer. A sub-graph could be a *t*Tile-operator or a group of *t*Tile-operators that can be fused. The `ExtractConnectedGraph` can leverage existing DNN compiler work [13, 43].

Given a sub-graph, it first infers the hints from the hardware. Specifically, it first selects the proper hardware configurations (e.g., the compute cores) (line 2), which prefers the **bit-nearest *t*Type** supported by the hardware. Because numeric types of more bits usually require more transistors to implement the hardware instructions [] and usually result in lower performance. For example, in NVIDIA A100 GPU, the NF4 type can be converted to FP16 or FP32 for processing, and LADDER will select the FP16 core (312 TFlops) rather than FP32 (19.5 TFlops). Then it finds the aligned granularity and shape for each hardware layer by **bit-alignment**, and configures the hints (line 1-11). Take the NVIDIA A100 as an example (Figure 5(b)), the `HintGranularity` is 16B required by `ldmatrix` and the `HintShape` is [4,8], where the inner dimension is 128B and aligns with the 32B transaction of global memory and the 128B transaction of shared memory. Then, the policy schedules this sub-graph from the top layer (i.e., core) to the bottom layer (i.e., DRAM) layer by layer (line 25-29). In each layer, the policy first schedules the *t*Tile-operator tiling via `ScheduleTiling` with hint (line 27), and then schedules the *t*Tile transformation (line 29). If the `ScheduleTiling` (line 27) schedules the operator tiling as multiple of [4,8] with 16B, the later `ScheduleTransform` can align this scheduling with the *t*Tile-device. Additionally, the `ScheduleTiling` can leverage existing tensor compilers [13,52,57]. In `ScheduleTransform`, the policy will check the alignment of both `shape` and `type` with the *t*Tile-device, and schedule corresponding transformations to align *t*Tiles (line 12-22). There may be some candidates after the scheduling, which will be profiled and returned the best (line 30).

ScheduleMap. The `map_func` in scheduling the `map` transformation is non-trivial. LADDER proposes a method to infer the `map_func`, i.e., mapping the elements in the *t*Tile to the required transaction size in row-major order. Figure 5(e) shows an example: at the granularity of 16B, to map the shape[16,2] in L0 to the required shape[8] in L1, elements are flatten in row-major order, resulting in shape[4,8]. `map` can also support other `map_funcs`.

This scheduling policy is not guaranteed as optimal. However, as shown in §5, this scheduling policy can already outperform state-of-the-arts and enable efficient low-precision DNN computing on GPUs. We also hope that this optimization space from the proposed scheduling mechanism could be further explored by future research on more advanced scheduling policies.

4 Implementation

LADDER is implemented by about 5K lines of code, including Python and C++, based on open-source DNN compilers: TVM [13], Welder [43], and Roller [57]. LADDER modifies TVM for implementing kernel schedules and generating kernel code, while Roller is leveraged to infer efficient *t*Tile configurations. Welder is the state-of-the-art DNN compiler that can holistically optimize DNN models, and is leveraged for end-to-end graph optimizations.

The input of LADDER is a PyTorch program. For PyTorch built-in data types, LADDER does not require any modifications on the DNN model program. Additionally, for new data types that PyTorch does not support, LADDER extends the PyTorch with custom operators for expressing tensor expressions on the user-defined data types. Given the PyTorch program, LADDER exports it to an ONNX graph. LADDER also extends ONNX to represent computation on new data types, where the *t*Type-annotated tensor expression is saved in the attribute of an ONNX graph node. With the exported ONNX graph and the *t*Tile-based specification file of the targeted hardware accelerator, LADDER automatically converts the ONNX graph into the *t*Tile-graph and performs the scheduling. Then, LADDER generates the device code for the targeted hardware accelerator.

We implemented LADDER for NVIDIA GPUs and AMD GPUs, recognizing their widespread use as the most popular accelerators for DNNs. In the rest of this section, we describe the LADDER implementation on NVIDIA GPUs in detail and briefly describe the implementation on AMD GPUs. Additionally, LADDER can be ported to new hardware instructions (e.g., FP8 tensor cores in the latest Hopper GPUs) and other hardware accelerators (e.g., Graphcore IPU) if they align with the *t*Tile-based hardware abstraction and provide programming interfaces of loading and storing data on the hardware hierarchy.

4.1 LADDER on NVIDIA CUDA GPUs

4.1.1 *t*Type and *t*Tile

LADDER has implemented the *t*Types for common data types, e.g., FP32, FP16, INT8, FP8, MXFP, INT4, NF4, INT1.

A GPU is a single instruction multiple threads (SIMT) architecture, and it prefers a group of threads process the same instruction on different data. Therefore, LADDER separately

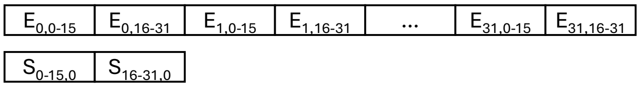

Figure 7: The storage of a MXFP8 *t*Tile of `shape[32, 32]` on NVIDIA GPU. E: elements. S: shared scaling in metadata.

stores the elements and each of the `metadata` in the *t*Tile. Figure 7 shows the storage of a MXFP8 *t*Tile of `shape[32,32]` on NVIDIA GPU. The elements are stored in an array, while the shared scaling factors are stored in another array. To access a *t*Tile, consecutive threads process consecutive elements, resulting in coalesced accesses.

Note that, there may be some data types that the `nElemBits` is not 2^n, e.g., 3-bit [22]. To support these data types, Ladder stores at the granularity of 4B due to the GPU specifications, e.g., 10 3-bit value can be stored in a 4B (32-bit) granularity.

4.1.2 Optimizing Code Generation with PTX Instruction

NVIDIA does not provides the assembly instructions for programming. Instead, NVIDIA introduces the Parallel-Thread-Execution (PTX) as a low-level virtual machine for NVIDIA GPUs, where the ISA (Instruction Set Architecture) on the PTX virtual machine can be considered as the instruction-level APIs for NVIDIA GPUs [8]. CUDA C++ code is first compiled to the PTX code and then compiled to the machine code for execution. CUDA provides both the C++ APIs and the PTX APIs for some units. For example, the tensor cores provides both the WMMA C++ APIs and the MMA PTX APIs, where a WMMA API is compiled as a group of MMA instructions by the nvcc compiler. The MMA PTX APIs have more flexibility and better performance than the WMMA C++ APIs. Ladder uses the MMA PTX APIs for codegen on tensor cores, and uses `cp.async` instructions for the new asynchronous memory copy feature on Ampere GPUs [3]. Additionally, we observed converting low-bit integers (e.g., INT4) to floats (e.g., FP16) may introduce significant overheads. Ladder implements the conversion of integers of lower than 4 bits with the `LOP3` instruction [8]. We modified the code generation module in TVM to implement these optimizations.

4.2 Ladder on AMD ROCm GPUs

AMD GPUs are similar to NVIDIA GPUs, which also have a hardware hierarchy of global memory shared by all CUs, local data store in each CU (similar to the shared memory), registers, and cores. Therefore, similar to NVIDIA GPUs, an AMD GPU can be abstracted as a four-layer *t*Tile-device with different *t*Tile configurations. ROCm provides the HIP programming model [1] for AMD GPUs, which is similar to CUDA's functionality and supports most CUDA statements. We implemented a new code generation backend for HIP in TVM to support AMD ROCm GPUs. Additionally, we use the `MFMA` (Matrix Fused-Multiply Add) ISA-level APIs to utilize the matrix core (the equivalent of the NVIDIA tensor core).

5 Evaluation

5.1 Evaluation Setup

Hardware platforms. We evaluate Ladder on a diverse range of GPUs from both NVIDIA and AMD to ensure a comprehensive assessment of performance across different hardware ecosystems. Our evaluation comprises three high-performance NVIDIA GPUs: Tesla V100 (16GB), A100 (80GB), and RTX A6000 (48GB), utilizing the CUDA toolkit version 12.1 for optimal performance. We extend to the AMD ecosystem with the inclusion of the AMD Instinct MI250 GPU (128GB), utilizing the ROCm toolkit version 5.7.0. The operating systems remain consistent, utilizing Ubuntu 20.04.

DNN models. We evaluate the effectiveness of Ladder by benchmarking the inference on a suite of state-of-the-art DNN models that span various domains and architectures. These models encompass large language models, such as LLAMA-70B [45] and BLOOM-176B [47], computer vision models, including ResNet-50 [24], ShuffleNet-V2 [34], and ViT-Base [19], as well as audio models like transducer Conformer-l [23]. The data type configurations used in these models are all from state-of-the-art research literature and have been evaluated by the deep learning community. Ladder follows these configurations and does not introduce additional model quality loss. The data type configurations, representing both weights and activations and denoted as $W_{\text{type}}A_{\text{type}}$, for the evaluated models are detailed below:

- **LLAMA-70B and BLOOM-176B:** Evaluated with data type configurations of $W_{\text{FP16}}A_{\text{FP16}}$ [45, 47], $W_{\text{INT4}}A_{\text{FP16}}$ [22, 31], $W_{\text{NF4}}A_{\text{FP16}}$ [15], $W_{\text{FP8}}A_{\text{FP8}}$ [37], $W_{\text{MXFP8}}A_{\text{MXFP8}}$ [41], and $W_{\text{INT1}}A_{\text{INT8}}$ [46].
- **ResNet-50:** Evaluated with data type configurations of $W_{\text{FP16}}A_{\text{FP16}}$ [24], $W_{\text{FP8}}A_{\text{FP8}}$ [37], $W_{\text{MXFP8}}A_{\text{MXFP8}}$ [41], and $W_{\text{INT1}}A_{\text{INT4}}$ [25].
- **ShuffleNet-V2:** Evaluated with data type configurations of $W_{\text{FP16}}A_{\text{FP16}}$ [34] and $W_{\text{FP8}}A_{\text{FP8}}$ [42].
- **ViT-Base:** Evaluated with data type configurations of $W_{\text{FP16}}A_{\text{FP16}}$ [19], $W_{\text{FP8}}A_{\text{FP8}}$ [27], and $W_{\text{INT4}}A_{\text{INT4}}$ [29].
- **Conformer-L:** Evaluated with data type configurations of $W_{\text{FP16}}A_{\text{FP16}}$ [23], $W_{\text{INT8}}A_{\text{INT4}}$ [18], and $W_{\text{INT4}}A_{\text{INT4}}$ [18].

We configure various batch size (BS) and sequence length (SEQ) settings to cover diverse deployment scenarios. For large language models such as LLAMA-70B and BLOOM-176B, we conduct tests with (BS, SEQ) settings of (1, 1), (32, 1), and (1, 4096) to comprehensively represent online and offline inference scenarios, as well as pre-fill and decoding stages. Additionally, models like ResNet-50, ShuffleNet-V2, ViT-Base, and Conformer-L are evaluated with batch sizes of both 1 and 128 to assess performance across online and offline inference scenarios.

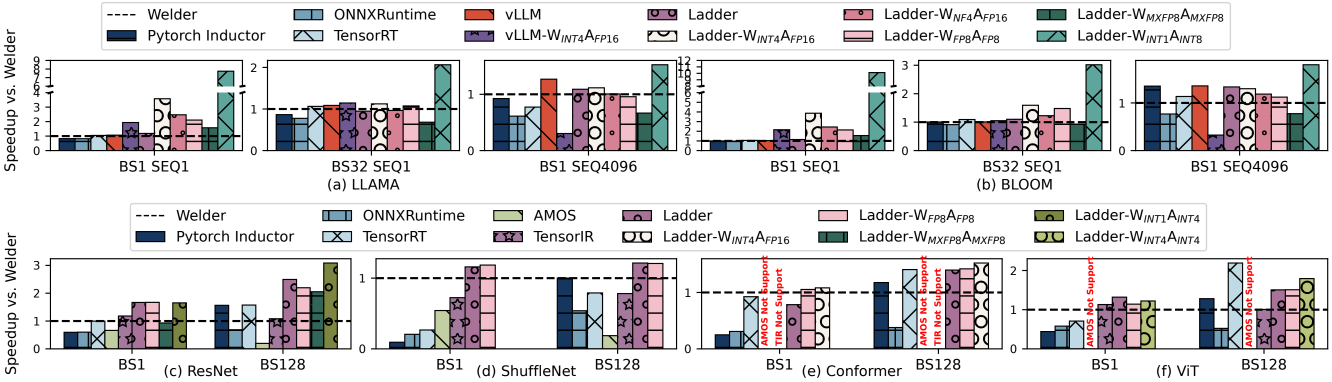

Figure 8: End-to-end performance on the NVIDIA A100 GPU.

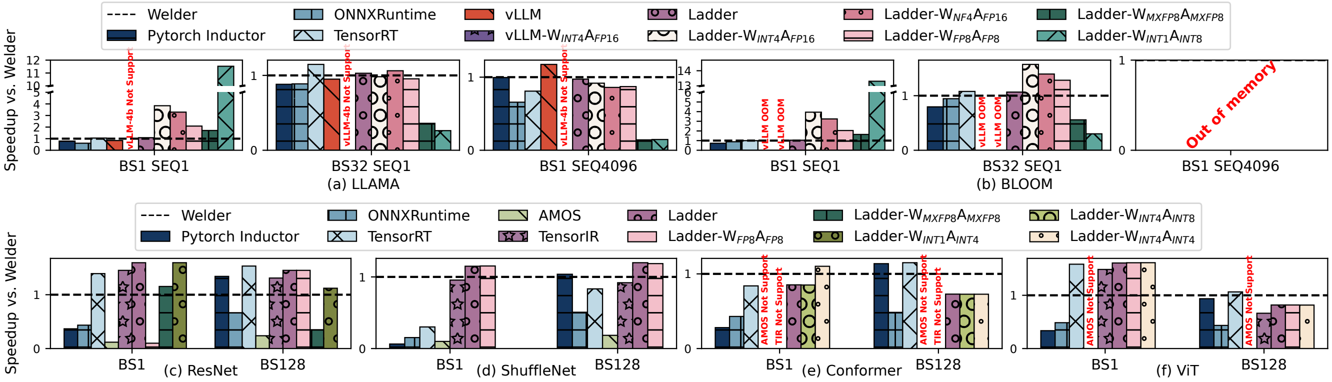

Figure 9: End-to-end performance on the NVIDIA V100 GPU.

Baselines. We compare LADDER against various well-established compilers and frameworks across different GPU platforms. For NVIDIA GPUs, we include comparisons with Welder [43], PyTorch-Inductor [38], ONNXRuntime [7], TensorRT [9], AMOS [56], TensorIR [21], vLLM [28], vLLM-$W_{\text{INT4}}A_{\text{FP16}}$ (the 4-bit quantized model support in vLLM) [28]. On AMD GPUs, we compare LADDER with Welder [43], PyTorch-Inductor [38], ONNXRuntime [7] and TensorIR [21]. To harness the MatrixCore capabilities on ROCm devices, we have integrated MIOpen and rocBLAS into Welder, and we have also enhanced TensorIR with rocWMMA Auto Tensorize support. For operator benchmarks, LADDER is evaluated against cuBLAS [4], CUTLASS [6], vLLM [28], cuDNN [5], AMOS [56] and TensorIR [21].

5.2 Evaluation on NVIDIA GPUs

5.2.1 End-to-End Performance

Inference latency. Our inference latency evaluation targets the previously detailed DNN models, executed on the Tesla A100, V100, and RTX A6000 GPUs. For large language models, such as LLAMA-70B and BLOOM-176B, due to GPU memory constraints, we evaluate the inference latency using one decoder layer of these models, which serves as a proxy for the full model's performance because each layer is the same and the latency is linear with the number of layers.

Figure 8 summarizes the inference latency results on the A100 GPU. In the data type configuration of $W_{\text{FP16}}A_{\text{FP16}}$, LADDER achieves notable performance enhancements. Compared to Welder, we report an average speedups of 1.0×, 1.2×, 2.0×, 1.2×, 1.1×, and 1.4× for LLAMA, BLOOM, ResNet, ShuffleNet, Conformer, and ViT, respectively. The reason is because Welder leverages Roller [57], cuBLAS [4] and CUTLASS [6] for kernel generations and suffers from kernel performance issues like shared memory bank conflicts, especially in ResNet where Conv2D operations introduce more irregular shapes. LADDER can achieve higher efficiency by resolving these kernel performance issues with tensor transformation scheduling, e.g., 1.1 ms and 7.6 ms latency on BS1 and BS128 of ResNet. In the data type configuration of $W_{\text{INT4}}A_{\text{FP16}}$ which is widely used in LLMs, LADDER achieves a remarkable 2.3× speedup on average over vLLM. Moreover, LADDER exhibits robust versatility by supporting custom data types not traditionally accommodated by other systems. For instance, in the case of $W_{\text{INT1}}A_{\text{INT8}}$ configuration, LADDER achieves an impressive speedup of up to 10× relative to Welder on one layer of BLOOM-176B-BS1SEQ1 with 0.32 ms latency.

Our inference latency evaluation extends to the Tesla V100 and RTX A6000 GPUs, with results shown in Figures 9 and Figure 10. The results on these platforms align closely with those observed on the A100. It is important to note that the V100, equipped with 16GB of memory, encounters limitations when handling even a single decoder layer of the BLOOM

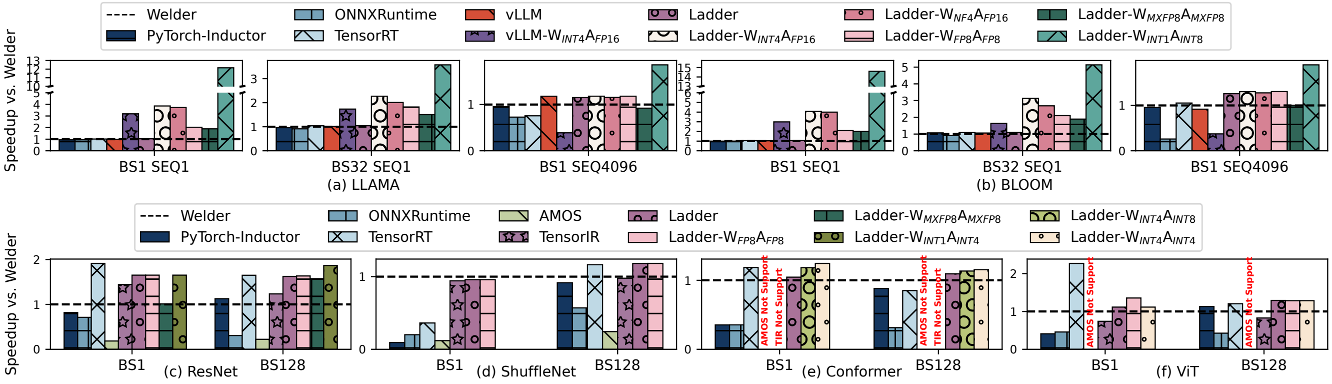

Figure 10: End-to-end performance on the NVIDIA RTX A6000 GPU.

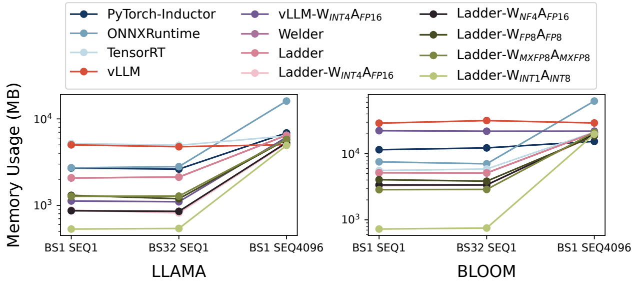

Figure 11: Memory usage of LLM inference on the NVIDIA A100 GPU across varying data type configurations.

Model (BS)	AMOS	TensorIR	Welder	LADDER
ResNet (1)	3852	156	11	31
ResNet (128)	2191	836	18	44
ShuffleNet (1)	3328	128	13	17
ShuffleNet (128)	3121	400	12	29

Table 2: Compilation time (in minutes) comparison of end-to-end models on NVIDIA A100 GPU.

model, resulting in out-of-memory errors. In terms of performance gains, with the $W_{\text{FP16}}A_{\text{FP16}}$ configuration, LADDER delivers an average speedup of 1.1× on the V100 and 1.2× on the A6000, compared to Welder on both platforms. With the $W_{\text{INT4}}A_{\text{FP16}}$ configuration, LADDER achieves an average speedup of 2.0× compared to vLLM on the A6000 GPUs, and also enables effective $W_{\text{INT4}}A_{\text{FP16}}$ inference on V100 GPUs. In scenarios utilizing the $W_{\text{INT1}}A_{\text{INT8}}$ configuration, LADDER reaches up to 13.3× speedup on the V100 and 14.6× speedup on the A6000, compared to Welder.

Memory usage. Employing reduced-precision data types is a critical strategy for alleviating the substantial memory requirements of large language models (LLMs). To quantify the benefits of this approach, we conduct a thorough investigation of memory usage across various data type configurations during LLM inference on the A100 GPU. The results are shown in Figure 11, which illustrates a near-linear decrease in memory usage corresponding to the reduction in bit width. This trend is particularly pronounced during the decoding phase with a sequence length of 1, highlighting the advantages of precision scaling in the memory-intensive decoding stage of inference. In the most extreme scenario, employing a weight precision of 1-bit and activation precision of 8-bit ($W_{\text{INT1}}A_{\text{INT8}}$), we observe substantial memory savings. Specifically, when compared to the full precision ($W_{\text{FP16}}A_{\text{FP16}}$) configuration, the memory footprint for LLAMA model inference is reduced by 74%, 74%, and 24% across three different batch size and sequence length combinations, respectively. For the BLOOM model, the memory footprint is reduced by 85%, 85%, and 6% for the corresponding settings.

Compilation time. To assess the efficiency of our system, we present a comparative analysis of compilation times in Table 2. Our evaluation compares LADDER against other prominent systems: AMOS, TensorIR, and Welder. The compilation times are measured for the end-to-end compilation of two representative neural network models, ResNet and ShuffleNet, with different batch sizes (1 and 128) on an NVIDIA A100 GPU. The results highlight that on average, LADDER demonstrates a significant reduction in compilation time compared to both AMOS and TensorIR. Notably, LADDER is an order of magnitude faster than TensorIR, and two orders of magnitude faster than AMOS. As LADDER enables supporting low precision arithmetic through tensor transformation and thus, inherently, a broader schedule space. While it allows LADDER to capitalize on the performance benefits of low-precision arithmetic, it also imposes additional overhead during the compilation process. Consequently, LADDER exhibits slightly higher compilation times compared to Welder.

5.2.2 Operator Benchmark

To assess kernel performance within LADDER, we constructed an operator benchmark incorporating commonly utilized operators from the LLAMA and ResNet models. The benchmark is composed of six matrix multiplication (MatMul) operators, labeled M0-M5, and eight 2D convolution (Conv2d) operators, labeled C0-C7. We tested each operator under a variety of data type configurations, including $W_{\text{FP16}}A_{\text{FP16}}$, $W_{\text{INT4}}A_{\text{FP16}}$, $W_{\text{NF4}}A_{\text{FP16}}$, $W_{\text{FP8}}A_{\text{FP16}}$, $W_{\text{INT1}}A_{\text{INT8}}$, $W_{\text{MXFP8}}A_{\text{MXFP8}}$, and $W_{\text{INT4}}A_{\text{INT4}}$. All experiments were executed on an NVIDIA A100 GPU to ensure consistency and

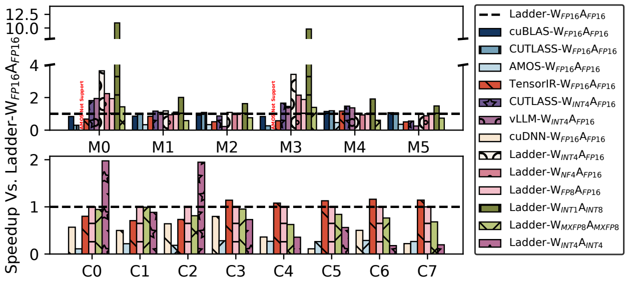

Figure 12: Operator benchmark on NVIDIA A100 GPU.

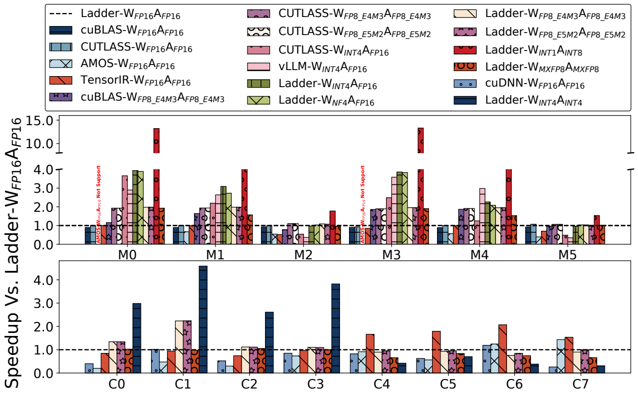

Figure 13: Operator benchmark on NVIDIA RTX 4090 GPU.

reliability in performance evaluation. As depicted in Figure 12, LADDER demonstrates optimal performance with the $W_{\text{FP16}}A_{\text{FP16}}$ configuration. Transitioning to $W_{\text{INT4}}A_{\text{FP16}}$, LADDER achieves an average speedup of 1.8×, while the $W_{\text{INT1}}A_{\text{INT8}}$ configuration enables an even further average speedup of 4.5×.

The Ada Lovelace, Hopper and Blackwell GPUs support $W_{FP8}A_{FP8}$ tensor core. We also conducted the operator benchmark on a NVIDIA RTX 4090 GPU with CUDA 12.4 to evaluate the hardware-supported $W_{FP8}A_{FP8}$ performance. Figure 13 shows the results. For $W_{FP8\_E4M3}A_{FP8\_E4M3}$, LADDER outperforms cuBLAS and achieves comparable performance over CUTLASS. For $W_{FP8\_E5M2}A_{FP8\_E5M2}$, LADDER achieves comparable performance over CUTLASS, while cuBLAS does not support this case. RTX 4090 only enables the $W_{FP8}A_{FP8}$ with FP32 accumulation which has the same theoretical performance as $W_{FP16}A_{FP16}$. Therefore, cuBLAS, CUTLASS and LADDER of $W_{FP8}A_{FP8}$ is similar to that of $W_{FP16}A_{FP16}$ on large matrices like M2 and M5. Although $W_{FP8}A_{FP8}$ with FP16 accumulation has double theoretical performance, it is not exposed by NVIDIA currently. LADDER achieves higher speedup on data types like $W_{NF4}A_{FP16}$ and $W_{INT1}A_{INT8}$ than those on A100, because RTX 4090 has more powerful cores for transforming data types.

5.2.3 Optimization Breakdown

Figure 14 illustrates the step-by-step optimizations LADDER applied to the LLAMA-70B model's kernels for both single (BS1 SEQ1) and large batch sequences (BS1 SEQ4096)

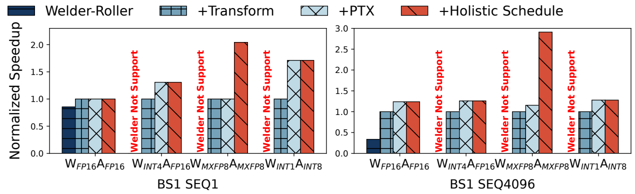

Figure 14: Optimization breakdown

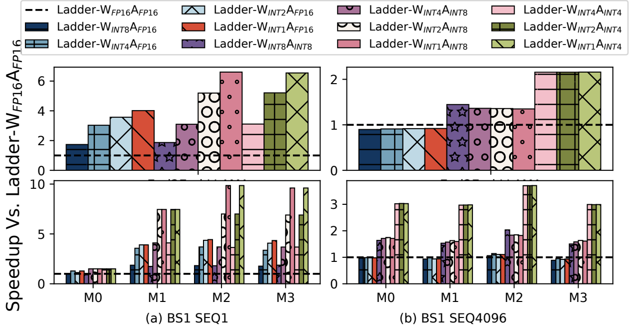

Figure 15: Scaling the bit width of weight and activation.

across different data formats. Tile-aware kernel transformation led to smoother data handling and a 2.0× speed boost over the Roller baseline, also enabling support for various data types. PTX-level optimizations reduced GPU memory load, and with advanced control over tensor operations and layout, LADDER achieved a further up to 1.7× speedup. A comprehensive scheduling strategy yielded a up to 2.5× speedup, especially benefiting memory-constrained types like MXFP8, by optimizing transformations. Overall, LADDER's optimizations enhance computational efficiency and adaptability, delivering marked performance gains across multiple operations.

5.2.4 Scaling Bit Width

Leveraging the versatile capabilities of LADDER, we are able to support a wide range of data types with arbitrary bit widths for both weights and activations. To thoroughly evaluate the performance implications of precision scaling, we conducted experiments across data type settings that progressively decrease bit widths. Our evaluation encompasses end-to-end performance as well as individual operator performance across two distinct batch size and sequence length configurations. The experimental outcomes are detailed in Figure 15. As we scale down the bit widths of W and A, we observe a corresponding escalation in speedup, reflecting the efficiency gains of lower precision arithmetic. In decoding scenarios with sequence length of 1, which are memory-bound, our experiments show a clear speedup increase with reduced W bit width (from $W_{\text{INT4}}A_{\text{INT4}}$ to $W_{\text{INT2}}A_{\text{INT4}}$, to $W_{\text{INT1}}A_{\text{INT4}}$). However, during encoding at sequence length of 4096, which is compute-bound, speedup remains unchanged across these configurations due to the reliance on higher-precision computations in mixed-precision operations.

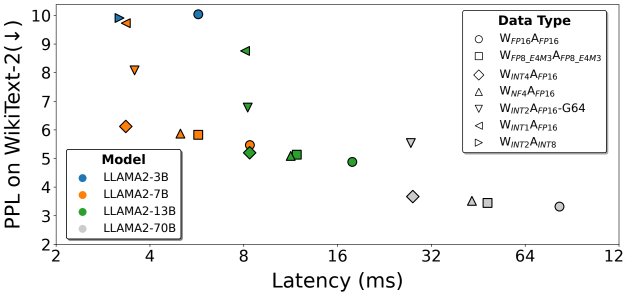

Figure 16: PPL on WikiText-2 (↓) and latency (ms) of decoding single token on A100 for different low-precision methods on LLMs. G64 of $W_{INT2}A_{FP16}$ indicates a group-wise scaling of 64 elements. LLAMA2-70B uses pipeline parallelism.

5.2.5 Efficiency and Accuracy of Low-Precision LLMs

Low-precision computing focuses on both model quality and model efficiency, thus there is usually an efficiency-accuracy trade-off in designing low-precision models. We take LLMs (i.e., LLAMA2-3B, LLAMA2-7B, LLAMA2-13B and LLAMA2-70B) as the example to evaluate both the efficiency and the accuracy of state-of-the-art low-precision methods. Specifically, we evaluated PTQ for $W_{FP8\_E4M3}A_{FP8\_E4M3}$ [2, 37], GPTQ for $W_{INT4}A_{FP16}$ [22], PTQ for $W_{NF4}A_{FP16}$ [16], BitDistiller for $W_{INT2}A_{FP16}$ [20], OneBit for $W_{INT1}A_{FP16}$ [49], and BitNet-b1.58 for $W_{INT2}A_{INT8}$ [35]. Both PTQ and GPTQ are post-training quantization methods, which does not include model training. BitDistiller and OneBit are quantization-aware training methods, leveraging distillation to achieve 2-bit and 1-bit weight quantization. BitNet-b1.58 trains LLMs from scratch to achieve ternary weights represented in $W_{INT2}A_{INT8}$.

Figure 16 shows the perplexity (PPL) on WikiText-2 and the latency of decoding single token on A100. Note that the lower PPL indicates the better model quality. The PPL of $W_{INT4}A_{FP16}$, $W_{NF4}A_{FP16}$ is reported by AFPQ [51]. The PPL of $W_{INT1}A_{FP16}$ is reported by OneBit [49]. The PPL of $W_{FP16}A_{FP16}$ on LLAMA2-3B is reported by BitNet-b1.58 [35]. The PPL of other models are evaluated with open-sourced model checkpoints and open-sourced implementations. $W_{FP8\_E4M3}A_{FP8\_E4M3}$, $W_{NF4}A_{FP16}$ and $W_{INT4}A_{FP16}$ show little affects on PPL, while achieve 1.6×, 1.7×, 2.5× on average, respectively. Quantizing LLMs to 2-bit weights with PTQ and GPTQ will result in NaN PPL [20, 49], while BitDistiller and OneBit leverage distillation to achieve stable results in 2-bit and 1-bit quantization. However, the group-wise scaling introduces extra computation cost to $W_{INT2}A_{FP16}$-G64, resulting in similar speedup as $W_{INT4}A_{FP16}$.

It is noticeable that BitNet-b1.58 achieves even better PPL with 1.8× speedup on the LLAMA2-3B configuration, when compared to the $W_{FP16}A_{FP16}$ model trained on the same dataset with same tokens [35]. This speedup does not achieve the theoretical speedup because the LLAMA2-3B is too small to saturate the GPU. We further evaluated BitNet-b1.58's $W_{INT2}A_{INT8}$ on the LLAMA2-70B configuration and achieved 4.6× speedup over $W_{FP16}A_{FP16}$, thus BitNet-b1.58 shows a good potential on both accuracy and efficiency.

When comparing across different model configurations, the model size has significant impact on both accuracy and efficiency. It is noticeable that LLAMA2-13B with $W_{INT4}A_{FP16}$ achieved better performance than LLAMA2-7B with $W_{FP16}A_{FP16}$ on both accuracy and efficiency, and the quantized LLAMA2-7B models also outperform LLAMA2-3B with $W_{FP16}A_{FP16}$ on both accuracy and efficiency. This shows the power of low-precision computing.

The community is actively exploring low-precision computing, and we hope LADDER can help researchers to explore this direction by providing feedback on efficiency.

5.3 Evaluation on AMD GPUs

We evaluate the efficient LADDER on AMD Instinct MI250 GPU by comparing it with Welder, PyTorch-Inductor and ONNXRuntime. Figure 17 shows the end-to-end performance of 6 models. In the data type of $W_{FP16}A_{FP16}$, LADDER achieves an average 2.1×, 2.35×, 1.5×, 10.5×, 1.6×, and 1.5× speedup over Welder for LLAMA, BLOOM, ResNet, ShuffleNet, Conformer, and ViT, respectively. Welder does not perform well on ShuffleNet because it leverages rocBLAS and MIOpen for matrix core and thus breaks fusion opportunities. LADDER not only generates efficient computing kernel for matrix core but also enables more fusion opportunities, resulting in 14.1× speedup over Welder on ShuffleNet-BS1 with 0.43 ms latency. In the data type configuration of $W_{INT4}A_{FP16}$ for LLMs, LADDER achieves up to 3.8× speedup on LLAMA with 0.73 ms latency on BS1SEQ1 and 4.5× speedup on BLOOM with 1.75 ms latency on BS1SEQ1 over Welder.

6 Discussion

LADDER's current implementation mainly focuses on model inference. We discuss some LADDER's limitations and future work in this section.

Multi-GPU serving. Multiple GPUs are required to deploying some large-scale models like BLOOM-176B and LLAMA2-70B, becuase these models cannot fit into a single GPU. Multi-GPU support is complementary with LADDER. LADDER focuses on supporting low-precision computing on a hardware accelerator. Multi-GPU frameworks [28, 30, 32, 53] focus on partitioning model and scheduling parallel computation across multiple GPUs. LADDER can collaborate with multi-GPU frameworks to enable parallel computation for low-precision models on multiple GPUs that multi-GPU frameworks partition a model and schedule the partitioned computation to LADDER on a device for execution. We leave integrating LADDER with multi-GPU frameworks to our future work.

Low-precision training. LADDER's design is not limited to inference. Both training and inference of low-precision

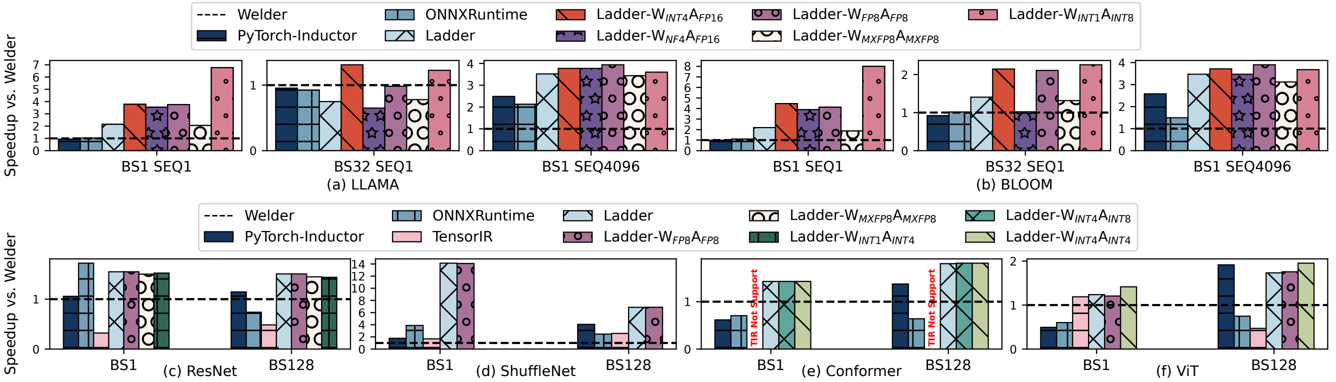

Figure 17: End-to-end performance on AMD Instinct MI250 GPU.

models require low-precision support of system and hardware. And the backward computation in training is similar to the forward computation. Low-precision model training can achieve gains from: 1) leveraging more efficient low-precision computation units, e.g., $W_{INT8}A_{INT8}$ tensor core supported on A100 has 2× throughput than that of $W_{FP16}A_{FP16}$, while $W_{INT4}A_{INT4}$ tensor core has 4×; and 2) less memory footprint from low-precision model representation enabling larger batch sizes which may improve the hardware utilization. We leave low-precision training to our future work.

7 Related Work

Deep learning compilers and frameworks. Most existing deep learning compilers, such as [10, 13, 33, 38, 43, 50, 52, 54, 57], focus on operator or model computation optimizations for mainstream data types, e.g., FP16 or FP32, with little emphasis on low-precision data types. However, many optimizations are complementary with low-precision computing, for example, Roller [57] is leveraged to infer efficient *t*Tile configurations, and Welder [43] is leveraged for end-to-end graph optimization in Ladder. SparTA [55] treats model pruning and quantization as model sparsity to holistically optimize sparse model inference and training, and Ladder can provide efficient low-precision kernels to further improve the performance. AMOS [56] has optimized for TensorCore computation, covering FP16 and INT8 types, but it is specific to NVIDIA GPUs. In comparison, Ladder is the first compiler to optimize for general low-precision computations that support general custom data types on different GPUs. Deep learning libraries or frameworks like ONNXRuntime [7] and TensorRT [9] support some low-bit operators for inference scenarios, but their coverage is still limited due to the significant effort required to implement those combinatorial cases. Some recent compilers like Triton [44] and TensorIR [21] allow users to directly write the computation pipeline of a DNN operator, providing flexibility in specifying scheduling in each stage. However, these compilers mostly focus on computation scheduling and have little support in data scheduling for custom data types, which is the primary focus of Ladder.

Model-specific low-precision optimization. Given the lacking efficient support of low-precision in existing compilers and frameworks, many works have conducted workload-specific low-precision optimizations. For example, some quantization and model training on low-precision types are optimized for Large Language Models (LLMs) [22, 28, 31, 35, 41, 45–47]. Previous work like [23–25, 34, 42] optimizes other models like ShuffleNet, Conformer, etc., into FP8 or FP16 precision. In comparison, Ladder provides a mechanism to allow one to more easily implement custom data types and optimization policies. Thus, these optimization approaches are complementary to Ladder, as they can be implemented or automatically optimized in Ladder.

8 Conclusion

In conclusion, this paper introduces Ladder, the first deep learning compiler designed to optimize general low-precision computation on accelerators like GPUs. Ladder exposes a general type system (*t*Type) and an extended tensor expression, enabling users to easily implement and express new data types in deep learning. It introduces a set of new tensor scheduling primitives to facilitate optimizations like tensor storage, access, and type conversions in a computing pipeline. The layer-wise hardware-aware optimization policy of Ladder navigates the complex transformation space, showcasing its capability to systematically support a wide array of low-bit precision custom data types. This enhances DNN computation performance on modern accelerators without requiring hardware modifications. This innovation empowers model designers to explore data type optimizations and offers hardware vendors a flexible solution to expand support for diverse precision formats.

CARAVAN: Practical Online Learning of In-Network ML Models with Labeling Agents

Qizheng Zhang, Ali Imran[†], Enkeleda Bardhi[‡], Tushar Swamy, Nathan Zhang,
Muhammad Shahbaz[†⋆], Kunle Olukotun
Stanford University [†]*Purdue University* [‡]*Sapienza University of Rome* [⋆]*University of Michigan*

Abstract

Recent work on in-network machine learning (ML) anticipates offline models to operate well in modern networking environments. However, upon deployment, these models struggle to cope with fluctuating traffic patterns and network conditions and, therefore, must be validated and updated frequently in an online fashion.

This paper presents CARAVAN, a practical online learning system for in-network ML models. We tackle two primary challenges in facilitating online learning for networking: (a) the automatic labeling of evolving traffic and (b) the efficient monitoring and detection of model performance degradation to trigger retraining. CARAVAN repurposes existing systems (e.g., heuristics, access control lists, and foundation models)—not directly suitable for such dynamic environments—into high-quality labeling sources for generating labeled data for online learning. CARAVAN also introduces a new metric, *accuracy proxy*, to track model degradation and potential drift to efficiently trigger retraining. Our evaluations show that CARAVAN's labeling strategy enables in-network ML models to closely follow the changes in the traffic dynamics with a 30.3% improvement in F1 score (on average), compared to offline models. Moreover, CARAVAN sustains comparable inference accuracy to that of a continuous-learning system while consuming 61.3% less GPU compute time (on average) via accuracy proxy and retraining triggers.

1 Introduction

Machine learning (ML) is being increasingly leveraged to better manage and operate networks today [27,30,35,37,45,49,54,77,80,82,97,101,104,105,111,114,116]. In academia, several proposals make a case for using ML to improve systems security through anomaly and intrusion detection [30,54,105] and to optimize systems performance through inference, diagnosis, and forecasting of systems' behavior [49,76,80,81]. Correspondingly, in industry, ML is being deployed to detect threats and bots in public and enterprise-scale cloud networks [1,9,10] for securing physical and virtual infrastructure and for providing better user experience by predicting network incidents and congestion early on [8]. Moreover, to operate at scale, with high throughput and low latency, the model inference is being offloaded to the data plane (e.g., programmable switches [15,114] and SmartNICs [17,101]) in the network (i.e., in-network ML)—to perform decision-making on a per-packet basis [37,104,122].

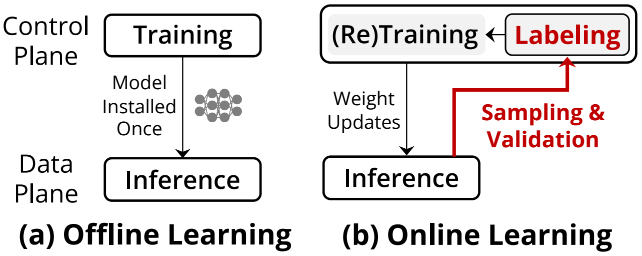

Figure 1: Comparison of in-network model learning. (a) Offline learning: trained and deployed once; (b) Online learning: trained and updated over time—requires iterative sampling, labeling, and validation.

Unlike conventional approaches (e.g., hand-crafted heuristics and static rulesets), ML models are better at revealing hidden patterns and characteristics in vast amounts of high-dimensional data—such as network traffic [35,54,71,104,111,116,117]. However, most efforts on replacing traditional approaches (e.g., heuristics and access control lists) with ML [35] are limited to using static models (aka offline learning, Figure 1a) [30,35,37,49,54,82,97,101,104,105,111,114,116]. These models are trained once using synthetic or controlled network traces and are expected to operate well in the real environment without further guidance (or retraining). While showing significant promise in stable (less volatile) environments, these static models perform poorly in the presence of fluctuations and unforeseen events—not captured by the traffic during the initial training phase [33,115,117]. These manifest as model drift either (a) when the network environment gradually evolves or suddenly changes due to traffic bursts, time-of-day, or rare events (called concept drift) [117] or (b) when new data patterns arrive or data distribution changes (called data drift) [33]. This model drift is shown to be prevalent in many online ML applications [33,94,100,115].

To keep these models up-to-date with new patterns and network behavior, one approach is to train and update them continuously on the incoming traffic—referred to as online learning or continuous learning [33,94]. For example, a (re)training pipeline in the control plane can continuously sample packets from the network (e.g., using INT [68] or NetFlow [7]), label them, and pass them to the model for retraining (Figure 1b). It then updates the weights on the data-plane device, performing model inference. As we show in our evaluations (§5), keeping the model current through online training allows it to handle new incidents with much higher accuracies compared to the static offline models (i.e., the average difference in accuracy is as high as 67%).

However, there are a number of challenges when it comes to enabling continuous learning in modern networking environments (processing Tbps of traffic for varying tenants and workloads) [32, 96, 119, 121]. First, unlike traditional online learning systems in other domains (e.g., recommendation systems and financial systems) where the new retraining data either contains labels (ground truth) [59, 103, 113] or can be easily labeled using existing approaches (like Data Programming [93] or Weak Supervision [91,92]), in networking the incoming data is raw (sampled) traffic with no labels. *Challenge #1: How can we prepare (and label) traffic data for retraining in-network models?* Second, we cannot rely on fixed interval-based or periodic retraining to ensure the installed models perform well. The network conditions are highly dynamic and erratic; a large interval will miss such variations, whereas frequent updates would be too costly in terms of resource usage (CPU/GPU cycles and network bandwidth). *Challenge #2: How to decide when to trigger retraining?*

In this paper, we present CARAVAN, an online learning system for in-network ML to tackle these challenges. To label new incoming network traffic, CARAVAN relies on labeling agents that use different user-defined knowledge sources to assist with labeling. In networking, many existing systems, such as heuristics, access control lists, deep learning, or even foundation models (e.g., GPT-4 [87], Gemini [106], Llama 3 [16]), fare poorly when used for real-time decision-making—they either fail to adapt to changing network conditions or take too much time to process. However, we observe that these can be used as knowledge sources to label incoming traffic for online learning of in-network models. For instance, using foundation models (which encode a broad spectrum of information about the environment [89,95,112]) and guidance from users (e.g., prompts [28] and document retrievals [72]), we can generate application-specific, weak-supervision labels to (re)train these models. We also introduce a new metric, *accuracy proxy*, to decide when to trigger retraining. Instead of relying on ground-truth labels to compute model accuracy, we compute accuracy proxy based on generated labels we receive from the labeling agents for model (re)training. Doing so allows CARAVAN to track degradation in model behavior through relative changes in the accuracy level on a temporal scale, and to trigger retraining. More specifically, if there is an abrupt change in the accuracy proxy (i.e., model drift exceeds a certain threshold), CARAVAN uses this as a signal to trigger retraining. This limits CARAVAN from excessively retraining the model under normal conditions.

We evaluate our CARAVAN system both in simulation (for microbenchmarks) and with a Taurus FPGA-based switch [104] (for end-to-end results). Our simulation results show that labels generated using knowledge sources perform similarly to ground-truth labels in terms of inference accuracy when used to label incoming traffic for retraining. Moreover, our accuracy proxy and retraining triggers save up to 74.55% GPU compute time compared to continuous online training while sustaining similar accuracy gains. With our Taurus FPGA testbed, we show that CARAVAN maintains 30% higher accuracy on average compared to offline models while using 56.23% less CPU and with similar memory footprint compared to continuous retraining baselines—with CARAVAN, the model operates at line rate while adapting to changing traffic dynamics.

In summary, we make the following contributions:

- We present CARAVAN, a practical online learning system for in-network ML. CARAVAN's labeling-agent strategy allows the use of existing network systems (e.g., heuristics, access control lists) and emerging foundation models (e.g., GPT-4, Gemini, and Llama 3) as knowledge sources to label incoming traffic. Using accuracy proxy further allows CARAVAN to efficiently retrigger the training pipeline while closely tracking changes in the network conditions.
- We implement CARAVAN as a software logic running in the control plane, and test it both in a simulation setting and using a real testbed with Taurus FPGA-based switches. Our CARAVAN prototype is available as open-source.[1]
- Our evaluations show that CARAVAN allows in-network models to track changes in the network at line rate while sustaining 30.3% higher F1 score (on average) compared to offline systems. Moreover, it consumes 61.3% less GPU compute time (on average) than a continuous-learning system by selectively triggering retraining via accuracy proxy.

2 Background & Motivation

In-network Machine Learning. Network operators face many challenges with managing the size and complexity of modern networks while maintaining their stringent (and ever-increasing) performance requirements [32,96,119,121]. Over time, the networking community has developed a plethora of hand-tuned heuristics permeating the network, which continuously introduce new parameters that must then be tuned to the given network (and workload). We see this with the constant iterations of congestion-control variants [55,73], active-queue management [23], load balancing algorithms [26,66], anomaly detection [25, 34, 38] and more. Relying on network developers and researchers to keep adding new parameters to each algorithm being used throughout the network, as the workloads change and evolve, has limited scalability as networks grow. Networking researchers have, therefore, begun to turn toward data-driven algorithms, in the form of ML, particularly deep-learning and neural networks [35, 40, 63, 80, 83, 105, 111, 116]. Rather than tuning individual model weights by hand, ML algorithms take training data as input and learn model weights to optimize for performance metrics (e.g., prediction accuracy).

To operate at scale with high throughput and low latency, these models are further offloaded to the network data plane

[1] Artifact: https://github.com/Per-Packet-AI/Caravan-Artifact-OSDI24

(e.g., programmable switches and SmartNICs) [17, 101, 104, 114, 125]. Doing so allows more fine-grained control over the traffic, with decision-making (and model inference) taking place at or near the packet level. For example, programmable switches (e.g., Intel Tofino series [15]) with match-action tables (MATs) can perform ML algorithms (such as SVMs and decision trees) [37, 114], with more recent data-plane devices incorporating MapReduce-based processing blocks to run deep neural networks (DNNs) directly in the network [104]. Likewise, emerging SmartNIC devices (e.g., Marvell Octeon 10 [17] and Xilinx SN1000 [2]) come equipped with on-board ML inference engines for per-packet inference. Similarly, data/infrastructure processing units (DPUs/IPUs) from Nvidia [6], AMD [4], and Intel [14] also provide computational resources capable of running ML inference alongside the packet-processing pipelines.

Online Learning and Model Drifts. Recent work on applying online learning in networking domains (such as video analytics and edge monitoring) shows promising results. For example, Ekya [33] and RECL [67] demonstrate that retraining computer vision models for video analytics applications with new video frames can effectively mitigate data drift for compressed ML models. Nazar [58] features online monitoring and adapts various ML models on mobile devices to relieve the problem of potential model drifts.

Through retraining ML models with new incoming data, online learning addresses two common issues these models face post-deployment: concept drift [117] and data drift [33]. Concept drift occurs as networks and traffic are subjected to dynamic signal interference due to environmental changes [123] (e.g., weather, temperature, or time-of-day), as well as changes in the network and user behavior (e.g., increased online activity during COVID-19 [46], addition/removal of devices and software due to upgrades or failures [75]). For example, a large file download may be classified as benign during the day when networks are more active but are marked as malicious during the night when the number of high-volume flows is smaller. On the other hand, data drift happens when the live traffic (or data) distribution diverges from the training data distribution after the model is deployed [33, 94]. For classification models, in particular, the arrival of new data classes (not already present in the offline training set) or a change in data class distribution could cause an ML model to perform poorly [33, 94]. For example, in network security, new attacks come up without warning, and it becomes challenging for a static ML model to detect such an attack since it was not trained on data featuring the new attack.

Network Data Labeling. The emerging interest in training and testing ML models for networking applications sparks extensive research in the area of obtaining labeled network data [42, 60, 98, 99]. Most recent work falls into three different categories: generating labeled network data in a controlled environment, synthetic data generation, and manual labeling through domain experts (i.e., network operators).

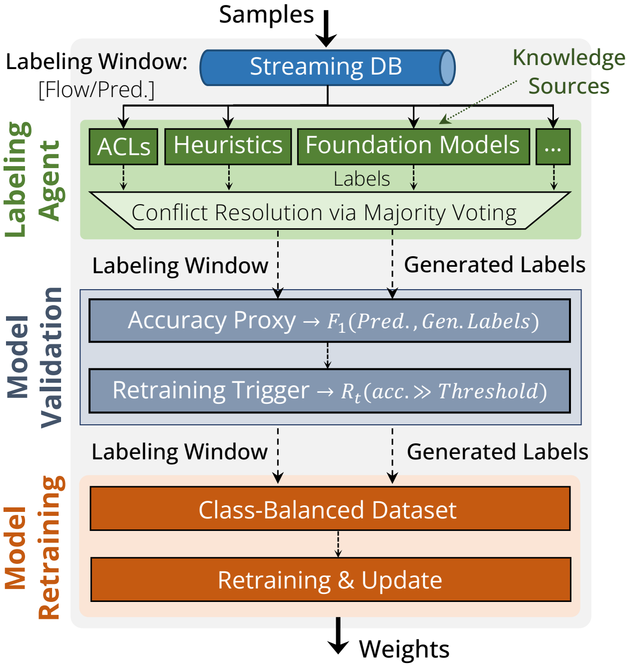

Figure 2: High-level design of CARAVAN. The three key components, Labeling Agent (§3.1), Model Validation (§3.2), and Retraining, work in tandem to keep the in-network ML model up-to-date.

Efforts like NetUnicorn [31] propose to collect and actively label network data in a controlled environment where operators can access different nodes (switches and hosts) in the network. Though labeling accuracy would be high since operators can choose to generate and collect selected traffic classes, this approach might not offer representative labeled data in real networks [53]—limiting its use in online learning. Other efforts feature synthetic data generation, where models like GANs [118] or diffusion models [65] are used to produce packet traces that match the feature distribution of input network data. However, the generation process takes a lot of time and cannot explicitly label new incoming data, making it impractical in an online setting. Also, it is unclear how closely the synthetic data reflects the traffic in a real environment (an open area of research [57, 107, 109]). The last resort is to ask human experts with domain knowledge to label all or selected network data. Though there are many efforts featuring selecting sampled data for human experts to label [53], this still requires a human-in-the-loop and may not operate at the timescales needed for automatic data labeling in networks.

3 Design of CARAVAN

We present CARAVAN, a system for practical online learning of in-network ML models deployed in the data plane. CARAVAN is designed to satisfy the following requirements: (1) generation of effective label datasets for retraining and (2) efficient monitoring and detection of model performance.

Overview. Figure 2 shows the high-level architecture of CARAVAN. The system periodically collects a window of samples, arriving from the data-plane device running in-network ML inference. Each sample contains a set of header fields (called flow) along with the prediction made by the deployed model. Once a window is full, a labeling agent (§3.1) generates application-specific (e.g., security) labels for each sample in the window in the form of class predictions (e.g., type of network attack) or confidence scores (e.g., the likelihood a flow being malicious). The agent relies on a collection of knowledge sources (§3.1.1), each generating its own labels. The label with the most votes (i.e., occurrences) is added to the final label set. Next, the validation stage (§3.2) monitors and detects the degradation in the model performance using a new metric, called *accuracy proxy* (§3.2.1), which uses predicted values and generated labels to measure the model's accuracy on the received samples in the window. Based on the accuracy values (e.g., exceeding a certain threshold), the retraining trigger stage decides whether retraining is necessary (e.g., in the presence of new types of attacks missed by the in-network ML model) for the current window of incoming samples. If an update is required, the final model retraining stage will generate a balanced dataset from the window of samples received, i.e., a mix of malicious and benign flows and generated labels. After training is complete, the in-network model is updated with the new weights to detect the new types of missed attacks.

3.1 Labeling Agent

The first component in CARAVAN is the labeling agent. It generates application-specific labels that can be used in the later stages of model validation and online retraining for: (1) computing an accuracy proxy that can signal potential model accuracy degradation to efficiently trigger retraining, and (2) generating a class-balanced labeled dataset for retraining when necessary. To generate labels for new incoming network traffic automatically and accurately, the labeling agent relies on external knowledge sources. Knowledge sources (§3.1.1) are defined to be entities or applications that can be repurposed to assist with data labeling (e.g., access control lists, heuristics, foundation models). They can be defined and provided by users through a user interface (§3.1.2).

When a full window of samples from the data plane is available, the labeling agent reads these samples and the associated inference results from a streaming database (e.g., InfluxDB [13] or Apache Kafka [5]). Then, it sends a labeling request to every knowledge source it relies on. With one label from each knowledge source, the labeling agent would do a majority voting to determine the final set of labels to be used (also called *generated labels*) for the current window of data samples. These generated labels will be sent to the next stage of CARAVAN for model validation (Figure 2).

3.1.1 Knowledge Sources. The labeling agent relies on knowledge sources for labeling. We define knowledge sources to be any entities or services that contain useful information about the user-defined application and can be repurposed to assist data labeling. Take network intrusion detection as an example. A common knowledge source is IP-based access control lists (ACLs) [52] that can block network flows or packets from certain source IP addresses considered to be of malicious origins. With IP-based ACLs as a knowledge source, the labeling agent is able to label a flow as *malicious* if its source IP is on the list. Another example is foundation models. With appropriate adaptation, a foundation model can assist with downstream tasks in networking, such as traffic classification, by functioning as a multi-class classifier [54].

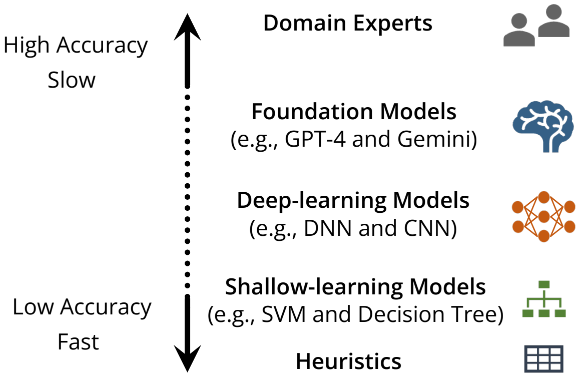

Figure 3: Classifying network knowledge sources across a spectrum based on accuracy and speed.

CARAVAN repurposes different knowledge sources in different ways for them to be used in the system for accurate and efficient labeling. In particular, CARAVAN focuses on two metrics of a knowledge source: (1) accuracy, which refers to how accurate the knowledge source is after being repurposed for labeling, and (2) speed (throughput and latency), which refers to how fast a knowledge source can be used to label data. Different knowledge sources can vary dramatically in these two metrics, and as illustrated in Figure 3, there exists a trade-off between these two metrics for a given knowledge source: sources with high accuracy (e.g., domain experts and foundation models) usually operate with lower throughput due to extra time needed for in-depth analysis, while high-speed sources (e.g., heuristics, IP-based ACLs) might not be able to provide accurate labels. The aim of CARAVAN is that through online learning, an in-network ML model can be turned into a model with both *high accuracy* and *high speed*, so it would be a good fit for real-time decision making in the data plane.

Low-Accuracy, Fast Knowledge Sources. Knowledge sources with a low accuracy but high speed (e.g., heuristics, IP-based ACLs) are a good fit for labeling large volumes of incoming data [24, 51, 108]. However, the main issue is that generated labels would be extremely noisy in this case. If we use these labels to retrain the in-network ML model, the accuracy of the retrained model can be even worse than that of the existing one in the data plane. To tackle this challenge, CARAVAN adopts the following solution: Instead of letting these low-accuracy knowledge sources provide a label for every unit of data in the current window, CARAVAN's labeling agent will ask these knowledge sources to label parts of data. These generated labels that cover a part of the dataset are usually called weak-supervision labels in the machine-learning community, and can reduce the amount of noise in the labels [92]. For example, when we use an IP-based ACL as a knowledge source for labeling, a straightforward way of repurposing it into a labeler is that we would label every flow with IP not on the blacklist as a benign flow. However, we could have mislabeled a lot of malicious flows as benign in this case and manually introduced a lot of noise into the final set of labels. With CARAVAN's solution of generating weak-supervision labels, we would only generate labels for flows whose IPs are on the blacklist (as we are more confident they would be malicious). Even though we would only be able to obtain a much smaller set of labeled data for model validation and retraining, with a large volume of incoming data, we would end up with a reasonable amount of labeled data with good accuracy (§5).

> **Insight 1:** *Low-accuracy but fast knowledge sources, such as heuristics and IP-based ACLs, can provide weak-supervision labels for training high-accuracy models.*

High-Accuracy, Slow Knowledge Sources. Knowledge sources characterized by low speed but high accuracy (e.g., domain experts and foundation models) are well-suited for labeling a small to medium amount of incoming data considered important or representative of the network (e.g., sampled data with network telemetry algorithms). For example, foundation models, like NetFound [54] and ChatGPT [20], are shown to be capable of solving downstream traffic analysis tasks with high accuracy and generalizing well across diverse network environments with no extra retraining. The main issue, however, is that they might either be too slow or use too many system resources (e.g., GPU/CPU memory and API costs) and thus cannot be activated frequently (for instance, at the end of every window of sampled data).

One insight that CARAVAN takes advantage of is that these knowledge sources can usually be transformed into cheaper rulesets or heuristics that are able to offer much higher throughput due to low latency or cost-effectiveness. In the machine-learning community, this insight was originally used to interpret black-box ML models [48, 62]. In CARAVAN, to avoid the costs associated with calling expensive knowledge sources at every labeling window, we introduce a *labeling rule cache*. Each time the knowledge source is activated for labeling, it is also asked to generate an ensemble of rulesets that will be stored in the labeling rule cache for fast and cheap labeling at the end of the next few labeling windows. For example, though foundation models, like GPT-4 [87], can be repurposed as a labeling source, the fees incurred by calling the GPT-4 APIs for inference can grow prohibitively expensive if we call these APIs at the end of every labeling window—GPT-4 turbo [11] can cost as high as $144 an hour for 1000-token labeling request/response per second (on average). CARAVAN specifically asks the language model to generate rules it relies on for decision-making and stores these in the rule cache for labeling the next few windows of data. Note that, in the evaluation section (§5), though we demonstrate that using the rule cache for labeling could save a lot on cost and system resources with little performance penalty, we also find that these rules could go stale quickly (Figure 7) and, therefore, must be updated occasionally.

> **Insight 2:** *High accuracy but slow knowledge sources, such as ChatGPT [20] and NetFound [54], can transform into rulesets or heuristics to facilitate fast and resource-efficient labeling for a limited duration, before becoming stale.*

3.1.2 User Interface. CARAVAN's labeling agent exposes an interface where users can conveniently specify what knowledge sources they would like to use for the labeling agent and how the labeling sources should be defined. To support a new knowledge source, the user only needs to complete a function called `label()`, which takes a window of data samples as input and returns a set of labels on this window as output.[2]

3.2 Model Validation

The model validation stage periodically monitors and evaluates the performance of the in-network ML model. It is also responsible for triggering online training when necessary, e.g., in the case of a potential concept drift or data drift when the performance of the model degrades due to changes in the network environment or due to new incoming classes. These actions take place at the end of a labeling window, after the labeling agent has generated labels for all data (samples) in the current window.

Next, we introduce two components for model validation that the user can define to express their intent or performance goal of the chosen application. (a) Accuracy proxy (§3.2.1) allows the user to specify what *signals* they would like to capture on a temporal scale from the generated labels and the inference results (e.g., drop in overall classification accuracy, the appearance of a particular type of new class, and more). (b) Retraining trigger (§3.2.2) allows the user to specify at what *occasion* they would like to initialize online training based on the observed signals through the accuracy proxy (e.g., retrain when model performance degrade or retrain when certain types of attacks show up).

3.2.1 Accuracy Proxy. We define accuracy proxy as the inference accuracy computed with generated labels as the reference ground truth, which we describe in detail below.

Ideally, for a given sample of incoming data (e.g., a network flow or a packet), the corresponding inference result

[2] As a case study, we show how to construct a new knowledge source for intrusion detection using LLMs in §4.1.

(e.g., in the form of a class label prediction, noted as ML_{labels} below) from the in-network ML model would be compared with the ground truth label in the validation stage. Ground truth labels (noted as $GndT_{labels}$ below), also called "golden" labels, are objectively correct reference results for the given application and are usually used to compute the performance accuracy of ML models. Acquiring such labels is typically challenging in practice as it necessitates domain knowledge from human experts, requiring a costly and time-consuming labeling process [53]. Moreover, during the online stage of in-network ML, where the volume of data for validation is immense, it is infeasible to obtain the ground truth labels for all new incoming data and calculate the actual performance accuracy of the in-network ML model. In CARAVAN, we instead utilize generated labels ($GenL_{labels}$) and compute the accuracy proxy for the current window of incoming data. For instance, in the intrusion detection case, using F1 score [50] as the performance metric, the real accuracy Acc_{real} is computed as follows:

$$Acc_{real} = F_1(ML_{labels}, GndT_{labels}) \tag{1}$$

The accuracy proxy, on the other hand, is computed with generated labels as ground-truth labels:

$$Acc_{proxy} = F_1(ML_{labels}, GenL_{labels}) \tag{2}$$

The accuracy proxy does not need to be defined in terms similar to the real accuracy. The user has the flexibility to define accuracy proxy to be any function as long as its definition is consistent with the user's intent or the application's performance goal, e.g., to signal potential concept or data drifts.

Without access to real accuracy values, we are unable to know the absolute accuracy level of the in-network ML model at the end of a labeling window. However, in our design, the primary responsibility of the validation stage is monitoring: it is expected to reveal potential model performance degradation and trigger online training, instead of giving users or operators the exact accuracy numbers of the in-network ML model.

In particular, we observe that accuracy proxy, though not numerically the same as the real performance accuracy, could signal a potential change in data distribution or class distribution based on its trend on a temporal scale. In our evaluation using the intrusion-detection example (§5.2.2), we observe that the arrivals of new types of attacks (unseen by the in-network ML model before) cause a drop in the relative level of accuracy on a temporal scale, and the values from accuracy-proxy can reveal that incident (Figure 8).

> **Insight 3:** *The accuracy proxy reveals potential concept and data drifts by capturing similar patterns of relative changes in accuracy levels as observed in real accuracy.*

3.2.2 Retraining Trigger. The goal of continuous model validation is to enable updating the in-network ML model through online training as and when necessary. The model validation stage will activate online training through a user-defined retraining trigger. A retraining trigger can take one of the following three forms, as pre-specified by the user of CARAVAN:

- **Window-based:** Retrain periodically once every X labeling windows. When $X = 1$, CARAVAN will perform continuous training for every window, similar to the approach in prior works [33, 85]. For window-based triggers, the validation stage will skip accuracy proxy since the trigger does not use it.
- **Accuracy-based:** Retrain if the values of accuracy proxy satisfy a certain pattern on a temporal scale. For example, users can set certain accuracy thresholds, and the retraining trigger will initialize retraining if the values of accuracy proxy continuously stay below the threshold.
- **Event-based:** Retrain when a particular event takes place, e.g., when the labeling agent or the human operator detects a particular type of attack.

The retraining trigger should ideally be defined together with accuracy proxy by the user: While accuracy proxy is able to catch meaningful signals (e.g., F1 score drop) on a temporal scale, the retraining trigger explicitly expresses at what occasions the user would like online training to happen, which can be very different given the particular user application in consideration.

In CARAVAN, we mainly focus on accuracy-based retraining triggers, in which we use values of accuracy proxy to determine if online training should occur. There are two types of decisions that the retraining trigger will need to make: (a) If we do not retrain at the end of the last labeling window, should we retrain for this window? CARAVAN's retraining trigger will initialize retraining if it observes an abrupt drop in the value of accuracy proxy in the current labeling window compared to the last one, since that could be an explicit signal of potential concept or data drifts. (b) If we retrain at the end of the last labeling window, should we stop retraining for this window? As we demonstrate in the evaluation section (Figure 8), if we continuously retrain for several windows, the marginal inference accuracy gain would gradually decrease, assuming that there are no new drifts that show up in this period. As a result, the retraining trigger stops retraining if we have retrained for the last few windows and obtained decent inference accuracy gain.

> **Insight 4:** *The marginal inference accuracy gain of online training would quickly diminish if no new sources of drifts are present (i.e., the network is stable).*

3.3 How to Select CARAVAN's Elements?

For knowledge sources, we can choose existing systems (e.g., IDS) or construct new ones (e.g., fine-tuned foundation models). It is important to evaluate the labeling accuracy and approximate speed of a knowledge source using an offline labeled dataset before deploying it in Caravan. When selecting accuracy proxy and retraining trigger, we should consider the application's performance objectives (e.g., low false-positive rate) and identify signals or events from the system that might indicate performance degradation (e.g., increased rebuffering events in video streaming).

4 Implementation

We implement an end-to-end version of Caravan using Python. To interact with in-network ML models, Caravan stores the samples of the arriving flows in a streaming database, InfluxDB [13]. We initialize InfluxDB with a predefined schema consisting of various header/feature fields and metadata of the arriving packet (e.g., duration, data rate, and 5-tuple) as well as the inference results (prediction) from the deployed in-network ML model (for validation purposes). Upon the arrival of a labeling window's worth of samples, the labeling agent queries these data samples from InfluxDB to generate labels.

For knowledge sources (e.g., heuristics, DNN-based classifiers, and foundation models), we define how it labels data by completing its `label()` function (as described in §3.1). Heuristics come in the form of labeling functions [91] and are easily defined by the user. The DNN-based classifiers load a pre-trained DNN classifier, and run batched inference upon calls of `label()` for labeling. For foundation models, we use GPT-4 API [87] for sending labeling requests in the form of prompts. In this setup, labeling is modeled as a text completion task, and we explicitly prompt the language model to produce a label for each input data sample. We present a case study of implementing a foundation model, LLM-based knowledge source in §4.1. With individual knowledge sources defined, we build a labeling agent by specifying what knowledge sources it will be using. The labeling agent calls each knowledge source's `label()` function to obtain all labels and selects the best ones (with the most occurrences) as final labels.

For model validation and retraining, we define a model validator that runs `compute_accuracy_proxy()` to compute the accuracy proxy (in §3.2.1) with generated labels and inference results (from InfluxDB) as input arguments. The retraining trigger is defined as a function that checks if we have retrained for the last window. If not, we check if there is a significant drop in accuracy proxy value to initialize retraining; if yes, we then check if the increase in accuracy proxy value is small enough to stop retraining. If retraining is necessary, we go on to form a class-balanced dataset based on iCaRL [94], keeping the same number of data samples from each class and maintaining a fixed upper bound for the size of the dataset (which can be specified by the user). For training ML models, we use PyTorch [88] and one Nvidia V100 Tensor Core GPU from AWS.

Caravan maintains a busy-waiting process for data labeling, model validation, and online learning. This process will periodically read data from InfluxDB and initialize data labeling as well as model validation at the end of a labeling window (determined by time or number of data samples). If retraining is necessary, it will conduct retraining and send out the weights to the in-network ML model as gRPCs [12] or PCIe writes.

4.1 `label()` with Foundation Model (LLM)

We now present a case study of developing a new knowledge source using large language models (LLMs). We use commercial off-the-shelf LLM, more specifically ChatGPT [20]. ChatGPT is not explicitly fine-tuned on network traffic data; but, as a foundation model, may have been trained on openly available data from the Internet. Please refer to §A.1 for details on the specific model (and snapshot) we use for labeling.

• **Instruction Following.** To ensure the LLM understands the structure of input data and properly follows the subsequent instructions, we compose system prompts §A.2 that are shared by all incoming inference requests (including labeling and rule extraction). The system prompts precisely state the objective of the application (e.g., flag malicious traffic for intrusion detection) and enumerate the names and meanings of each feature in the network dataset.

> **In-context Learning Prompt (P1):** To begin with, here are some labeled flows for your reference later. The last field is the binary label (0 for benign and 1 for malicious): `[Flows, their features and labels go here]`. Next, I will give you some unlabeled flows for labeling. Please let me know if you understand the requirement by answering yes or no.

• **In-context Learning.** We take advantage of in-context learning [36, 90] to improve LLM's ability to label network data (or packets) with higher accuracy without (re)training or fine-tuning the original model. We provide a few labeled examples from the CIC-IDS2018 dataset [98]. The network traffic in these examples contains similar attack types (such as brute force attacks and DDoS attacks) to those present in the evaluation dataset (CIC-IDS2017). However, it is collected from a different network and at a different time. Using these labeled examples, we construct an in-context learning prompt (P1) shared by all subsequent inference requests.

> **Data Labeling Prompt (P2):** Please give me a label for each of these unlabeled flows. No explanation or analysis needed, label only; one flow on each line. Format for each line: (flow number) label. `[Flows and their features go here]`.

• **Data Labeling.** Whenever we invoke the `label()` function, we first compose a labeling prompt (P2). This prompt specifies the expected response format, facilitating easy parsing of responses for per-packet labels. Additionally, it includes all the data to be labeled, and structured in accordance with the system prompt. We concatenate the system prompt, the in-context learning prompt, and the labeling prompt, and submit an API request to the LLM.

> **Rule Extraction Prompt (P3):** To begin with, here are some example input flows for your reference later. `[Flows and their features go here]`. Based on these example input flows, can you do some analysis and help me come up with some rules or heuristics (in the form of a Python function) to determine if an unlabeled flow is benign or not? Make sure that in the Python function, you label a flow as malicious only when you are very confident. Name the function `label_flow_with_rule_cache()`, and pass it in a format that can be executed by `exec()`. The input of the function should be the 16 features in the system prompt (in order), and the output should be 0 (benign) or 1 (malicious).

• **Rule Extraction.** To extract rules to store in the labeling rule cache for fast and resource-efficient labeling, we construct a rule-extraction prompt (P3). This prompt explicitly requests the LLM to generate rules and heuristics for data labeling as a Python function, specifying the expected input/output formats to simplify the parsing of the generated responses. §A.3 shows an example function generated by the LLM for fast labeling.

5 Evaluation

In our evaluation, we show: (a) using three different choices of knowledge sources, Caravan is able to efficiently label new incoming network traffic for the purpose of model validation and retraining, and can achieve almost the same level of inference accuracy gains compared to using ground-truth labels (§5.2.1). (b) Caravan's accuracy proxy and retraining trigger allow us to efficiently determine when to initialize or stop retraining. As compared to continuous retraining, the use of accuracy proxy and retraining trigger has the potential to reduce GPU compute cost by an average of 74.55% without significantly hurting inference accuracy gain (§5.2.2). (c) In software simulation (§5.3.1), Caravan is able to achieve a 30.3% improvement in F1 score (on average) compared to static offline models across three chosen applications. Caravan's accuracy proxy and retraining trigger enable 61.3% saving in GPU compute time (on average) for retraining without significantly compromising inference accuracy gains. (d) In the end-to-end Taurus FPGA testbed (§5.3.2), Caravan continuously keeps in-network ML models up-to-date with changing traffic dynamics and maintains high inference accuracy at network line-rate. With accuracy proxy and retraining trigger, Caravan improves over static models in terms of F1 score by an average of 30% with 56.23% less CPU usage and similar memory footprint as continuous retraining baselines.

5.1 Experiment Setup

Use Cases. To evaluate Caravan, we select two network traffic analysis applications widely used and evaluated by prior work in the domain of in-network ML (Table 1). (a) *Network Intrusion Detection*: The goal is to flag network flows or network packets regarding whether they involve malicious activities. We expect the in-network ML model to offer a preliminary analysis of the network flows through binary classification before running more expensive downstream security analysis instead of providing complete end-to-end protection of a networked system. This application is an example of how in-network ML could improve the *security* of networked systems. (b) *IoT Traffic Classification*: The goal is to assign an IoT device type to a network flow or packet. Classification results from the in-network ML model enable operators to know what different flows might entail (e.g., application or data type) early in the network, and to act correspondingly based on different devices, applications, or data types to optimize for the quality of service (QoS) or user quality of experience (QoE). For example, network flows from video cameras might require allocation to a less congested network path, since the user will likely be in a live video conference. In this case, fewer packet retransmissions and lower latency are critical to good user perception of video and service quality. This application is an example of how in-network ML could improve the *performance* of networked systems.

Datasets and In-network ML Models. We closely follow prior work in the domain of in-network ML when choosing datasets and in-network ML models. A summary of these datasets and related statistics is available in Table 1.

For network intrusion detection, we follow prior work [101, 125] to use CIC-IDS2017 [98] and UNSW-NB15 [84]. With CIC-IDS2017, we use the same features from pForest [37] and a deep neural network with similar architecture to the one from Taurus [104]. With UNSW-NB15, we use the same features and one of the deep neural networks from the intrusion detection example of N3IC [101]. For IoT traffic classification, we follow prior work [101,125] to use UNSW-IoT [102]. For the in-network ML model, we follow the IoT traffic classification example of N3IC [101] in terms of feature selection and model architecture. For multi-class classification, we use one of N3IC's four-layer deep neural networks, which have 16, 64, 32, and 10 neurons on each layer, respectively; we replace the binary weights with 32-bit weights.

Choices and Configuration of Knowledge Sources. We choose three knowledge sources for the labeling agent to use. (a) A *DNN-based classifier* for intrusion detection on CIC-IDS2017: The DNN-based classifier has 8 layers and 13,222 parameters in total. The architecture is similar to a stacked autoencoder in DeepPacket [78]. It is trained on a small part of CIC-IDS2017 (a subset that is not used during testing) and a small part of CIC-IDS2018 [98] (a different intrusion detection dataset from the same publisher). (b) A *large language model* for intrusion detection on UNSW-NB15: The large language model is based on GPT-4 [87] text completion APIs. We program the user prompts properly so the language

Application	Dataset	# Samples	# Features	# Classes	# Drifts
Network Intrusion Detection	CIC-IDS2017 [98]	7,000	16	2	7
	UNSW-NB15 [84]	5,000	20	2	5
IoT Traffic Classification	UNSW-IoT [102]	108,000	16	10	9

Table 1: Network applications and datasets used in our evaluation with input features listed in §A.2 and [101]. A drift occurs in intrusion detection with the arrival of new attack traffic, and in IoT classification with unseen IoT device traffic.

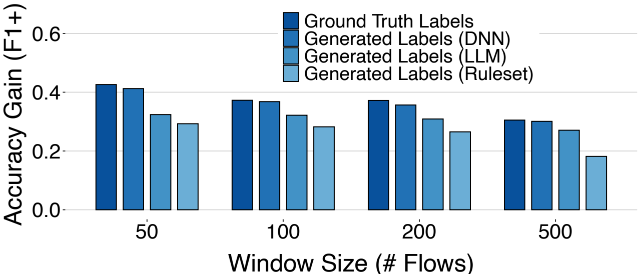

Figure 4: Caravan's labeling agent generates labels for online training, bringing comparable levels of accuracy gain as ground-truth labels across three different knowledge sources.

model can understand the particular format of our input network flows and generate labels in a format easily parsed by the labeling agent. To improve labeling accuracy, we take advantage of *in-context learning* and give the language model 10–20 labeled flows (not used during testing) for reference. (c) An *IoT device list* for IoT traffic classification on UNSW-IoT: We use the device list provided by the original dataset publishers. To ensure that the device list will generate strictly worse labels than the ground-truth labels, we modify the MAC address of some network flows so that the device list is unable label them. Overall, the device list can identify and label 10% of all the network flows in the dataset.

Quality and Usage Metrics. For accuracy, we use the F1 score [50] as the performance metrics for evaluating the quality of an in-network ML model. In machine learning, the F1 score is often preferred over basic metrics like classification accuracy. It provides a more nuanced measure of a model's performance, especially when class distributions are imbalanced or when the costs of false positives and false negatives differ. This preference for accuracy metrics aligns with previous research in the field [37, 101, 104, 122]. To better model the performance gain of the validation and online learning processes, we use the metrics of *accuracy gain*, defined as the increase in the F1 score of the retrained in-network ML model compared to that of the offline one. To determine the accuracy of a specific experiment, we first calculate an F1 score based on the model predictions and ground-truth labels at the end of each labeling window using the data from that window. Ultimately, we report the average F1 score, or the average increase in F1 score (i.e., F1+) compared to the offline model, as the final accuracy metric or accuracy gain.

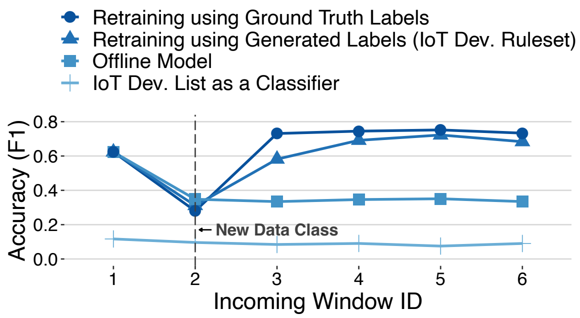

Figure 5: A comparison of generated labels using Caravan's labeling agent versus ground-truth labels for a low-accuracy and fast knowledge source (IoT device list) during data drift (i.e., encountering new data classes).

To quantify the system resource usage for online training, we use the metrics of *GPU compute time*, defined as the time spent on the GPU during online training. When using large language models as a knowledge source, we also use *tokens used for labeling* to demonstrate the cost of using an expensive knowledge source for labeling, defined to be the aggregate number of tokens (an addition of prompt tokens by the user and completion tokens by the language model) used for the labeling task.

End-to-End Testbed. We use the Taurus FPGA-based testbed [104] for end-to-end evaluation. A 32-port programmable Tofino Wedge100BF-32x switch [21] is used to sample packets for the control plane and manage the Taurus ML core, which is emulated as a bump-in-the-wire FPGA. The switch bypasses its internal traffic through the Xilinx Alveo U250 FPGA [3], which is used to emulate the in-network ML model. The control plane runs a process to perform model validation and retraining on the sampled packets and update the model weights in the FPGA via PCIe. It also runs the ONOS controller [18] and a Python REST API to install forwarding rules on the switch. Two 80-core Intel Xeon servers generate and receive traffic via ScaPy [19] or MoonGen [44]. The in-network ML model has been compiled to Verilog using the Spatial [70] compiler and installed on the FPGA for evaluations.

5.2 Microbenchmarks

5.2.1 Effectiveness of the Labeling Agent. We find that noisy labels and partial-coverage labels generated by imperfect knowledge sources can still lead to decent inference accuracy gains after online training.

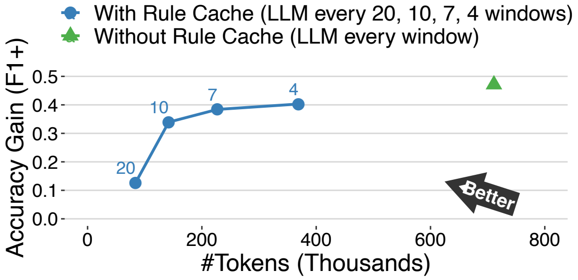

Figure 6: With a validation rule cache, CARAVAN conserves language model request tokens used for labeling, without significantly compromising the accuracy gains from retraining.

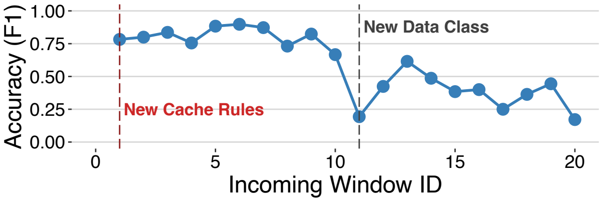

Figure 7: Though labeling rule cache generated by LLMs are subject to data drift, they generate accurate labels in a short local period of time.

Effectiveness of Noisy Labels. Noisy labels are defined to be labels that might be incorrect, and may be generated by knowledge sources like DNN-based classifiers or large language models in our case. Though these two knowledge sources (DNN-based classifier and language model) can generate a label for every sample of new incoming window when requested, we find that the overall quality of generated labels is around 0.7 to 0.8 in terms of F1 score on a small development set, indicating that there is a non-trivial level of noise in generated labels. We use these generated labels for a simple experiment of continuous online training, in which we skip validation and retrain at the end of every labeling window. We find that even with noisy labels, we are able to obtain a level of inference accuracy gain that is similar to the gain if we retrain with ground-truth labels under different labeling window sizes (Figure 4). The reason accuracy gain tends to decrease as window size increases is that we use a fixed number of 30 epochs for training; with larger training data sizes, it generally takes longer for the model to converge.

Effectiveness of Weak Supervision Labels. In the case of CARAVAN, weak supervision labels are defined to be labels that only cover a subset of all the samples in a labeling window and can be generated by low-accuracy but fast knowledge sources (e.g., an IoT device list) as discussed in §3.1.1. In our setup, the IoT device list can only label around 10% of all network flows in the dataset. To verify whether such a knowledge source can effectively mitigate model drift, we continuously retrain an ML model when new types of devices are present in the incoming data. We find that even with weak supervision labels that have partial coverage, we can achieve a comparable level of inference accuracy gain when data drift occurs (after the arrival of a new class) to that of retraining with ground-truth labels (Figure 5). At the same time, we find that the device list cannot be used independently to classify incoming data with high accuracy due to partial coverage, as depicted in Figure 5.

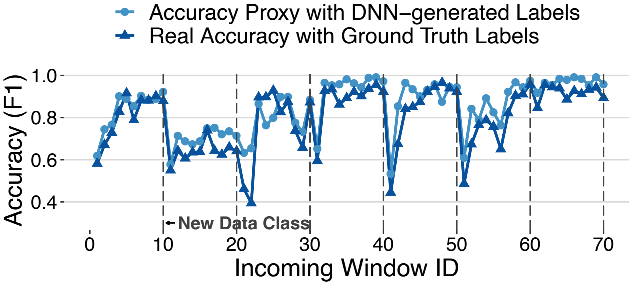

Figure 8: CARAVAN's accuracy proxy F1 scores align with the real F1 scores in terms of relative changes in accuracy on a temporal scale, particularly in instances of data drift.

5.2.2 Effectiveness of Labeling Rule Cache, Accuracy Proxy, and Retraining Trigger.

Labeling Rule Cache. As discussed in §3.1.1, when using expensive knowledge sources like large language models, we can request the knowledge source to generate temporary rules or heuristics in a rule cache that can be used for fast and cost-effective labeling for the following few labeling windows. In our experiment, we call language models for labeling and rule generation (in the form of a simple executable function) every 4, 7, 10, and 20 labeling windows. We use the generated function as the rule cache for labeling at the end of all other windows. By invoking the language model every 4, 7, or 10 windows, we achieve nearly the same level of inference accuracy gain after online training compared to employing language models for labeling at every window, while utilizing 65.4% fewer tokens on average (Figure 6). Note that the rules or heuristics in the rule cache can quickly go stale, especially in the case of a concept or data drift (Figure 7), so the rule cache should be updated frequently to avoid the generation of highly noisy labels.

Accuracy Proxy. We set up accuracy proxy in the same way as defined in §3.2.1, and verify if it is consistent with our insight that it can be used to reveal potential concept or data drifts even though it is not numerically equivalent to the real accuracy. In an incremental-class learning setup, where a new data class shows up in the incoming data every 10 labeling windows, we find that accuracy proxy is consistent with the real accuracy in terms of overall trend and relative changes in accuracy level on a temporal scale (Figure 8).

Retraining Trigger. To demonstrate the potential of using retraining triggers to avoid excessive retraining and save GPU compute time, we set up a window-based retraining trigger

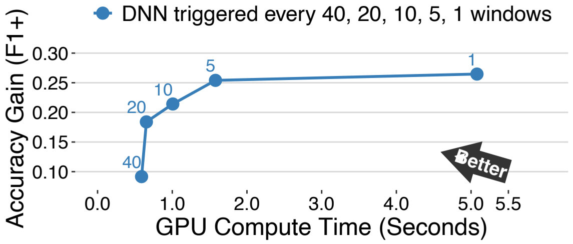

Figure 9: With a window-based retraining trigger, Caravan saves GPU compute time without significantly compromising retraining accuracy gain.

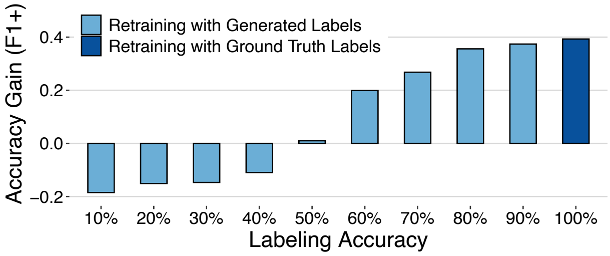

Figure 10: The relationship between Caravan's retraining accuracy gain and the labeling accuracy of the knowledge source. (Labeling accuracy is the percentage of data that can be correctly labeled by the knowledge source, compared to ground truth labels.)

that reduces the frequency of retraining from once every labeling window to once every 5, 10, 20, and 40 labeling windows. We observe that even with this straightforward retraining trigger, we manage to save an average of 74.55% GPU compute time, with at most a 0.05 reduction in inference accuracy gain in terms of F1 score when retraining occurs every 5 or 10 windows (Figure 9).

5.2.3 Sensitivity to External Knowledge Sources. Caravan assumes that users will be able to provide reliable knowledge sources that be adapted for data labeling. When inaccurate knowledge sources are used, the accuracy gain from Caravan's retraining may decrease and sometimes even drop below zero, as illustrated in Figure 10. We discuss potential solutions to this issue in §6.

5.3 End-to-End Improvement

We evaluate the end-to-end improvements of Caravan in software simulation and on the Taurus FPGA testbed [104].

5.3.1 Software Simulation. In software simulation, we find that Caravan is able to achieve a 30.3% improvement in F1 score (on average) as compared to static offline models across three chosen applications (Figure 12). We also find that the gap between inference accuracy gain of continuous online learning with ground-truth labels and with labeling-agent generated labels stays as little as 0.4–2.1% for intrusion detection with DNNs as knowledge source, and 0.5–1.8% for IoT traffic classification with device lists as knowledge source. Though that gap can be as large as 11% for intrusion detection with a large language model as a knowledge source, we believe that performance can be further improved when specialized network foundation models are used as knowledge sources in the future. Moreover, Caravan's accuracy proxy and retraining trigger enable 61.3% savings in GPU compute time (on average) for retraining without significantly compromising inference accuracy gain.

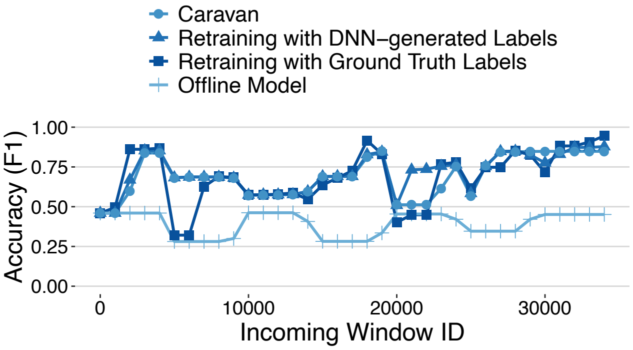

Figure 11: End-to-end results on the Taurus FPGA testbed. Caravan keeps in-network ML models up-to-date against changing traffic when operating at line rate.

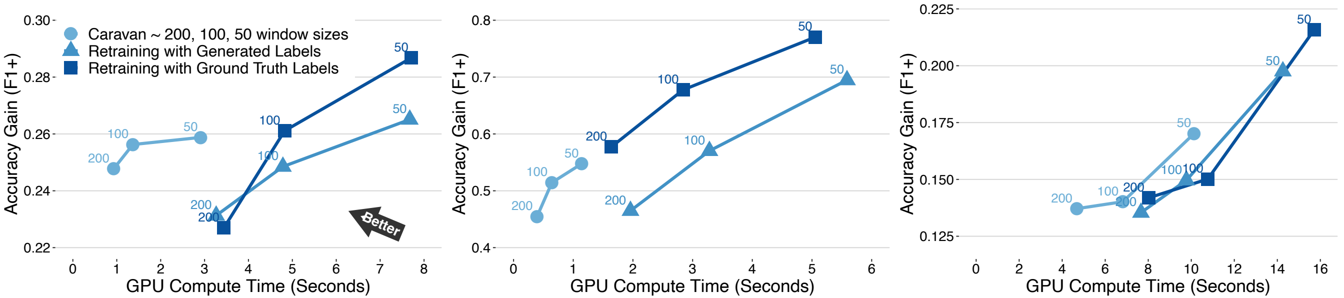
System	LUT%	FFs%	BRAM%	Power (W)
Taurus: Offline	6.49	4.35	4.15	16.86
Caravan	6.81	4.71	4.15	17.16

Table 2: Resource usage of Caravan's in-network model for intrusion detection on the Taurus FPGA testbed.

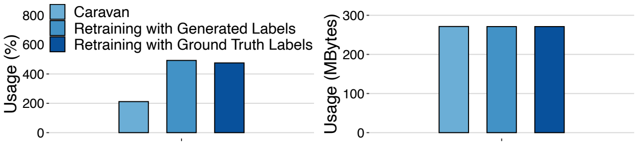
5.3.2 FPGA-based Experiments. In the Taurus FPGA testbed [104], we run an intrusion detection application with the same in-network model as in software simulation, programmed with Spatial [70]. We generate traffic by sampling 35 M packets from the CIC-IDS2017 dataset, while ensuring a uniform distribution of the seven attacks present in the dataset (i.e., 5 M packets for each attack). We preserve the order of the attacks as in the original dataset. Using Moongen [44], we send packets at 0.5 Million packets per second, and set the sampling rate to about 0.1%. Each labeling window receives about 500 packets. We find that Caravan can continuously keep in-network ML models up-to-date with changing traffic dynamics and maintain high inference accuracy under network line rate on a temporal scale (Figure 11). With accuracy proxy and retraining trigger, Caravan further improves upon static models in terms of F1 score by an average of 30%. It is worth noting that at times, the accuracy of Caravan can surpass that of the continuous retraining baselines. This is because continuous retraining for small in-network models may lead to overfitting, whereas Caravan's retraining trigger helps mitigate this issue.

5.3.3 Resource Usage & Latency Breakdown. Table 2 shows the FPGA's percentage resource count in terms of lookup tables (LUTs), flip flops (FFs), on-chip memory



(a) IDS with a DNN labeler on CIC–IDS2017 (b) IDS with an LLM labeler on UNSW–NB15 (c) IoT Classif. with Ruleset on UNSW–IoT

Figure 12: Tradeoff between inference accuracy gain and GPU compute time for CARAVAN and continuous retraining baselines across two applications (intrusion detection and IoT classification), three datasets, and three knowledge sources.



(a) CPU (b) Memory

Figure 13: CPU and memory usage of CARAVAN's busy-waiting process for labeling data, retraining model, and updating model weights.

Retraining Step	Latency (ms)
- Retrieving data from InfluxDB	6.041 ± 1.114
- Labeling data with DNN-based IDS	1.015 ± 1.238
- Computing accuracy proxy	1.732 ± 0.073
- Retraining in-network ML model	14.775 ± 0.982
- Installing new model weights	46.145 ± 0.507

Table 3: Latency breakdown of CARAVAN's retraining steps on a window of 100 packets for the network intrusion detection application.

(BRAM), and power (W). In contrast to the vanilla Taurus implementation (i.e., Offline ML) [104], which lacks support for online weight updates, CARAVAN introduces minimal additional overhead in FPGA resource usage while supporting live weight updates.

We also measure the CPU and memory usage of the CARAVAN's busy-waiting process that retrieves incoming data from a streaming database (i.e., InfluxDB), labels it, computes accuracy proxy, retrains models, and issues weight updates (§4). We see that CARAVAN reduces CPU usage by an average of 56.23% compared to continuous retraining baselines, without incurring any additional memory overhead (Figure 13). Table 3 further shows a breakdown of each these retraining steps in CARAVAN.

6 Limitations & Future Work

Optimizing Sample Selection for Online Learning. CARAVAN employs random sampling to reduce the volume of input data sent to the labeling agent. Existing research in online learning systems shows that network traffic is heavy-tailed and empirically variable [115], which could undermine the effectiveness of online learning in real-world deployments if training samples are not carefully selected [43]. While it is straightforward to modify the input data sampling and retraining data formation logic in CARAVAN, developing efficient and effective algorithms for online sample selection remains a future research direction that requires further understanding of both machine learning techniques and the characteristics of network traffic.

Reverting In-network ML Models. CARAVAN focuses on updating and improving models using continuous sampling of and selective retraining on the network's data, which lets them adapt to new events. However, in scenarios where data is compromised, it would be necessary to revert or reset these models to a previous good state. If online data (such as network traffic) is being used to retrain and update models, bad actors can poison training data by intentionally feeding bad traffic in the network. Future research may detect and protect against these attacks and restore models to a clean state.

Network Telemetry Data for ML. CARAVAN focuses on retraining models with sampled data but does not dictate how the collection of such data is performed. However, extensive research is needed on how to collect and sample data for the express purpose of retraining ML models. For instance, some data may not contribute to an increase in the fidelity of the model, even with further training iterations. In these cases, the data may simply be orthogonal to the task the ML model is built for. On the other hand, the system may need to sample more frequently in cases where notable network events are detected. For example, a server running out of resources may indicate a network attack that breaches security. Packets must be collected so as to classify and inoculate future ML models to these attacks. In short, collection systems for online training need to leverage dynamic sampling rates at various points throughout the network in order to ascertain when and where to get the best training data.

Creating Domain-Specific Knowledge Sources. In this paper, we repurpose GPT-4 as a knowledge source for network intrusion detection. We recognize that GPT-4 was not originally designed or trained for cybersecurity applications; instead, it is used primarily as a proof-of-concept foundation model for data labeling. An emerging research direction involves pre-training or fine-tuning domain-specific foundation models for networking or security on larger traffic traces (e.g., NetLLM [112], NetFound [54], Lens [110]). Another direction from the machine-learning community aims to enhance foundation models to better follow human intents and self-improve through feedback, whether human-generated or model-generated (e.g., constitutional AI [29] and self-improving LLMs [56, 61, 120]). These efforts could lead to developing knowledge sources that can generate accurate labels and better align with human expertise and intentions.

Evaluating and Validating Knowledge Sources. CARAVAN assumes that the provided labeling sources are sufficient to cover the space of input data for a given networking use case. As a next step, these labeling sources must be vetted further to ensure high-quality label generation. Common accuracy metrics such as F1, precision, or recall are all valid for assessing how well these labeling sources are performing (on a given dataset), but additional metrics are required to assess the full coverage of application space. For example, in a security context, how many of the commonly seen network attacks can the labeling source cover? Furthermore, the network community should start making its labeling sources public to allow retraining systems more effectively—similar to how various ML communities have put forth public collections of data and benchmarks. For instance, in the case of foundation models, public benchmarks feature open and comprehensive evaluations of models on specific applications, such as chat [124], code generation [74], and question answering [41]; these benchmarks help users select the best model for their particular use case. Finally, as suggested in Snorkel [92], multiple labeling sources can be aggregated for greater coverage and fidelity. In this way, aggregate labeling sources can generate more accurate labels than individual sources, effectively allowing a given source to cover the blind spots of another source.

Generalizing to Larger Control-Plane ML Models. Although CARAVAN is designed for online learning of in-network ML models, we believe that its core insights and techniques—such as using weak supervision for labeling data in an online setup, employing accuracy proxies, and utilizing retraining triggers to detect and mitigate model quality degradation—can be generalized to larger ML models deployed in the control plane. These control-plane ML models also face similar challenges like data or concept drifts [75] and a lack of labels for model monitoring and retraining in an online setup [53].

7 Related Work

Systems for Online Learning. Ekya [33] and RECL [67] discuss how online learning can be done for computer vision models on an edge server jointly with inference, while CARAVAN studies the case of in-network ML models in which data-plane inference does not interfere with control-plane online learning. Nazar [58] features how to mitigate data drift for ML models on mobile devices, and differs from CARAVAN as it does not address essential components of online learning (e.g., data labeling).

Data Collection and Generation for Networking. The emerging need to train ML models for networking tasks and design new network telemetry algorithms sparks extensive research in designing better tools for network data collection and network data generation. NetUnicorn [31] is a platform for collecting and actively labeling network data for developing offline generalizable ML models. It features a human-in-the-loop approach where users can select what data to collect and label, and it is different from our focus since CARAVAN features automatic online data labeling after ML models have been deployed. NetShare [118] enables synthetic IP-header generation for network flows but has a different focus from CARAVAN and does not study data labeling for downstream traffic analysis tasks.

Interpretability of ML Models. With the growth of ML models in networking, many existing efforts focus on the interpretation of these black-box models to make their decision-making logic transparent to network operators. For example, Trustee [62] proposes a framework that determines whether or not a given ML model suffers inductive biases by extracting a high-fidelity decision tree from the model being analyzed. However, such diagnosis of the ML models is not yet automatized and needs a human-in-the-loop. Indeed, CARAVAN can use Trustee as an orthogonal system component for diagnosing the behavior of the online learning model.

Programmatic Data Labeling. CARAVAN complements and augments (rather than competes with) existing data programming systems, such as Snorkel [92]. Snorkel uses generative models to estimate the accuracies of different knowledge sources, and can potentially be used for conflict resolution in CARAVAN's labeling agent. CARAVAN is similar to Snorkel in the aspect that both point out that weak knowledge sources can be used for labeling data and training ML models instead of using them for independent decision-making. However, CARAVAN focuses on how automatic data labeling helps online learning of ML models and mitigates drifts (by incorporating knowledge sources, accuracy proxy, and retraining trigger), while Snorkel focuses on enabling users to label datasets with multiple knowledge sources for training better ML models offline.

Weak Supervision in Networking. The concept of weak supervision has been extensively applied in networking, particularly in cybersecurity and internet measurement applications [47, 69, 86]. CARAVAN differs from these works by focusing on enabling weak supervision in an online setup to detect model quality degradation and retrain outdated models.

Label-free Data Drift Mitigation. Recent efforts in networking and security domains feature data drift mitigation with no need for labels. For example, CADE [117] proposes to train a neural network that can help determine if new incoming data has drifted away from training data. However, Caravan focuses on the continuous adaptation of an online model, where the training data are constantly evolving. Moreover, CADE uses root cause analysis to fix drifted models offline when there is no explicit requirement on how fast model update needs to happen, which is in contrast to Caravan's focus on the online setting when model updates must be done fast and automatically to keep up with the high inference rate. In summary, Caravan aims to be a more generalized framework designed for various in-network ML applications.

8 Conclusion

Once deployed online, in-network machine learning (ML) models can experience accuracy degradation owing to fluctuations in traffic patterns and changes in online data distribution. While online learning is a promising solution, it is challenging in practice due to the need for automatic labeling of evolving network traffic and the efficient monitoring of model performance degradation. To overcome these challenges, we present Caravan, the pioneering system for practical online learning of in-network ML models. Caravan addresses the issue of labeling new incoming traffic data for retraining by leveraging diverse knowledge sources that, otherwise, are unsuitable for real-time decision-making. Moreover, Caravan introduces the accuracy proxy metric to monitor model degradation and potential data drifts, providing an effective signal to trigger model retraining. Our evaluation shows that Caravan can keep in-network ML models up-to-date, achieving a 30.3% improvement in F1 score (on average) and reducing GPU compute time for training by 61.3% (on average), while achieving similar accuracy gains as continuous retraining. We hope the development of such a system will not only contribute to the domain of ML for networking and traffic analysis applications but also influence the design of practical and efficient machine-learning systems in general.

A Details on LLM-based Knowledge Source

A.1 Model Choice & Reproducibility

We use the `gpt-4-1106-preview` model snapshot from the OpenAI API service as the LLM—the latest model available at the time of implementation and evaluation of Caravan. We anticipate that future model snapshots released by OpenAI (such as `gpt-4-turbo` and `gpt-4o`) or Google (such as `Gemini Ultra` and `Gemini Flash`) could be adapted for data labeling using similar prompts, as long as the model supports a sufficiently large context window. The same would hold true for emerging open-source LLMs, such as those from Meta (e.g., Llama 3 series [16]) and Mistral AI (e.g., Mixtral 7B [64]).

The behavior of commercial LLM APIs may evolve over time, even using the same model snapshot and prompts [39]. To ensure reproducibility, one strategy would involve leveraging open-source LLMs instead of third-party APIs. However, these LLMs necessitate high-end GPUs or aggressive compression before deployment; we do not use these in our paper. Another approach is to decrease the temperature [22] during the generation process to minimize variability across different runs when utilizing third-party APIs.

A.2 System Prompts

a. System Prompt (UNSW-NB15): You are an expert in network security. The user is now labeling a network intrusion detection dataset, and he/she wants to assign a binary label (0 for benign or 1 for malicious) to each traffic flow in the dataset based on each flow's input features. He/She will give you a few labeled flows for reference, and you will then help him/her label another few unlabeled flows. Feel free to use your own expertise and any information the user gives you. These are the features of the input flows and meanings of the features: dur (record total duration), proto (transaction protocol, which will be categorized), sbytes (source to destination transaction bytes), dbytes (destination to source transaction bytes), sttl (source to destination time to live value), dttl (destination to source time to live value), sload (source bits per second), dload (destination bits per second), spkts (source to destination packet count), dpkts (destination to source packet count), smean (mean of the packet size transmitted by the src), dmean (mean of the packet size transmitted by the dst), sinpkt (source interpacket arrival time (mSec)), dinpkt (destination interpacket arrival time (mSec)), tcprtt (TCP connection setup round-trip time), synack (TCP connection setup time, the time between the SYN and the SYN_ACK packets), ackdat (TCP connection setup time, the time between the SYN_ACK and the ACK packets), ct_src_ltm (no. of connections of the same source address in 100 connections according to the last time), ct_dst_ltm (no. of connections of the same destination address in 100 connections according to the last time), ct_dst_src_ltm (no. of connections of the same source and the destination address in 100 connections according to the last time).

b. System Prompt (CIC-IDS2017): You are an expert in network security. The user is now labeling a network intrusion detection dataset, and he/she wants to assign a binary label (0 for benign or 1 for malicious) to each traffic flow in the dataset based on each flow's input features. He/She will give you a few labeled flows for reference, and you will then help him/her label another few unlabeled flows. Feel free to use your own expertise and any information the user gives you. These are the features of the input flows and meanings of the features: flow IAT min (minimum packet inter-arrival time in microseconds), flow IAT max (maximum packet inter-arrival time in microseconds), flow IAT mean(average packet inter-arrival time in microseconds), packet length min (minimum packet length), packet length max (maximum packet length), packet length mean (average packet length), total packet length (total packet length), number of packets (total number of packets in the flow), SYN flag count (number of TCP SYN flags), ACK flag count(number of TCP ACK flags), PSH flag count (number of TCP PSH flags), FIN flag count (number of TCP FIN flags), RST flag count (number of TCP RST flags), ECE flag count (number of TCP ECE flags), flow duration (duration of flow in microseconds), and DST port (destination port).

A.3 A Rule Extraction Output by LLM

In Figure 14, we show an example heuristics-based labeling function generated by the LLM, based on 500 unlabeled flows from the UNSW-NB15 dataset. The model generates all comments along with the function.

A.4 Concerns Regarding Data Contamination

In the domain of machine learning, data contamination [79] occurs when pre-trained language models, trained on extensive web-based datasets, inadvertently incorporate downstream test sets into their pretraining corpus. This phenomenon can lead to biases in evaluation metrics and diminish the generalization capacity of large language models. In Caravan, the issue of data contamination is also pertinent, as we adhere to previous methodologies by utilizing public datasets for evaluation.

While it is not feasible to entirely eradicate the issue of data contamination through retraining a new model from scratch, we implement the following measures to mitigate its potential impact on our evaluation: (a) We ensure that the LLM never generates *trivial* labels, meaning labels that precisely match the ground truth labels. (b) We carefully examine the labeling rule functions produced by the LLM to ensure they do not generate labels through *memorization* based on features, such as IP address.

B Artifact Appendix

B.1 Abstract

The artifact includes the software simulation and the FPGA/P4 testbed we built for implementing and evaluating Caravan. We also include a detailed guide with step-by-step

```python
def label_flow_with_rule_cache(flow):
    """
        Labels a network flow as benign (0) or malicious (1) based on certain heuristics.
        This function is designed to be conservative and only labels a flow as malicious when it is highly confident.

        :param flow: A tuple containing features of the flow.
        :return: An integer label, 0 for benign and 1 for malicious.
    """

    # Unpack the flow features
    dur, proto, sbytes, dbytes, sttl, dttl, sload, dload, spkts, dpkts, smean, dmean, sinpkt, dinpkt, tcprtt, synack,
    ackdat, ct_src_ltm, ct_dst_ltm, ct_dst_src_ltm = flow

    # Define thresholds and conditions for a flow to be considered malicious
    # These thresholds are derived from cybersecurity expertise and unlabeled data provided
    conditions = [
        # If the source to destination time to live value is maximum (255) and the destination to source packet count
        # is 0, it is likely to be a scan or a DoS attack.
        sttl == 254 and dpkts == 0,

        # If the number of connections to the same source address in the last 100 connections is high (above 30),
        # it might indicate a scanning activity or a distributed attack.
        ct_src_ltm > 30,

        # If the number of connections to the same destination address in the last 100 connections is high (above 30),
        # it might indicate a scanning activity or a distributed attack.

instructions for automatically running the key experiments and plotting the figures presented in the paper.

B.2 Scope

The `simulation/` folder contains the source code to automatically run key experiments from the paper and reproduce the corresponding figures (i.e., Figures 4–10, 12). The `testbed/` folder contains the new code changes and the instructions to set up and run the FPGA/P4-based evaluations for CARAVAN.

B.3 Contents

The artifact is provided as a self-contained repository available at https://github.com/Per-Packet-AI/Caravan-Artifact-OSDI24.

- **`simulation/`** contains the software code for reproducing evaluated figures, with automation scripts for generating data and producing figures located at `simulation/scripts/experiments.sh` and `simulation/scripts/plots.sh`, respectively.
- **`testbed/`** contains a modified version of the Taurus FPGA testbed [104] for testing CARAVAN's use cases.

B.4 Hosting

CARAVAN is hosted on GitHub: https://github.com/Per-Packet-AI/Caravan-Artifact-OSDI24.

B.5 Requirements

Hardware. CARAVAN requires at least an 8-core server with 16 GiB of RAM, one CUDA 12.1-compatible GPU (e.g., Nvidia V100), along with Internet connectivity to access OpenAI API endpoints. We recommend using a Google Compute Engine (g2-standard-8) instance.

Software. CARAVAN runs with Python version 3.10 or later with CUDA support. The complete list of dependencies is available in `simulation/pyproject.toml` and gets installed automatically using `pip install -e .` from the `simulation/` directory.

nnScaler: Constraint-Guided Parallelization Plan Generation for Deep Learning Training

Abstract

With the growing model size of deep neural networks (DNN), deep learning training is increasingly relying on handcrafted search spaces to find efficient parallelization execution plans. However, our study shows that existing search spaces exclude plans that significantly impact the training performance of well-known DNN models (e.g., AlphaFold2) under important settings, such as when handling large embedding tables in large language models.

To address this problem, we propose nnScaler, a framework that generates efficient parallelization plans for deep learning training. Instead of relying on the existing search space, nnScaler advocates a more general approach that empowers domain experts to construct their own search space through three primitives, `op-trans`, `op-assign`, and `op-order`, which capture model transformation and the temporal-spatial scheduling of the transformed model of any parallelization plans. To avoid space explosion, nnScaler allows the application of *constraints* to those primitives during space construction. With the proposed primitives and constraints, nnScaler can compose existing search spaces as well as new ones. Experiments show that nnScaler can find new parallelization plans in new search spaces that achieve up to 3.5× speedup compared to solutions such as DeepSpeed, Megatron-LM, and Alpa for popular DNN models like Swin-Transformer and AlphaFold2.

1 Introduction

Deep neural networks (DNN) have shown remarkable success [2, 27, 35]. However, training a large DNN model today requires resources far exceeding the capacity of a single computing device, such as a GPU. Therefore, a common practice has been to partition a large model, schedule the partitioned model to a large number of GPUs, and then construct a well-coordinated execution plan across the GPUs (i.e., a parallelization plan) for deep learning training [24, 26, 39].

It is challenging to find an efficient parallelization plan for DNN model training. A DNN model is often represented as a data flow graph (DFG) that can consist of thousands of nodes [56], with each node representing a DNN operator, e.g., matrix multiplication. A parallelization plan requires deciding on a partitioning choice for each operator, which can have many different partition choices [26]. Additionally, each partitioning choice for all operators in the DFG further requires the selection of a spatial-temporal scheduling scheme from many scheduling options designed for thousands of GPUs. This creates a vast *search space* with prohibitive combinatorial complexity for identifying an effective parallelization plan that dictates model partitioning and scheduling.

Due to the immense search space, model training often depends on carefully designed parallelization plans. For example, Megatron-LM [50] incorporates the well-known, parameterized parallelization plans known as data/tensor/pipeline parallelism to support GPT-like models (§2). This approach essentially constructs a few well-studied classes of parallelization plans within the large search space. More recently, Alpa [65] organized parallelization plan choices into a two-level hierarchical space, where the system first searches a parallelization plan on pipeline (inter-operator) parallelism and then on tensor (intra-operator) parallelism within each pipeline stage. This approach offers a larger search space and so often results in better parallelization plans. However, existing search spaces exclude several configurations in the parallelization plans (§2, §4.2). Our study shows that this limitation significantly impacts training performance on well-known models such as Swin-Transformer [35] and AlphaFold2 [27] (§8).

While existing work studies specific parallelization plans or searches within a carefully-crafted search space, we argue that domain experts should be empowered with the capability to *compose their own search space*. Given the wide variety of model architectures and the expansive domain knowledge of an expert, this approach could expose more parallelization opportunities. To this end, we propose three primitives, `op-trans`, `op-assign`, and `op-order`, that enable the com-

[*] This work was done when the authors were with Microsoft Research.

position of search space with arbitrary model partitioning (op-trans), as well as spatial (op-assign) and/or temporal scheduling (op-order) of the partitioned model. We show that existing parallelization plans or search spaces can be elegantly expressed by the three primitives with *constraints* on model partitioning and spatial-temporal scheduling. More importantly, with the new constraints, searching within the space composed by the three primitives can lead to new parallelization plans that significantly outperform those found in existing search spaces or specific parallelization plans. Essentially, the three primitives, along with the necessary constraints, represent a more general abstraction to characterize parallelization plans.

Based on the above insight, we built nnScaler, a framework that facilitates the search, generation, and optimization of parallelization plans for deep learning training. Domain experts first use nnScaler to construct the desired search space for parallelization plans through the three primitives (§3). Specifically, given a model, op-trans designates how each operator can be partitioned; op-assign denotes the placement of each partitioned operator on GPUs; and op-order specifies the preferred temporal order across multiple operators when they are assigned to the same GPU.

nnScaler also allows the application of *constraints* to the primitives (§4). An example of a constraint applied to op-trans is one that only evenly splits an operator into 2, 4, 8, and 16 partitions. The use of constraints, especially those leveraging the characteristics of DNN models (e.g., the large embedding table in §4.2), greatly reduces the search space. As a result, with proper search policies applied to such a constrained search space (§5), nnScaler can discover unconventional parallelization plans that significantly outperform existing ones.

Given the sophisticated model partitioning and spatial-temporal scheduling enabled by nnScaler, a parallelization plan may deviate significantly from the original dataflow graph representing the DNN model. To ensure the correctness of a generated plan, nnScaler introduces vTensor-pTensor (§6), a tensor abstraction that tracks the "lineage" across operators before and after partitioning. This allows nnScaler to maintain correct data dependency during graph partitioning and detect cycles in the graph that could lead to deadlocks, thereby excluding invalid plans. Moreover, vTensor-pTensor also enables automatic communication adaptation when an operator is split and assigned across multiple devices. Finally, nnScaler lowers the discovered parallelization plan into executable code, enabling parallel deep learning training on each device.

Implemented based on PyTorch [43], nnScaler demonstrates great power and flexibility, facilitating the discovery of new parallelization plans (§4.2, §8) that achieve up to 3.5× speedup over existing parallel training systems, such as DeepSpeed [47], Megatron-LM [39], and Alpa [65], for popular deep learning models in computer vision (Swin-Transformer [34]), language translation (T5 [45]), and biological analysis (AlphaFold2 [27]). nnScaler has been used to develop, train, and finetune next generation deep learning models across Microsoft. The code is available in [5].

2 Background and Motivation

Search space for parallelization plans. A parallelization plan refers to a training execution plan that specifies the model partitioning and corresponding spatial-temporal scheduling scheme on a given set of GPUs. Training a large model with hundreds of billions of parameters requires thousands of GPUs [9]. A large model may consist of approximately 100 layers, each representing a sub-neural architecture (e.g., attention [58]) with tens of operators handling tensors with tens of thousands of dimension size (e.g., the hidden dimension). The vast partitioning choices (for a large model) and the enormous spatial-temporal scheduling choices (on a large number of GPUs) combine to create a prohibitively large, combinatorial search space for parallelization plans.

Existing approaches rely on well-studied, handcrafted parallelization plans or search space to address this problem. For example, *data parallelism*, a special parallelization plan, partitions an operator along the batch dimension of its associated tensors. These partitioned operators are then replicated across multiple devices (GPUs) and shared with the same model parameters (weights) to enable concurrent model training.

Tensor parallelism is a class of more general plans that permit the partitioning on dimensions not limited to the batch dimension [26, 50, 59]. This approach allows the partitioned operators to be distributed across different devices, accommodating models too large to fit into a single device.

As a large DNN model typically consists of multiple layers, it is also possible to partition a model into multiple stages, with each stage containing one or several layers. The stages are placed on different devices and executed in a pipeline, hence the name *pipeline parallelism*. To improve pipeline efficiency, a batch of training samples is further divided into micro-batches, and are then executed following a carefully designed temporal order [18, 24, 30].

The aforementioned parallelism schemes can be combined into a new scheme, known as *3D parallelism*, to further improve training efficiency. Megatron-LM [39] incorporates 3D parallelism, which integrates data, tensor, and pipeline parallelism in a parameterized manner to support GPT-like models. Given N devices, Megatron-LM partitions a model into K stages, with each stage divided into M partitions. The model is executed using K-stage pipeline parallelism and M-way tensor parallelism. For a sufficiently large N, Megatron-LM can also employ $(\frac{N}{M*K})$-way data parallelism to achieve further improvement in training performance. 3D parallelism represents a few well-studied classes of parallelization plans within the large search space.

Alpa [65] further generalizes these parallelism schemes to handcraft a two-level hierarchical search space. This hierarchy enables the use of efficient searching techniques like dynamic programming. Alpa has been shown to produce superior parallelization plans due to its larger search space, i.e., a combination of SPMD [61] (a generalized tensor-parallelism space) and pipeline parallelism.

Limitations of existing search space. Although existing handcrafted parallelization search space is shown effective for mainstream models with similar model architectures, it relies on assumptions that simplify the search and construction of parallelization plans. These simplifications, however, may exclude promising plans from considerations (§4.2).

In tensor parallelism, it is assumed that partitioned operators and their corresponding split tensors are distributed across *disjoint* devices. For example, to train a vision model with high fidelity images (e.g., [34]), tensor parallelism splits the large tensors associated with the large image and distributes the divided tensors among disjoint devices. This excludes cases where the split operators are placed on fewer devices, meaning multiple operators share one device and compute in a streamlined manner to reduce memory consumption and inter-device communication costs simultaneously [11] (detailed in §4.2 and §8).

Pipeline parallelism assumes that the training involves one forward pass and one backward pass. However, models like AlphaFold2 [17, 27] require three forward passes coupled with a single backward pass. This unconventional training approach renders existing pipeline parallelism [24, 38, 39] inapplicable.

Pipeline parallelism also assumes that different pipeline stages are spread across *disjoint* devices and prohibit any two stages from sharing the same set of devices through temporal multiplexing. For example, multi-lingual LLMs [45, 62, 64] often employ a large embedding table in the early computational stage in the model. This results in significant GPU memory consumption (>40%) but small computation utilization (<5%). Given the disjoint device assignments in pipeline parallelism (and also in tensor parallelism), the imbalance in hardware utilization is unavoidable.

The later handcrafted search spaces (e.g., [61, 65]) that combine tensor and pipeline parallelism (and others), inherit these assumptions and, therefore, suffer from the same limitations. This motivated us to design a more *flexible* method for space construction that can enable domain experts to find more effective training plans for their models (§3, §4, §5).

New challenges due to flexibility. Introducing a more flexible way to construct parallelization plan space brings new challenges. While existing frameworks like Megatron-LM [50], Alpa [65], and DeepSpeed [47] only implement a few well-studied partitioning, scheduling, and communications schemes that support parallelization plans in well-understood parallelization spaces, the new space could uncover new ways of operator partitioning, new operator scheduling with unconventional communication patterns. Furthermore, more flexible parallelization plans are less studied and hence could be error-prone. To address the above challenges, we designed a compiling process to detect and prevent potential errors in parallelization plans (e.g., cycles in a transformed DFG), and to generate the runtime code with efficient communication operations for the discovered parallelization plan (§6).

Primitives	**Usage**
`op-trans(op,algo,n)`	`algo` $\in$ `op.algos()` `n` $\in \mathbb{N}$, natural numbers
`op-assign(op,d)`	`d` $\in \mathbf{D}$, a set of devices
`op-order(op1,op2)`	`op1` executes before `op2`

Table 1: Primitives for parallelization space construction.

3 Parallelization Search Space Construction

A parallelization plan can be naturally expressed by the *model partitioning* and the *spatial-temporal* scheduling of the partitioned model. Correspondingly, nnScaler proposes three primitives, `op-trans`, `op-assign`, and `op-order` (summarized in Table 1), to capture the three aspects of a parallelization plan. Combined, the primitives can be used to compose any search space for a parallelization plan given arbitrary models and accelerator devices.

`op-trans`. `op-trans(op,algo,n)` transforms an operator `op` into `n` sub-operators according to a transformation algorithm `algo`, selected from the algorithm set corresponding to the type of `op`. For example, `matmul`$(A_{i,k}, B_{k,j})$, the matrix multiplication operator, can be partitioned into two `matmul` operators along dimension i of tensor A while replicating tensor B. In fact, most operators can be partitioned along a certain dimension (e.g., i or k in A or B) of the associated tensors and the computation of partitioned (sub) operators would remain the same as that of the original operators. Based on this observation, nnScaler implements the partitioning algorithms for the major operators in most DNN models. Domain experts can then reuse the desired algorithm via the `algos()` interface. nnScaler can also integrate custom transformation algorithms, such as those developed by domain experts, for any given operator. Note that the transformation algorithm can be more than just operator partitioning. For instance, an operator can be augmented by an additional recomputing operator or a memory-swapping operator to save memory [11, 23, 28, 41, 53]. In this paper, we use the term "transformation" and "partitioning" interchangeably.

`op-assign`. Given a set of devices $\mathbf{D}$ and an operator `op`, `op-assign(op,d)` denotes that `op` will be executed on the `d`-th device in $\mathbf{D}$.

op-order. When non-dependent operators, e.g., op1 and op2, are assigned to the same device, op-order(op1,op2) ensures that op1 must execute before op2. Execution order for non-dependent operators can play a vital role in training performance. For example, in pipeline parallelism, an operator in a pipeline stage can be partitioned into multiple micro-batches along the batch dimension. We denote these (sub)operators as op.mb$_1$, op.mb$_2$, etc., where mb$_i$ designates the corresponding microbatch ID. The operators op.mb$_i$ can be executed in an arbitrary order with regard to op.mb$_j$ ($i \neq j$). Nonetheless, various research shows that once these operators are being orchestrated carefully in temporal dimension, it is possible to minimize the pipeline "bubble" [24, 54] to significantly improve training efficiency.

With the three primitives mentioned above, domain experts can write Python codes to compose arbitrary search spaces for parallelization plans given any DNN model. These codes are not necessarily tied to specific DNN models. Consequently, nnScaler separates the model codes from the codes related to search space and search policy. Note that to ease programming efforts, op in the primitives can represent a sub-graph, where the primitive applies to each of the operators in the sub-graph.

Due to the flexibility of the primitives and the scale of large DNN models, the constructed parallelization search space often contains hundreds and thousands of operators with combinatorial search complexity. To address this issue, nnScaler allows domain experts to impose *constraints* when applying those primitives. These constraints can significantly reduce the search space (§4), thereby enabling effective search methods (§5).

4 Applying Constraints in the Search Space

In nnScaler, constraints are expressed as parameterized arguments to the primitives in Table 1. When all arguments become specific values, the whole space is reduced to a concrete parallelization plan. Below, we illustrate how well-studied parallelization plans like data, tensor, and pipeline parallelism can be expressed by using the three primitives and constraints (§4.1). Several new constraints that lead to novel parallelization plans are discussed in §4.2.

4.1 Constraints for Existing Search Spaces

Constraints for data and tensor parallelism. Table 2 shows the primitives and the associated constraints for data and tensor parallelism. Both data parallelism and tensor parallelism partition an operator evenly into n partitions. The partition is performed along a certain dimension, depicted by algo, where each partitioned sub-operator is assigned to a distinct device for concurrent execution, i.e., constraints ② and ③ in Table 2. Note that data parallelism always partitions along the batch dimension, hence the selection of algo is more restricted compared to tensor parallelism.

Primitives	Constraints
① sub-ops = op-trans(op,algo,n)	$n = \lvert \mathbf{D} \rvert$
② op-assign(sub-op$_i$,d$_i$) ③ op-assign(sub-op$_j$,d$_j$)	$d_i, d_j \in \mathbf{D}$, $d_i \neq d_j$

Table 2: Constraints for data and tensor parallelisms.

Constraints for pipeline parallelism. Given a device set $\mathbf{D}$, pipeline parallelism divides a model G in to sub-graphs G_i ($0 \leq i < \lvert \mathbf{D} \rvert$), where i denotes the i-th pipeline stage. And those sub-graphs will be assigned in disjoint devices, shown in Table 3.

To minimize the bubble, pipeline parallelism divides a batch of samples into micro-batches. A sub-graph, denoted as (G$_i$,n), operates on the the n-th micro-batch. We further denote a forward pass subgraph as fG$_i$ and a backward pass subgraph as bG$_i$, the constraints to schedule the well-known 1F1B [24] pipeline parallelism can be summarized in Table 4.

Primitives	Constraints
① op-assign(G$_i$, d$_i$) ② op-assign(G$_j$, d$_j$)	$d_i, d_j \in \mathbf{D}$, $d_i \neq d_j$

Table 3: Constraints for dividing a model G into $\lvert \mathbf{D} \rvert$ stages.

Primitives	Constraints
① op-order((fG$_i$,m),(fG$_i$,n)) ② op-order((bG$_i$,m),(bG$_i$,n))	$m < n$
③ op-order((fG$_i$,m+$ofst$),(bG$_i$,m)) ④ op-order((bG$_i$,m),(fG$_i$,m+$ofst$+1))	$ofst = \lvert \mathbf{D} \rvert - i$, $m \geq 0$

Table 4: Constraints for 1F1B schedule.

As illustrated in Figure 1, Constraints ① and ② in Table 4 ensure that: in stage i, the execution order of micro-batches must be the same for both forward and backward passes. That is, given any two micro-batches m and n, where $m < n$, fG_m should be executed before fG_n (①). The same applies to bG_m and bG_n in the backward pass (②).

Constraints ③ and ④ in Table 4 specify the subtle scheduling order of 1F1B. They define $ofst$, the offset with respect to the current stage. The earlier the stage in the pipeline, the larger the offset. Therefore, given G_i, the backward pass of the earlier microbatch should be executed later w.r.t. the forward pass (③). And the forward pass of the later micro-batch should be executed in adjacency to the backward pass of the earlier micro-batch (④).

The hierarchical combination of tensor parallelism and pipeline parallelism forms the space of Alpa [65], where tensor parallelism is nested within each stage of pipeline parallelism. This can be constructed by replacing d_i in the pipeline constraints in Table 3 with a set of devices D_i for each stage.

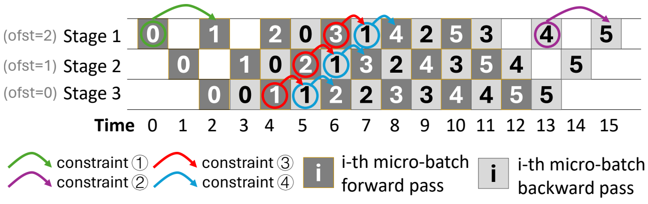

Figure 1: The constraints from Table 4 for 1F1B pipeline.

The stage is then applied with the constraints of tensor parallelism within D_i. For ease of exposition, the construction of this handcrafted parallelization space for certain sub-operators of a model, along with the constraints, is collectively defined in a general interface named `staged_spmd(ops, devices)`, to be used later.

4.2 New Constraints

In addition to existing search spaces, domain experts can apply new constraints to construct customized search spaces to search for new, more performant parallelization plans for various models, as we will elaborate next.

Constraints for Swin-Transformer. To enhance capability in vision tasks, there has been a growing trend to adopt higher resolution images to train large vision models such as Swin Transformer [34]. The use of larger images results in larger intermediate tensors during training, especially in the attention (Attn) and feedforward (FF) operators (for transformer-based models). It requires larger memory that a single GPU cannot accommodate.

Tensor parallelism is the standard practice used to address this issue. Given a pipeline, operators in Attn and FF are split and assigned to $|M_i|$ devices, where M_i denotes the set of devices accommodating operators in the i-th stage. Operators split by tensor parallelism are placed disjointedly, and so each device holds only one split operator. However, we observe that sometimes multiple split operators can share a single device and compute in a streamlined manner, resulting in fewer devices required for each pipeline stage and less memory consumption. Although the streamlined computing of multiple split operators may slow down the computing process, the reduced communications across fewer devices can lower cost and speed up the overall process.

Given any operator `op` from Attn and FF in stage i, let `sub_op` to be any transformed sub-operator of `op`. Suppose we allow C of such `sub_ops` to share one device, leading to a set of devices D_i assigned to stage i operators, where $|D_i| < |M_i|$. The constraints are as specified in Table 5. The rest operators can be described by the existing search space, namely the one defined in [65]. Note that C is a hyper-parameter where the value can be searched by the policy in §5.

Operators	Primitives	Constraints

`op` $\in$
 $\{\text{Attn} \cup \text{FF}\}$
	`sub_ops =`
	 `op-trans(op,algo,n)`
		$n = C \cdot \mid \mathbf{D}_i \mid$

	`op-assign(`$\texttt{sub\_op}^{j}_{i}$`,`$\texttt{d}_\texttt{i}$`)`	$0 \leq j < \lvert C \rvert$ $d_i \in \mathbf{D}_i$

Table 5: Constraints for Swin-Transformer.

Constraints for T5. Multi-lingual models such as T5 [45] often employ a large embedding table, say **E**, which contains vocabulary embeddings from multiple languages [64]. The table **E**, required only in the first and last layers of an LLM, incurs significant memory consumption but requires little computation cost. Pipeline parallelism would prioritize the device assignment to accommodate **E**, leaving the remaining devices for the other operators. This arrangement results in imbalanced hardware utilization, with devices containing **E** exhibiting low GPU cycle usage but high memory usage.

Thanks to nnScaler's three primitives and constraints, we can split **E** across the entire device set **D**. All other operators across all pipeline stages can then share the remaining resource left in **D** by constructing a search space following the conventional search space. These constraints, highlighted in Table 6, breaks the conventional assumption that operators in different pipeline stages cannot share the same set of devices. Similar solutions are also applicable to the training of graph neural networks [19].

Operators	Primitives	Constraints

`op` $\in \mathbf{E}$	`sub_ops =`
	 `op-trans(op,algo,n)`
	 `op-assign(`$\texttt{sub\_op}_\texttt{i}$`,`$\texttt{d}_\texttt{i}$`)`
		$n = \lvert\mathbf{D}\rvert$
		 $d_i \in \mathbf{D}$
		 $0 \leq i < \lvert D \rvert$

`ops` $\notin \mathbf{E}$	`staged_spmd(ops,` $\mathbf{D}$`)`	

Table 6: Constraints for T5.

Constraints for AlphaFold2. In AlphaFold2 [27], training each micro-batch requires three forward passes and one backward pass, i.e., 3F1B. Traditional 1F1B pipeline parallelism cannot support this type of pattern. As shown on the left side of Figure 2, a naive approach of training one micro-batch after another is inefficient due to pipeline bubbles and the accumulation of many unnecessary intermediate results. Therefore, we decided to interleave the forward and backward passes across different micro-batches while maintaining constraints on temporal orders. Let f_pG_i denote the forward sub-graph fG_i at the i-th pipeline stage in the p-th forward pass, and let *ofst* be $S - i$, where S denotes the total number of pipeline stages. Table 7 highlights the constraints for 3F1B.

Constraints ① and ② in Table 7 interleave the three forward passes of consecutive micro-batches in decreasing order. Constraint ③ specifies that the smallest micro-batch in the last executed forward pass should be executed before the corresponding backward pass sub-graph on a micro-batch ID with an offset (*ofst*) relative to the current stage, where *ofst* is defined similarly to that in Figure 1 of §4.1.

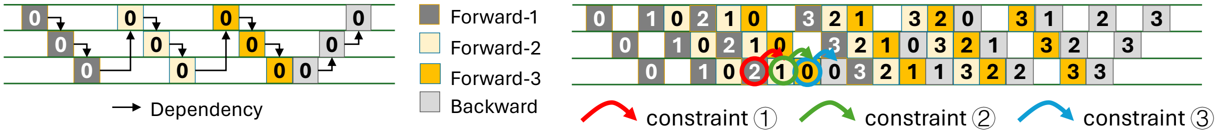

Figure 2: 3F1B schedule for AlphaFold2.

Primitives	Constraints
① op-order((f$_1$G$_i$,m+2),(f$_2$G$_i$,m+1))	$m \geq 0$
② op-order((f$_2$G$_i$,m+1),(f$_3$G$_i$,m))	$m > 0$
③ op-order((f$_3$G$_i$,m),(bG$_i$,m-ofst))	$m > ofst$

Table 7: Constraints for AlphaFold2.

In addition to Table 7, the search space for 3F1B also reuses the primitives and constraints in Tables 2 and 3. As shown on the right side of Figure 2, these constraints together form a space comprising unconventional parallelization plans that exhibit improved training performance (§8).

4.3 Discussion

Constraints are a powerful abstraction for customizing various parallelization plans and defining the search space for the plans. To design effective constraints, nnScaler assumes its users, usually domain experts, are knowledgeable on model architecture and parallel training. With such knowledge, it becomes intuitive to construct a search space using the three primitives. Based on our own experiences, effective constraints can be derived by identifying performance bottlenecks in the training, e.g., excessive GPU memory usage, computation/communication imbalance. The constraints can then be defined to alleviate the bottlenecks. And constraints can be refined iteratively along with the changing bottlenecks after the adjustment in constraints [33]. Through the refinement of constraints, nnScaler makes the generation of parallelization plans significantly easier than previous approaches.

5 Plan Search Policy

With the new user-defined search space, nnScaler incorporates a general policy framework to search for an efficient parallelization plan. As illustrated in Algorithm 1, the policy takes model graph G and a user-specified search space as inputs. We denote a space as C_{trans}, C_{assign}, C_{order}, corresponding to the three primitives op-trans, op-assign and op-order, along with augments associated with the constraints. The policy gradually shrinks the space with increasingly stringent constraints, ultimately reducing the space to a unique parallelization plan, denoted as C^{final}_{trans}, C^{final}_{assign}, C^{final}_{order}. A key feature of this policy framework is that it allows developers to "carve out" a sub-space from the new search space, where existing search polices are applicable. Specifically, the search process consists of two phases: operator partitioning and placement search, and temporal ordering search.

Algorithm 1: The policy framework of plan search.

```
Input: $G$, Model graph; $C_{trans}$, $C_{assign}$, $C_{order}$, the space
       defined by the primitives with constraints.
Output: $C^{final}_{trans}$, $C^{final}_{assign}$, $C^{final}_{order}$, that determine a concrete
        parallelization plan.
  /* Operator partitioning & placement search   */
  /* Subgraph search with existing search algo */
1 $G^{sub}$, $C^{sub}_{trans}$, $C^{sub}_{assign}$ ← GetSubSpace($G$, $C_{trans}$, $C_{assign}$);
2 $C^{new}_{trans}$, $C^{new}_{assign}$ ← Alpa($G^{sub}$, $C^{sub}_{trans}$, $C^{sub}_{assign}$);
  /* Search in the rest option space            */
3 $C_{trans}$, $C_{assign}$ ← ShrinkSpace($C_{trans}$, $C^{new}_{trans}$, $C_{assign}$, $C^{new}_{assign}$);
4 $C^{final}_{trans}$ $C^{final}_{assign}$ ← ILP($G$, $C_{trans}$, $C_{assign}$, objective=$eq.1$);
  /* Temporal ordering search                   */
5 $C^{final}_{order}$ ← Tessel($G$, $C^{final}_{trans}$, $C^{final}_{assign}$, $C_{order}$);
6 return $C^{final}_{trans}$, $C^{final}_{assign}$, $C^{final}_{order}$; /* a concrete plan */
```

Operator Partitioning and Placement Search. The goal of this phase is to evenly distribute computations across devices while minimizing communication costs. Various partitioning options for an operator yield different communication costs. For instance, partitioning the batch dimension involves an allreduce on parameters, while partitioning parameters leads to replicating input activation tensors across devices. Different placement options for operators also result in varying execution times for each device. Therefore, the execution time on a device d is the sum of its assigned operators' computation time $Comp_d$ and the associated communication time $Comm_d$. Overall runtime is dictated by the slowest device [54, 65], which is formulated as:

$$\text{minimize} \quad \max_{d \in \mathbb{D}} \{Comp_d + Comm_d\}. \tag{1}$$

By representing partitioning and placement options as integers, this optimization problem can be viewed as an integer linear programming problem, which is NP-hard.

With the application of constraints, the space in Equation 1 can be greatly reduced, thus enabling a faster search process (§8). nnScaler searches within a gradually reduced space by leveraging multiple policies. It firstly inspects the constructed search space and extracts a subspace (e.g., staged_spmd) that can leverage existing search policies like Alpa [65] through GetSubSpace (line 1 in Algorithm 1), an interface that reduces the search space through the input constraints. The extracted subspace may only consist of a subset of operators, leaving the rest operators undetermined. Once the transformation and placement decisions are made for the operator subset, the search space can be further reduced. Then, nnScaler fetches the reduced search space through `ShrinkSpace` (line 3 in Algorithm 1) and proceeds to use other policies (e.g., ILP solvers) within it, until finding the transformation and placement decisions for every operator.

For example, Table 5 reduces the operator assignment space to C operators per device; and Table 7 mainly specifies temporal order. The remaining subspace of these two cases can be organized like the space defined by `staged_spmd`. Additionally, Table 6 evenly pre-allocates the embedding table **E** to all devices evenly, with the remaining space corresponding exactly to `staged_spmd`. Consequently, the framework can apply the search policy in Alpa [65] to these sub-spaces to find a specific partitioning and assignment scheme for the involved operators (possibly a subset), i.e., C_{trans}^{new} and C_{assign}^{new} (line 2). These two new constraints, combined with their original versions, produce a smaller search space (line 3), where the framework can apply an ILP solver to find the final partitioning and assignment solution for the entire model, denoted as C_{trans}^{final} and C_{assign}^{final} (line 4). Note that as a general framework, users can replace the policies in Algorithm 1 by other search policies such as FlexFlow [26] or Tofu [59].

Temporal Ordering Search. After operator transformation and assignment, the temporal order of some operators is already specified by the data dependency in the transformed graph. However, it is possible for two operators on the same device to have no direct dependency, which means they can be executed in arbitrary orders. Moreover, for pipeline parallelism, the order of the same operator computed on different micro-batches within one batch is unspecified. nnScaler leverages Tessel [32], a state-of-the-art search policy, to determine the execution orders for these operators. Tessel groups operators within a micro-batch on each device into sub-graphs and formulates their execution order as an ILP problem. The optimization goal is to minimize the end-to-end execution latency of a mini-batch. Each sub-graph is assigned to an integer time slot, and the search, powered by Z3 Solver, enumerates possible order options without violating data dependencies. User-specified constraints on `op-order`, acting as Z3 constraints, play a crucial role in effectively reducing the search cost (line 5 in Algorithm 1).

Note that nnScaler does not claim contributions on individual search policies discussed in this section. It is the abstraction of primitives and constraints that makes the efficient search of parallelization plans possible.

6 Parallelization Plan Compilation

nnScaler compiles a model and the generated parallelization plan into executable codes, following the end-to-end process illustrated in Figure 3. The system first converts a deep learning model into a data flow graph, known as Graph IR. With the search space defined by the primitives and the associated constraints, nnScaler leverages a search policy to generate a parallelization plan. The plan compilation then applies the primitives and the constraints defined in the plan to the Graph IR. Data dependency tracking is performed during this step with the vTensor-pTensor abstraction. The resulting Graph IR, describing the new data dependency and the additional communication operations incurred due to operator distribution across devices, will be further materialized into parallel executable code.

Figure 3: System overview of nnScaler.

Tensor Abstraction vTensor and pTensor are introduced to track changing data dependencies during the application of the three primitives. As depicted in Figure 4, a pTensor represents a tensor in the original logical model; vTensors are the resulting tensors after applying the three primitives to the pTensor. A vTensor links to a pTensor and maintains a mask indicating the accessed portion of the pTensor that this vTensor represents. A pTensor can be associated with multiple operators. At the top of Figure 4, the output of operator `A` serves as the input for operator `B`. Both operators are linked to the same pTensor through their respective vTensors.

With vTensor, each operator can be transformed, assigned, and ordered independently. When applying an `op-trans`, nnScaler partitions vTensors through the "mask", leaving pTensors unchanged. For instance, in Figure 4, operator `A` only splits itself and its output vTensor, while the vTensor of operator `B` remains unaffected. For other type of primitives, vTensor's mask remains unchanged. Therefore, given a producer vTensor (e.g., in `A`) and a consumer vTensor (e.g., in `B`) that are linked to the same pTensor, nnScaler can detect whether they have data dependency by intersecting their masks. With a dataflow graph, each operator in the graph consumes and produces vTensors according to underlying pTensors, thus facilitating the fine-grained data dependency tracking. During runtime execution, only vTensors will be instantiated to real GPU tensor instances.

With the data dependency tracking enabled by vTensor-pTensor abstraction during data flow graph transformation, nnScaler can detect cycles in the new graph that leads to

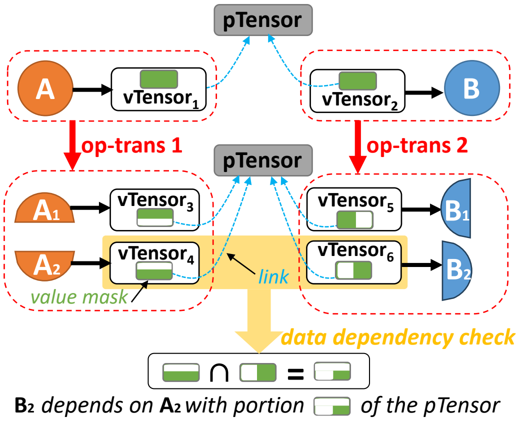

Figure 4: Tracks data dependencies with pTensor-vTensor.

deadlock, thus excluding invalid parallelization plans.

Data Dependency Materialization After applying primitives and constraints, nnScaler materializes the new data dependencies described by vTensor-pTensor into concrete data operations and communications. For a consumer vTensor (e.g., B_1 in Figure 4), nnScaler identifies dependent producer vTensors (e.g., A_1 and A_2) and inserts tensor manipulation operations, such as `torch.split` or `torch.chunk`, to extract the corresponding tensor fragments. When producers and consumers reside on different devices (due to `op-assign`), peer-to-peer send-recv communication operators [44] will be inserted during materialization.

To improve communication efficiency, certain communication patterns across vTensors within the same pTensor can be implemented using collective communication primitives, such as allgather, allreduce, or alltoall [44]. For instance, in Figure 4, communications between vTensors 3, 4 of A and vTensors 5, 6 of B can be materialized using the more efficient alltoall primitive. nnScaler employs simple pattern matching to identify appropriate collective primitives for each pTensor and its associated vTensors.

7 Implementation and Experiences

We implemented nnScaler based on PyTorch [43] with 24K lines of Python code. nnScaler takes a PyTorch model developed for a single device, and converts it into an intermediate graph representation (IR). After the transformation, the spatial-temporal scheduling, and the insertion of communications and tensor manipulation operations specified in a parallelization plan, each device will receive a sub-graph represented by the IR. nnScaler then converts the sub-graph back to a PyTorch code file. And PyTorch runs the code files (i.e., using `torchrun`) in parallel for distributed training.

To support a wide range of PyTorch models, nnScaler implements an augmented graph converter based on TorchFX [55], comprising 2,243 lines of Python code. This converter combines TorchFX's symbolic execution with value tracing of `torch.jit.trace` to handle control flow, which is a typical barrier when converting PyTorch models to TorchFX. By default, PyTorch models usually contain only the forward pass. nnScaler automatically completes the backward pass using autograd functionality with the chain rule [40]. So far, nnScaler has successfully converted 26319 out of 31301 (84.1%) PyTorch models from HuggingFace [25] Natural Language Processing tasks. The conversion failures are mainly due to unsupported operators, e.g., the custom operators designed for specific models. We are actively exploring way to support more operators, along with their corresponding transformation algorithms.

7.1 Experiences

nnScaler has been used by multiple projects across different teams in Microsoft to support the pretraining and fine-tuning of next generation DNN models on several generations of NVIDIA and AMD GPUs. This includes RetNet [51], YOCO [52], LongRoPE [16], Phi-3 series [7][1], and a large science foundation model consisted of a transform-based model combined with a graph neural network. The model size ranges from 3 billion to 92 billion parameters.

The decision to use nnScaler is based on two key factors. First, incorporating new models into existing distributed training frameworks presents intricate engineering challenges. This involves tasks such as the parallelization of the new modules, identifying suitable partition options, and ensuring the end-to-end training correctness, which includes tasks like data loading, gradient normalization (*gnorm*) [12], and optimizer. This process typically takes two experienced engineers about two months to complete. Compounding to the problem, existing parallelization plans often do not works well on new models, resulting in unsatisfactory Model FLOPs Utilization (MFU). Second, the research on new models often requires changes to model architectures, configurations, and training settings. This, in turn, may necessitate further adjustments to be made to the parallelization plan for efficient training, a daunting task for machine learning researchers. nnScaler precisely targets these pain points. Since nnScaler separates codes for the logical model from codes for the parallelization plan, it enables a separation of concerns: model developers can focus on model architecture innovations while system developers can study better parallelization plans. Moreover, our collaboration with these teams have yielded a number of insights, which will be discussed next.

Debugging nnScaler. nnScaler offers great flexibility in model training, but the new primitives and constraints also contribute to increased system complexity, rendering certain parallelization plans error-prone. nnScaler enables a modular approach to debugging system problems, where a new,

[1] nnScaler is used in some post training steps for the long context version of Phi-3, not for the model pretraining.

less-studied sub-graph generated by a new constraint can be replaced with a well-tested constraint. For instance, nnScaler can selectively apply data parallelism, which is less likely to have bugs, to a portion of the model while maintaining the existing parallelization plan for the rest of the model unchanged. This adjustment does not require model code modification; it simply configures the pre-build parallelization plan. By iteratively changing the suspected modules in the plan, it facilitates the identification of the problematic module.

Model accuracy. Achieving high model accuracy is the ultimate goal of model training. However, oftentimes, even a small bug in the training framework or model code can result in a degraded accuracy. Further complicating matters is that while the situation may appear normal in the early training stage, the loss curve tends to deteriorate over an extended training period (e.g., thousands of steps for a 7B LLM) and may eventually diverge. Directly comparing the loss and gradient values with well-tested training plans like data parallelism is impractical. For example, as the reduce operations (e.g., `matmul` or `allreduce`) in more complicated plans introduce drifts in floating-point values due to different orders of summation [20], which is an expected behavior. This makes it difficult to discern if it is an expected numeric deviation or a semantic bug. With respect to this issue, nnScaler firstly evaluates the correctness of a large-scale parallelization plan for a model by reducing the model's hidden dimension to fit the training in a single device. This makes debugging the correctness a much easier task. The model change is easily achievable by slight changes in the model code, thanks to the clean separation between the model code and training code. Subsequently we applied the searched parallelization plan to the reduced model and then assessed the overlap of the loss and gnorm curves with their counterparts in the well-tested data parallelism training. We observed that the gnorm curve is a good indicator, amplifying divergence at earlier stages and signaling potential bugs in the system.

In-place operators. To improve training performance, in-place operators like `Tensor.add_` update tensors in-place. However, partitioning in-place operators could become problematic. For example, if the partitioning of the in-place operator leads to the cloning of a tensor that originally implements in-place updates, the resulting non-inplace sub-operator would not preserve the original effect of the in-place operator's effect. This is due to a violation of the Static Single Assignment (SSA) form [14] when mixing in-place and non-inplace operators. To avoid this problem, nnScaler follows SSA during graph transformation, then replaces some of the non-inplace operators with their original in-place versions in the later optimization phase.

8 Evaluation

The evaluation of nnScaler covers the expressiveness of parallelization primitives and the search efficiency of parallelization plan with constraints. More importantly, we evaluated the performance of the newly searched parallelization plans on real-word models to demonstrate the effectiveness of the entire system in achieving efficient parallelization of new models and settings. In summary, the evaluation results show that:

- The parallelization primitives in nnScaler can construct various parallelization plans, including both existing handcrafted ones (§8.1) and newly innovated ones, as introduced in this paper(§8.2).
- End-to-end evaluation of the three novel parallelization plans on SwinTransformer, T5, and AlphaFold2 shows up to 3.5×, 2.5×, 1.4× speedup, respectively, compared to the baselines of Megatron-LM [39], Alpa [65], DeepSpeed [47], and DAP [13]. (§8.3)
- Parallelization space with constraints helps nnScaler quickly discover efficient plans, resulting in an 11.7× search speedup compared to the searches without constraints.

8.1 Expressiveness of Plan Construction

We evaluated the expressiveness of the three primitives for plan construction by implementing popular handcrafted parallelization plans listed in Table 8. These plans can be decomposed into operator transformation, placement and ordering, which is well aligned with the three primitives in Table 1. 14 out of 17 parallelization plans can be successfully supported by nnScaler. The parallelization plans under SPMD are implemented through `op-trans`. Data and flexible tensor parallelism can be easily supported. Transformer Parallelism and DAP are handcrafted tensor parallelisms for Transformer and AlphaFold2, respectively. Sequence Parallelism and ZeRO stage-3 are special tensor parallelisms, that decouple the partitioning of the operator and its input tensor to optimize memory usage. nnScaler supports them by inserting an `identity` operator between the input tensor and its operator through `op-trans`, facilitating easy decoupling.

The parallelization plans under MPMD are different types of handcrafted pipeline parallelism. They can be supported using `op-order` without implementing a new execution engine. Notably, nnScaler does not support PipeDream due to its asynchronous training method, as nnScaler respects the original training semantics of a model. For TeraPipe, nnScaler currently lacks access to concrete values in tensors, preventing it from determining data dependency at the token level (*i.e.,* tensor masks), a requirement for TeraPipe. In the future, nnScaler can implement TeraPipe through instrumentation tools for deep learning models like [21].

Beyond parallelisms, nnScaler also accommodates memory optimization techniques (e.g., recompute, swap) and the overlapping of computations and communications. Its support of recompute relies on a customized `algo` of `op-trans`

to transform an operator to its recompute version, similar to `torch.utils.checkpoint` in PyTorch [6], while deferring the materialization to the compilation phase. nnScaler does not support ByteScheduler [42], which overlaps two consecutive mini-batches. This is because the boundary of transformation and scheduling in nnScaler is a single mini-batch, though it could potentially be extended to multiple mini-batches.

8.2 Plan Search Results

With the new constraints described in §4.2, nnScaler searches within each constructed space and discovers three novel parallelization plans that show superior training performance.

Coshard. Figure 5 illustrates Coshard, which is used for models with large tensors like SwinTransformer. It can co-exist with tensor parallelism to reduce peak memory of activation tensors. For example, A_1 is partitioned into two, placed on the same device, and executed sequentially. After applying recompute of A_1, the peak activation size of A_1 is halved. Due to the reduced peak memory, tensor parallelism can now span fewer devices (e.g., from 8-way to 4-way), reducing communication cost.

Interlaced pipeline. Figure 6 shows the pipeline schedule searched under the constraints specified in Table 6. The embedding layer is partitioned across four devices using tensor parallelism. The remaining components (i.e., non-embedding layers) are separated to distinct device groups following `staged_spmd`. During the ordering search, all the layers compose into a schedule that resembles executing embedding layers and an 1F1B-like schedule following a time-sharing pattern. There are two columns with 0-th embedding because the embedding layer is used twice, one at the beginning of the model and the other at the end. Thanks to the scheduling search, the pipeline can reach a stable phase with zero bubbles as shown on the right of the figure.

3F1B pipeline. Figure 2 displays the timeline for the 3F1B pipeline which has been described in §4.2. The constraints outlined in Table 7 define how forward and backward passes interleave in the stable state of the pipeline. The schedule for the warm-up and cool-down phases remains unspecified. These phases are tailored through the search process.

8.3 End-to-End Performance

We evaluate the three new parallelization plans on Swin-Transformer, T5, and AlphaFold2, respectively, with different model configurations and on varying number of GPUs.

8.3.1 Experimental Setup

Machine configurations. Our evaluation is performed on DGX-2 clusters with 32 NVIDIA Tesla V100 (32GB) GPUs. Each server is equipped with 16 GPUs that are connected via NVLink [4]. Servers are interconnected with 8 InfiniBand 100 Gbps network adapters. All the servers are installed with NCCL 2.14 [3] and PyTorch v2.0.1 [43]. As 8 × 100 Gbps InfiniBand is a high-end hardware configuration, we also demonstrate the training performance on commodity hardware that is prevalent in many organizations [8]. Specifically, we conducted experiments on DGX-1 clusters with 32 NVIDIA Tesla V100 (32GB) GPUs, each equipped with 1 InfiniBand 100 Gbps network adapter in §8.3.5.

Model configurations. Table 9 summarizes the configurations of SwinTransformer, T5, and AlphaFold2, each of which has four different model configurations ranging from small models to large ones. For each configuration, we list its number of parameters, number of layers, hidden dimensions, and number of heads. For example, <1.8B, 32 layers, hidden size 512, 16 heads> is a configuration for SwinTransformer. The four small to large configurations for each model run on 4, 8, 16, and 32 GPUs respectively.

Baseline systems. We compared nnScaler with three popular distributed training systems: 1) Megatron-LM [39] is designed to train transformer-based models, which hierarchically combines pipeline parallelism with data and tensor parallelism. For pipeline parallelism, it evenly partitions model layers into

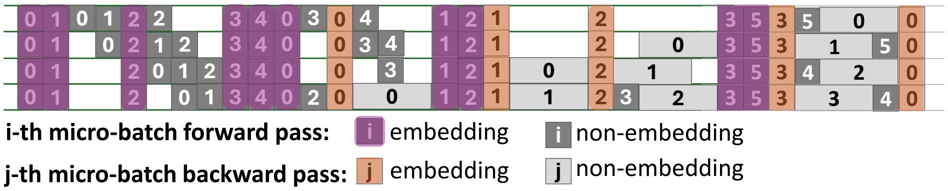

Figure 6: Interlaced pipeline plan found by nnScaler.

pipeline stages, and each stage can be further applied with data and tensor parallelism. 2) Alpa [65] is an automatic parallelization system for deep learning models under the 3D parallelization space. Its search algorithm and training system are currently based on TensorFlow. To conduct a side-by-side comparison, we implemented the Alpa's search algorithm as a policy in nnScaler. 3) DeepSpeed [47] is a distributed training system similar to Megatron-LM. It supports pipeline, data, and tensor parallelism, Additionally, it incorporates techniques including ZeRO [46] and ZeRO-Offload [48] to optimize GPU memory usage. ZeRO mainly optimizes memory usage of optimizer states by keeping a single copy in data parallelism. ZeRO-Offload offloads weights to CPU memory to reduce the memory pressure of GPU and retrieves them after they are used. It does not support offloading activation tensors.

Neither Megatron-LM nor DeepSpeed features automatic search for parallelization plans in their supported parallelization space. Therefore, we manually found the best-performing plans for them by separately traversing the degrees of pipeline, tensor, and data parallelism respectively. In all the following experiments, we applied layer-wise recompute [11] to reduce the memory consumption of activation tensors. Following the common practice [29, 65], we used the aggregated effective TFLOPS as our performance metric.

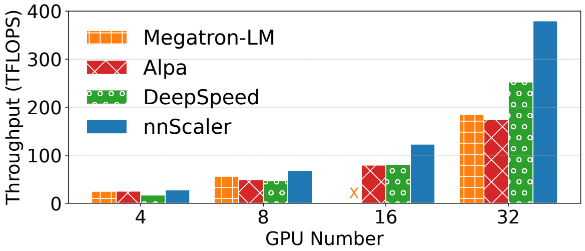

Figure 7: End-to-end training throughput of SwinTransformer. "×" denotes failure due to out of memory.

8.3.2 Results of SwinTransformer

Figure 7 illustrates the end-to-end training throughput of SwinTransformer on four systems. Both Megatron-LM and Alpa use pure tensor parallelism for all model configurations due to the substantial size of activation tensors is huge (e.g. 21GB for the first transformer layer for a 5.0B model), even with recompute applied. DeepSpeed employs ZeRO-Offload and ZeRO stage3 to optimize memory usage. Therefore, DeepSpeed is able to apply 2-way tensor parallelism for the 4 GPUs setting and 4-way tensor parallelism for the remaining three settings. Data parallelism is further applied to scale out across all the available GPUs. nnScaler applies Coshard on the first four layers (Attention+MLP) of SwinTransformer, because these layers occupy a large proportion of memory due to activation tensors. nnScaler applies 2-way, 2-way, 4-way, and 8-way tensor parallelism to the four configurations, respectively, combined with 2-way, 4-way, 4-way, and 4-way pipeline parallelism, respectively. Coshard has 6 partitions sequentially executed on each GPU for the 8 GPUs setting and 4 partitions for the remaining three settings. As shown in Figure 7, nnScaler is 1.2×, 1.5×, and 1.5× faster than DeepSpeed on 8, 16, and 32 GPUs, respectively. Although with ZeRO stage3 to reduce the degree of tensor parallelism to control the communication overheads, ZeRO stage3 still introduces heavy communication costs for weights on the critical path of forward and backward passes, especially when it is applied on 32 GPUs, which involves cross-node communication. In contrast, nnScaler applies Coshard to reduce peak memory, making it possible to use a less degree of tensor parallelism, which reduces communication costs.

Coshard is also used in the long-context post training of the Phi-3 series models to reduce the excessive memory usage due to the long context window [16].

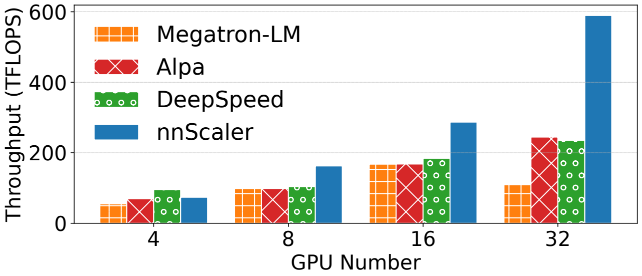

Figure 8: End-to-end training throughput of T5.

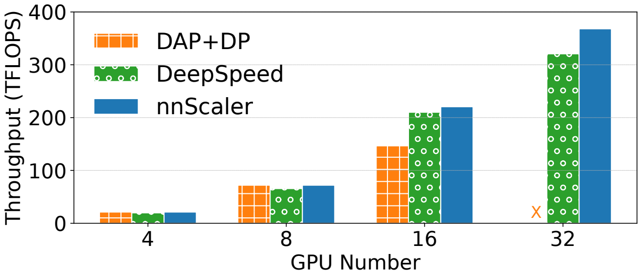

Figure 9: End-to-end training throughput of AlphaFold2. "×" denotes failure due to out of memory.

8.3.3 Results of T5

Figure 8 illustrates the end-to-end training throughput of T5. Megatron-LM uses 2-way tensor parallelism with 2-way pipeline parallelism for 4 GPUs, and uses pure tensor parallelism for 8, 16, 32 GPUs. For 4 GPUs, Alpa uses 3-way pipeline parallelism with the middle stage applying 2-way tensor parallelism. It *must* use pure tensor parallelism for 8, 16, and 32 GPUs due to large memory consumption. As T5 of 3.9B parameters is relatively small, DeepSpeed can use data parallelism with ZeRO stage3 for 4 GPUs. It applies 4-way tensor parallelism for 8, 16, and 32 GPUs, with ZeRO-Offload and ZeRO stage3 applied. Additionally, data parallelism is further applied to scale out to all the available GPUs. nnScaler applies the interlaced pipeline. The large embedding layer uses tensor parallelism on all the available GPUs. The remaining layers apply 4-way pipeline parallelism, with each stage applied 1-way, 2-way, 4-way, and 8-way tensor parallelism for 4, 8, 16, and 32 GPUs, respectively.

nnScaler performs 1.5×, 1.6×, and 2.5× better than DeepSpeed for 8, 16, and 32 GPUs respectively. Megatron-LM and Alpa have a low performance because the high degrees (e.g., 32) of tensor parallelism introduces high communication overheads, especially when the tensor parallelism spans more than one node. This is why Megatron-LM performs much worse with 32 GPUs. As Alpa searches for suitable partition options for tensor parallelism, many operators (e.g., dropout or layernorm) are replicated across nodes to reduce communication costs, and so it performs better than Megatron-LM. Although DeepSpeed has a lower degree of tensor parallelism, its performance is only comparable to Alpa because DeepSpeed uses ZeRO-Offload and ZeRO stage3 to make lower degrees of tensor parallelism feasible. ZeRO-Offload introduces high overheads due to the offloading of large embedding weight (e.g., 12GB in the 21B model). ZeRO stage3 also introduces high communication costs, such as the online gathering of (embedding) weights on the critical path. This shows the effectiveness of the proposed interlaced pipeline on models like T5, compared to conventional approaches like tensor parallelism, ZeRO-Offload, and ZeRO stage3. Note that to highlight the advantage of interlaced pipeline, nnScaler tentatively disables ZeRO in the experiments in Figure 8. And nnScaler still outperforms others in most cases except for the 4-GPU case when T5 is small enough to fit-in memory after applying data parallelism with ZeRO (i.e., DeepSpeed's plan).

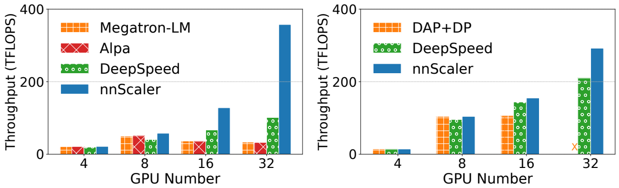
8.3.4 Results of AlphaFold2

Figure 9 shows the end-to-end training throughput of AlphaFold2. In this experiment, we compared nnScaler with two baselines. One is DAP [13], which is a handcrafted tensor parallelism specifically designed for AlphaFold2. We also applied data parallelism to scale out DAP, referred to as DAP+DP. For 4 and 8 GPUs, DAP+DP uses pure data parallelism since the models are small. It uses 4-way tensor parallelism with 4-way data parallelism for 16 GPUs. The other baseline is DeepSpeed. As the model sizes are much smaller than those of SwinTransformer and T5, the application of ZeRO-Offload is not necessary. DeepSpeed uses pure data parallelism for 4, 8, and 16 GPUs with ZeRO stage3, and uses 2-way tensor parallelism with 16-way data parallelism for 32 GPUs. nnScaler also uses pure data parallelism for 4 and 8 GPUs. It applies the 3F1B pipeline for 16 and 32 GPUs. For 16 GPUs, nnScaler uses 4-way pipeline parallelism with 4-way data parallelism, while for 32 GPUs it uses 2-way tensor parallelism with 2-way pipeline parallelism and 8-way data parallelism.

nnScaler performs 1.5× better than DAP+DP on 16 GPUs and 1.1× better than DeepSpeed on 32 GPUs. DeepSpeed performs better than DAP+DP on 16 GPUs, because the activation tensors in AlphaFold2 are large, and the communication of activation tensors using 2-way tensor parallelism is more efficient than that using 4-way tensor parallelism. nnScaler performs better than DeepSpeed because the customized 3F1B pipeline reduces communication costs. The training conducted on multiple nodes, which is common for large model training, amplifies the advantage of pipeline parallelism.

8.3.5 Experiments on Less Powerful Hardware

To demonstrate the effectiveness of the new parallelization plans and understand how different hardware affects training performance, we evaluate SwinTransformer and AlphaFold2 in the DGX-1 cluster. As shown in Figure 10a, nnScaler is 1.9× and 3.5× faster than DeepSpeed on 16 and 32 GPUs, respectively. Compared with data shown in Figure 7, for 32 GPUs, the performance of nnScaler is degraded by 6%, while that of DeepSpeed, Alpa, and Megatron-LM is degraded by 60%, 82% and 82%, respectively. The degradation of nnScaler is smaller because the parallelization plan (i.e., Coshard) used by nnScaler optimizes the communication cost, and thereby it tolerates the changes in communication bandwidth. Figure 10b shows the results of AlphaFold2 on DGX-1. The relative performance gain of nnScaler is also improved to 1.1× and 1.4× over DeepSpeed on 16 and 32 GPUs, respectively. The lower bandwidth cross nodes in DGX-1 further amplifies the advantage of pipeline parallelism, rendering the 3F1B pipeline much faster than tensor parallelism in DAP+DP and DeepSpeed. These experiments indicate that with the flexible customization of parallelization plans and automatic plan search, nnScaler can adapt more flexibly to changes in hardware.



(a) SwinTransformer

(b) AlphaFold2

Figure 10: End-to-end training throughput on DGX-1. "×" denotes the failure of training due to out-of-memory.

8.4 Search Efficiency with Constraints

Algorithm 1 suggests that the parallelization plan search cost in nnScaler consists of: (1) operator transformation and placement cost (i.e., line 1-4 in Algorithm 1), and (2) operator temporal ordering cost (i.e., line 5 in Algorithm 1). Figure 11 illustrates the end-to-end search cost, as well as the breakdown time of the three customized spaces defined in §4.2 for different model configurations using the policy illustrated in §5. The search on SwinTransformer's space takes less than 150s. The search time increases with the increase of model size as the number of operators increases. The ordering search for T5 takes around 150s due to an absence of constraints on the ordering in T5's space. There is almost no search cost of the ordering in SwinTransformer and AlphaFold2. For SwinTransformer, the order is largely determined by data dependencies, and for AlphaFold2, the ordering constraints greatly reduces the space.

Figure 12 further shows the temporal ordering search time of the 3F1B schedule with and without constraints. The left figure shows that the search time increases exponentially with the increase of stage number. However, with constraints applied, the search time is kept within 60s, resulting in 11.7× speedup in finding the efficient temporal ordering for 4 stages. This is attributed to the temporal ordering constraints in Table 7, where the ordering constraints of independent forward and backward operators from different micro-batches are explicitly specified, leading to a significantly reduced search space exposed to the search algorithm (i.e., Tessel). For the case of 4 stages, the right figure further shows the search time as each ordering constraints from Table 7 is applied one by one. The first constraint reduces the search time by 100s. The second constraint further reduces it by 50% of search time. This demonstrates the importance of constraints.

9 Related Work

Existing parallelization search spaces. Recently, data, tensor, and pipeline parallelisms [1, 18, 24, 30, 46] have been widely used in distributed DNN training. Various memory optimizations [11,23,28] have also been adopted to exploit large-scale model training under GPU memory constraints. Systems such as Megatron-LM [29,39,50], DeepSpeed [47], Piper [54], Unity [57], and Alpa [65], combine multiple parallelisms and memory optimizations to accelerate distributed DNN training. However, these solutions fall short in because they rely on empirical parallelism configurations and have limited execution scheduling choices. Thus, despite their successful applications on existing training workloads, they still fail to fully utilize hardware capabilities. In contrast, nnScaler provides a different approach to parallelization, supporting the expression of parallelization sub-spaces with fine-grained transformation and scheduling primitives. Consequently, nnScaler is compatible with them as all these solutions can be achieved using particular constraints. In additional, nnScaler is able to support more flexible and efficient parallelization plans that extend beyond the aforementioned parallelization sub-spaces, which is considerably crucial for continuously evolving DNN models.

Explorations on specific parallelization plans. Parallelization strategies tailored for specific scenarios play a crucial role in optimizing the performance of parallel computing frameworks. For instance, Transformer Parallelism [50], DAP [13], and Sequence Parallelism [29] are designed for specific model architectures, showcasing a nuanced approach to parallelization. To address the need for optimized pipeline orchestration, innovative scheduling strategies have been proposed by GPipe [24], 1F1B [18, 50], and Chimera [30]. Furthermore, optimizations such as Gradient Accumulation [60], Recompute [11], Chain-recompute [28], Swap [23], and All-reduce Overlap [49] specifically target improvements in memory or communication efficiency. These strategies can be seamlessly incorporated into nnScaler's plan with appropriate constraints, eliminating the need for a comprehensive system overhaul and demonstrating the platform's adaptability.

Parallelization plan search and others. To improve training performance with combined parallelisms, DNN systems [22, 26, 37, 54, 59, 63, 65] use different searching techniques to find efficient parallelism configurations. Most recently, Alpa [65] leverages both integer programming and dynamic programming solvers, and Tessel [32] enables the exploration of schedule search in pipeline parallelism, significantly harnessing performance potential beyond manually crafted pipeline schedules. nnScaler, as a parallelization plan engine that emphasizes customizing the parallelization space through constraints, is complementary to the above algorithms and can leverage them to speedup the search within a customized space.

Kernel fusion and tuning optimizations. Besides efficient parallelization plans, kernel fusion and tuning [10, 15, 36, 66] can also improve execution efficiency on a device by fusing multiple consecutive operators into a single more performant GPU kernel. For instance, Flash-Attention [15] fuses multiple operations within the attention layer into a single kernel to improve performance with reduced I/O. These techniques are complementary to nnScaler as they can be applied after nnScaler partitions computation across devices, to further enhance the local computation efficiency on each device.

10 Conclusions

nnScaler is a framework that enables domain experts to leverages three primitives, `op-trans`, `op-assign`, and `op-order`, along with constraints to construct arbitrary search spaces for parallelization plans given any DNN model. This approach represents a more general abstraction to describe both existing parallelization search spaces and new spaces. Experiments show that nnScaler is able to construct new spaces that lead to the discovery of new parallelization plans for deep learning training on emerging DNN models as well as mainstream models, significantly outperforming existing plans.

ChameleonAPI: Automatic and Efficient Customization of Neural Networks for ML Applications

Yuhan Liu[‡], Chengcheng Wan[*], Kuntai Du[‡], Henry Hoffmann[‡], Junchen Jiang[‡], Shan Lu[‡†], Michael Maire[‡]
[‡]*University of Chicago* [*]*East China Normal University* [†]*Microsoft Research*

Abstract

ML APIs have greatly relieved application developers of the burden to design and train their own neural network models—classifying objects in an image can now be as simple as one line of Python code to call an API. However, these APIs offer the same pre-trained models *regardless* of how their output is used by different applications. This can be suboptimal as not all ML inference errors can cause application failures, and the distinction between inference errors that can or cannot cause failures varies greatly across applications.

To tackle this problem, we first study 77 real-world applications, which collectively use six ML APIs from two providers, to reveal common patterns of *how ML API output affects applications' decision processes*. Inspired by the findings, we propose *ChameleonAPI*, an optimization framework for ML APIs, which takes effect without changing the application source code. ChameleonAPI provides application developers with a parser that automatically analyzes the application to produce an abstract of its decision process, which is then used to devise an application-specific loss function that only penalizes API output errors critical to the application. ChameleonAPI uses the loss function to efficiently train a neural network model customized for each application and deploys it to serve API invocations from the respective application via existing interface. Compared to a baseline that selects the best-of-all commercial ML API, we show that ChameleonAPI reduces incorrect application decisions by 43%.

1 Introduction

The landscape of ML applications has greatly changed, with the rise of ML APIs significantly lowering the barrier of ML application developers. Instead of designing and managing neural network models by themselves via frameworks like TensorFlow and PyTorch, application developers can now simply invoke ML APIs, provided by open-source libraries or commercial cloud service providers, to accomplish common ML tasks like object detection, facial emotion analysis, etc. This convenience thus gives rise to a variety of ML applications on smartphones, tablets, sensors, and personal assistants [9, 29, 50, 65].

Although ML APIs have eased the integration of ML tasks with applications, they are suboptimal by serving different applications with the same neural network models. This issue is particularly striking when applications use the ML API results to make control-flow decisions (also referred to as *application decisions* in this paper). Different applications may check the result of the same ML API using different control-flow code structures and different condition predicates, a process that we refer to as the application's *decision process* (see §2 for the formal definition). Due to the heterogeneity across applications' decision processes, we make two observations.

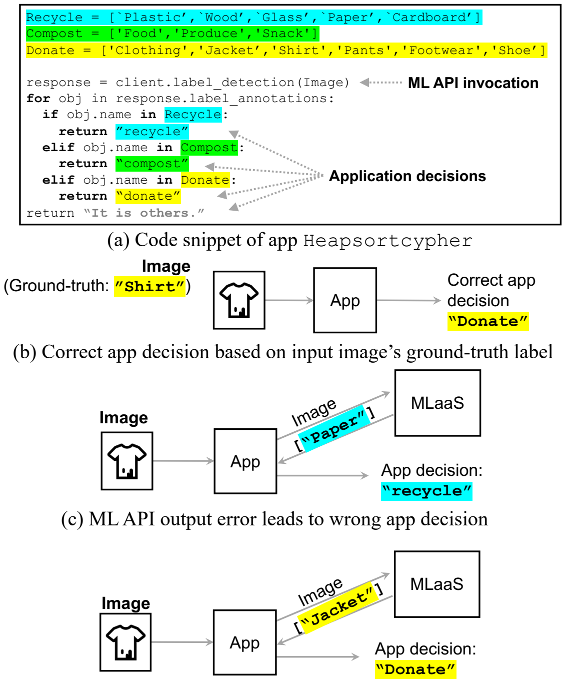
- First, some incorrect ML API outputs may still lead to correct application decisions, with only certain *critical errors* of API output affecting the application's decision.
- Second, among all possible output errors of an ML API, which ones are critical *vary* significantly across applications that use this API. That is, the same API output error may have a much *greater* effect on one application than on another.

Figure 1 illustrates the decision process of a garbage-classification application `Heapsortcypher` [49]. It first invokes Google's classification API upon a garbage image. Then, based on the returned labels, a simple logic is used to make the *application decision* about which one of the pre-defined categories (`Recycle`, `Compost`, and `Donate`) or `others` the image belongs to. For example, for an input image whose ground-truth label is `"Shirt"`, the correct application decision is `Donate`, as shown in Figure 1 (b).

For this application, when the classification API fails to return `"Shirt"`, the application decision may or may not be wrong. For example, Figure 1 (c) and (d) show two possible wrong API output: if the output is `"Paper"`, the application will make a wrong decision of `Recycle`; however, if the output is `"Jacket"`, the application will make the correct decision of `Donate` despite not matching the ground-truth label. More subtly, if the API returns a list of two labels, `"Shirt"` and `"Paper"`, the application would make a correct decision if `"Shirt"` is ordered before `"Paper"` by the API, but would make a wrong decision if `"Paper"` is ordered before `"Shirt"`. The reason is that the application logic, the `for` loop in Figure 1 (a), checks one API-output label at a time. As we will see later, there are also other ways that applications check the API-output list, which will affect application decision differently.

As we can see, for a specific application, some errors of an ML API may be critical, like mis-classifying the shirt to `"Paper"` in the example above, and yet some errors may be non-critical, like mis-classifying the shirt image as `"Jacket"` or classifying the shirt image as both `"Shirt"` and `"Paper"` in the examples above. Which errors are critical varies, depending on the application's decision process.

These observations regarding the critical errors specific to



```
Recycle = [`Plastic',`Wood',`Glass',`Paper',`Cardboard']
Compost = ['Food','Produce','Snack']
Donate = ['Clothing','Jacket','Shirt','Pants','Footwear','Shoe']

response = client.label_detection(Image)
for obj in response.label_annotations:
  if obj.name in Recycle:
    return "recycle"
  elif obj.name in Compost:
    return "compost"
  elif obj.name in Donate:
    return "donate"
return "It is others."
```

(a) Code snippet of app `Heapsortcypher`

(b) Correct app decision based on input image's ground-truth label

(c) ML API output error leads to wrong app decision

(d) ML API output error still leads to correct app decision

Figure 1: *An example ML application whose decision depends on the output of ML API (multi-label classification), but not all errors of ML API output have the same effect.*

each application suggest substantial room for improvement by customizing the ML API, essentially the neural network model underneath the API, for individual application's decision process. In particular, for a given application, the customized model can afford having more errors less critical to the application for the benefit of having fewer critical errors that cause wrong application decisions.

Thus, our goal is to allow ML APIs and their underlying neural network models to be *automatically* customized for a given application, so as to *minimize* incorrect application decisions *without* changing the application's source code or interface between ML API and software exposed to developers. This way, application developers who do not have the expertise to design and train customized ML models can still enjoy the accessibility of generic ML APIs while getting closer to the accuracy of ML models customized for the application.

No prior work shares the same goal as us. The closest line of prior work specializes DNN models for given queries [7, 8, 36, 37, 43], but they require application developers to use a domain specific language (*e.g.,* in SQL [36]) instead of general programming languages, like Java and Python, and mostly focus on reducing the DNN's size. In contrast, we keep both the ML API interface and the application source code intact while avoiding incorrect decisions for ML applications.

With the aforementioned goal, this paper makes two contributions. *First,* we run an empirical study over 77 real-world applications that collectively use six ML APIs to reveal several common patterns of how the outputs of ML APIs affect the application decisions (§2).

Our study identifies two types of ML API output that are used by applications to make control-flow decisions (categorical labels and sentiment scores), and three types of decision types (True-False, Multi-Choice, and Multi-Selection) with different implications regarding which ML API output errors are critical to the application.

Our study also quantitatively reveals opportunities of model customization. (1) Although popular image-classification models are trained to recognize as many as 19.8K different labels, the largest number used by any one application for decision making is only 54. Consequently, mis-classification among the remaining tens of thousands of labels are completely irrelevant to an application. (2) More importantly, applications tend to treat multiple labels (4.7 on average) as one equivalence class in their decision making, such as labels `Plastic`, `Wood`, `Glass`, `Paper`, and `Cardboard` in Figure 1(a). Mis-classification among those labels inside one equivalence class does not matter. (3) Which labels are relevant to an application's decision making vary greatly across applications, with only 12% of application pairs share any labels used for their decision making.

Second, inspired by the empirical study, we propose ChameleonAPI, which customizes and serves ML models behind the ML API for each given application's decision process, without any change to the existing ML API or the application source code (§3). ChameleonAPI works in three steps. First, it provides a parser that analyzes application source code to extract information about how ML inference results are used in the application's decision process. Based on the analysis result, ChameleonAPI then constructs the loss function to reflect which ML model output is more relevant to the given application as well as the different severity of ML inference errors on the application decisions. The ML model will be retrained accordingly using the new loss function. Finally, when the ML API is invoked by the application at runtime, a customized ML model will be used to serve this query.

We evaluate ChameleonAPI on 57 real-world open-source applications that use Google and Amazon's vision and language APIs. We show that ChameleonAPI's re-trained models reduce 48% of incorrect decisions compared to the off-the-shelf ML models and 50% compared to the commercial ML APIs. Even compared with a baseline that selects the best-of-all commercial ML API, ChameleonAPI reduces 43% of incorrect decisions. ChameleonAPI only takes up to 24 minutes on a GeForce RTX 3080 GPU to re-train the ML model.

Our code is publicly available at `https://github.com/UChi-JCL/chameleonAPI`.

2 Understanding Application Decision Process

We conduct an empirical study to understand how applications make decisions based on ML APIs (§2.3), and how this

ML API name	ML task	Provider	# of apps
label_detection	Vision::Image classification	Google	29
detect_labels	Vision::Image classification	Amazon	11
object_localization	Vision::Object detection	Google	8

Table 1: *Summary of applications used in our empirical study.*

decision making logic implies the different severity of ML inference errors (§2.4). This study will reveal why and how to customize the ML API backend for each application. As a representative sample of ML APIs, this study focuses on cloud AI services due to their popularity.

2.1 Definitions

Preliminaries: We begin with basic definitions.

- *Application decision*: the collective control-flow decisions (i.e., which branch(es) are taken) made by the application under the influence of a particular ML API output.
- *Incorrect ML API output:* a situation when the API output differs from the API input's human-labeled ground truth. We refer to such ML API outputs as *API output errors*.
- *Correct decision*: the application decision if the API output is the same as the human-labeled ground-truth of the input.
- *Application decision failure*: a situation when the application decision is different from the correct decision, also referred to as *application failure* for short in this paper.

Software decision process: Given these definitions, an application's *software decision process* (or decision process for short) is the logic that maps an ML API output to an application decision. The code snippet in Figure 1 shows an example decision process, which maps the output of a classification ML API on an image to the image's recycling categorization specific to this application.

Critical and non-critical errors: For a given decision process, some API output errors will still lead to a correct decision, whereas some API output errors will lead to an incorrect decision and hence an application failure. We refer to the former as *non-critical errors*, and the latter as *critical errors*.

2.2 Methodology

Our work focuses on applications that use ML API output to make control-flow decisions. To this end, we look at 77 open-source applications which collectively use six widely used vision and language APIs [10,65] offered by two popular cloud AI service providers, as summarized in Table 1.

These applications come from two sources. First, we study all 50 applications that use vision and language APIs from a recently published benchmark suite of open-source ML applications [66]. Second, given the popularity of image classification APIs [11, 12], we additionally sample 27 applications from GitHub that use Google and Amazon image classification APIs (16 for the former and 11 for the latter). We obtain these 27 by checking close to 100 applications that use image classification APIs and filtering out those that directly print out or store the API output. Every application in our benchmark suite uses exactly one ML API for decision making.

Threats to validity: While many applications use the APIs listed in Table 1, there are a few other APIs not covered in our study. A few vision and language-related ML tasks are not as popular and hence are not covered in our study (*e.g.,* face recognition and syntax analysis). Speech APIs are not covered, because their outputs are rarely used to affect application control flow based on our checking of open-source applications. Finally, our study does not cover applications that use ML APIs offered by other cloud or local providers.

2.3 Understanding the decision mechanism

***Q1**: What types of ML API outputs are typically used by applications to make decisions?*

ML APIs produce output of a variety of types. The sentiment analysis API outputs a list of floating-point value pairs (`score` and `magnitude`), describing the sentiment of the whole document and every individual sentence; the other five APIs in Table 1 each produces a list of categorical labels ranked in descending order of their confidence scores, which is also part of the output. Some APIs' output also contains other information, like coordinates of bounding boxes, entity names, links to Wikipedia URLs, and so on. Among all these, only two types have been used in application decision processes of our studied application: the floating-point pair (`score` and `magnitude`) and the categorical labels.

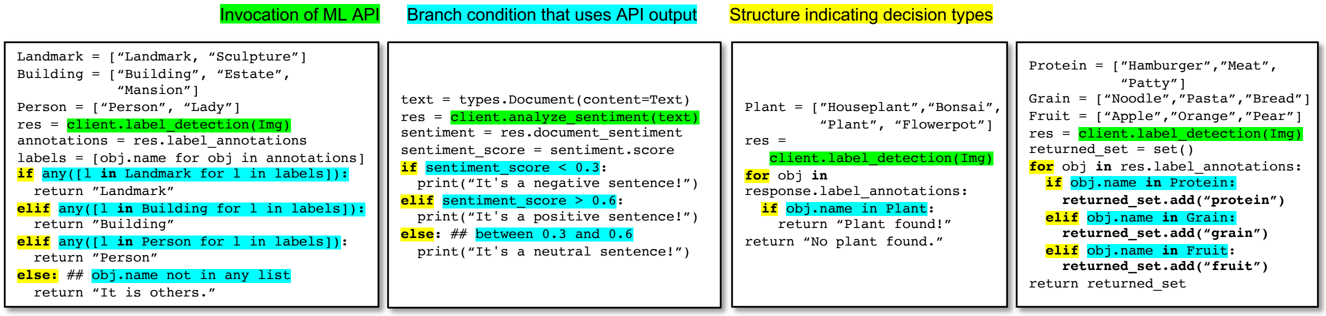
For the 63 applications that use categorical-label output from the five APIs (all except `analyze_sentiment` in Table 1), they each define one or more *label lists* and check which label list(s) an API output label belongs to. The code snippet of a landmark classification application in Figure 2(a) is an example of this. It calls the `label_detection` API with a sight-seeing image and checks the output labels to see if the image might contain `Landmark`, or just ordinary `Building`, or `Person`.

For the 14 applications that use the `analyze_sentiment` API, they each define several *value ranges* and check which range the sentiment `score` and/or `magnitude` falls in. The code snippet of `FoodDelivery` [48] in Figure 2(b) is an example. This application calls `analyze_sentiment` with a restaurant review text, and then checks the returned sentiment `score` to judge if the review is negative, positive, or neutral.

***Q2**: What type of decisions do applications make?*

We observe three categories of ML-based decision making, which we name following common question types in exams:

(1) True-False decision, where a single label list or value range is defined and one selection is allowed: either the ML API output belongs to this list/range or not. This type occurs



Invocation of ML API
Branch condition that uses API output
Structure indicating decision types

```
Landmark = ["Landmark, "Sculpture"]
Building = ["Building", "Estate",
            "Mansion"]
Person = ["Person", "Lady"]
res = client.label_detection(Img)
annotations = res.label_annotations
labels = [obj.name for obj in annotations]
if any([l in Landmark for l in labels]):
  return "Landmark"
elif any([l in Building for l in labels]):
  return "Building"
elif any([l in Person for l in labels]):
  return "Person"
else: ## obj.name not in any list
  return "It is others."
```

(a) `Aander-ETL`
(Label output, Multi-Choice, App-Order)

```
text = types.Document(content=Text)
res = client.analyze_sentiment(text)
sentiment = res.document_sentiment
sentiment_score = sentiment.score
if sentiment_score < 0.3:
  print("It's a negative sentence!")
elif sentiment_score > 0.6:
  print("It's a positive sentence!")
else: ## between 0.3 and 0.6
  print("It's a neutral sentence!")
```

(b) `FoodDelivery`
(Float-point value output, Multi-Choice)

```
Plant = ["Houseplant","Bonsai",
          "Plant", "Flowerpot"]
res =
   client.label_detection(Img)
for obj in
response.label_annotations:
  if obj.name in Plant:
    return "Plant found!"
return "No plant found."
```

(c) `Plant-watcher`
(Label output, True-False)

```
Protein = ["Hamburger","Meat",
           "Patty"]
Grain = ["Noodle","Pasta","Bread"]
Fruit = ["Apple","Orange","Pear"]
res = client.label_detection(Img)
returned_set = set()
for obj in res.label_annotations:
  if obj.name in Protein:
    returned_set.add("protein")
  elif obj.name in Grain:
    returned_set.add("grain")
  elif obj.name in Fruit:
    returned_set.add("fruit")
return returned_set
```

(d) `The-Coding-Kid`
(Label output, Multi-Select)

Figure 2: *Code snippets from five example applications where ML API output affects control flow decisions in different ways.*

in about one third of the applications in our study. For example, the plant management application `Plant-watcher` [57] (Figure 2(c)) checks to see if the image contains plants or not.

(2) Multi-Choice decision, where multiple lists of labels or value ranges are defined, and one selection is allowed. The ML API output will be assigned to *at most one* list or range; the application's decision making logic determines which of these lists/ranges the output belongs to, or determines that the output belongs to none of them. This type of decision is the most common, occurring in about 45% of benchmark applications. The garbage classification application discussed in §1 makes such a Multi-Choice decision. It decides which one of the following classes the input image belongs to: `Recycle`, `Compost`, `Donate`, or none of them.

(3) Multi-Select decision, where multiple label lists or value ranges are defined, and *multiple* selections are allowed about which label lists or value ranges the ML API output belongs to. This type of decisions occur in close to a quarter of the applications. Figure 2(d) illustrates such an example from the nutrition advisor application `The-Coding-Kid` [62]. This application defines three label lists to represent nutrition types: `Protein`, `Grain`, and `Fruit`, and it checks to find all the nutrition types present in the input image.

In the remainder of the paper, we will use **target class** to refer to a label list (or a value range) that is used to match against a categorical label (or a value). For instance, the code snippet in Figure 2(a) has three label lists as its target classes (`[Landmark, Sculpture]`, `[Building, Estate, Mansion]`, and `[Person, Lady]`), and the code snippet in Figure 2(b) has three value ranges as its target classes (`<0.3`, `>0.6`, and in between).

Q3: How do applications reach Multi-Choice decisions?

When the ML API outputs multiple labels, the outcome of a Multi-Choice decision varies depending on which *matching order* is used. First, the matching order can be determined by the API output. For example, the garbage classification application (Figure 1) first checks whether the first label in the API output matches any target class. If so, later API output labels will be skipped, even if they might match with a different class. If there is no match for the first label, the second output label is checked, and so on. These labels are ranked by the API in the descending order of their associated confidence scores, so we refer to such a matching order as API-order. It is used by 80% of applications that make Multi-Choice decisions.

The matching order can also be specified by the application, referred to as App-order. For instance, regardless the API output, application `Aander-ETL` [1] (Figure 2(a)) always first checks if the `Landmark` class matches with *any* output label. If there is a match, the decision is made. Only when it fails to match `Landmark`, will it move on to check the next choice, `Building`, and so on. This matching order is used by 20% of applications that make Multi-Choice decisions.

2.4 Understanding the decision implication

Q4: Does an application need ML APIs that can accurately identify thousands of labels?

ML models behind popular ML APIs are well trained to support a wide range of applications. For example, Google and Microsoft's image-classification APIs are capable of identifying more than 10000 labels [44], while Amazon's image-classification API can identify 2580 labels [3]. However, for each individual application, its decision making only requires classifying the input image into a handful of target classes: 7 at most in our benchmark applications. The largest number of image-classification labels checked by an application is 54, a tiny portion of all the labels an image-classification API could output.

Clearly, for any application, a customized ML model that focuses on those target classes used by the application's decision process has the potentially to out-perform the big and generic ML model behind ML APIs. How to accomplish the customization without damaging the accessibility of ML APIs will be the goal of ChameleonAPI.

Q5: Are there equivalence classes among ML API outputs in the context of application decision making?

For the 63 applications that make decisions based on API output of categorical labels, they present 121 target classes in total, each containing 4.7 labels on average (3 being the median). Only 35 target classes in 22 applications contain a single label. For the 14 applications that make decisions based on floating-point sentiment `score` and `magnitude`, their target classes *all* contain an infinite number of `score` or `magnitude` values. In other word, no class contains just a single value.

Clearly, the wide presence of multi-value target classes creates equivalence classes among output returned by the API—errors within one equivalence class are *not* critical to the corresponding application. This offers another opportunity for ML customization.

***Q6**: How much difference is there between different applications' target classes?*

Overall, the difference is significant. We have conducted pair-wise comparison between any two applications in our benchmark suit, and found that 88% of application pairs share *no* common labels in any of their target classes. Similarly, among the 381 labels that appear in at least one application's target classes, 88% of them appear in only one application (*i.e.,* 335 out of 381 labels).

Clearly, there is *little overlap* among the target classes of different applications, again making a case for *per-application* customization of the ML models used by the ML APIs.

***Q7**: Do different decision mechanisms imply different sensitivity to output errors of ML APIs?*

Even for two applications that have the same target classes, if they try to make different types of decisions, they will have different sensitivity to ML API output errors—some API errors might be critical to one application, but not to the other. For example, errors that affect the selection of different target classes are equally critical to Multi-Select decisions. However, this is not true for Multi-Choice, where only the first matched target class matters. Furthermore, the matching order of a Multi-Choice decision affects which errors are critical. When the API-output order is used (*e.g.,*`HeapsortCypher` in Figure 1), an error on the first label in the API output is more likely to be critical than an error on other labels in the output. However, when App-order order is used (*e.g.,*`Aander-ETL` in Figure 2(a)), errors related to labels in the first target class (*e.g.,*`Landmark`) are more likely to be critical than those related to labels in later target classes (*e.g.,*`Person`).

Clearly, to customize ML models for each application, we need to take into account what is the decision type and what is the matching order (for Multi-Choice decisions).

3 Design of ChameleonAPI

Inspired by the study of §2, we now present ChameleonAPI which automatically customizes ML models for applications.

3.1 Problem formulation

Goal: For an application that uses ML APIs, our goal is to **minimize critical errors** in the API outputs for this application by efficiently re-training the original generic neural network models underneath these APIs into customized models; our approach stands in contrast to typical approaches that minimize *all* inference errors. In other words, the new ML

Figure 3: *The logical steps of how ChameleonAPI customizes d for individual applications.*

model should return outputs that lead the application process to the same decision as if the ground-truth of the input is returned by the ML API.

To formally state this objective, we denote how an application makes a decision by $App(API(\mathbf{x}))$, where $\mathbf{x}$ is the input to the ML API and $API(\mathbf{x})$ is the API output. Then for a given application decision process of $App(\cdot)$ and an input set $\mathbf{X}$[1], our goal is to train an ML model $DNN(\cdot)$ such that

$$\min_{\mathbf{x}_i \in \mathbf{X}} \left| \{\mathbf{x}_i | App(API(\mathbf{x}_i)) \neq App(\widehat{API}(\mathbf{x}_i))\} \right|,$$
$$\text{where } API(\mathbf{x}_i) = F(DNN(\mathbf{x}_i)) \qquad (1)$$

Here, $\widehat{API}(\mathbf{x}_i)$ is a hypothetical API function that always returns the ground truth of input $\mathbf{x}_i$, and $F(\cdot)$ represents the postprocessing used by the API to translate a DNN output to an API output. For instance, an image classification model's output is a vector of confidence scores between 0 and 1 (each for a label), but the ML API will use a threshold θ to filter and return only labels with scores higher than θ, or the top k labels with the highest confidence scores.

Our goal in Eq 1 differs from the traditional goal of an ML model, which minimizes any errors in the API output, *i.e.,*

$$\min_{\mathbf{x}_i \in \mathbf{X}} \left| \{\mathbf{x}_i | API(\mathbf{x}_i) \neq \widehat{API}(\mathbf{x}_i)\} \right|. \qquad (2)$$

Given that it is hard to obtain a DNN with 100% accuracy, the difference between the two formulations is crucial, since not all API output errors in Eq. 2 will cause incorrect application decisions in Eq. 1. Thus, compared to optimizing Eq. 2, optimizing Eq. 1 is more likely to focus the DNN training on reducing the critical errors for the application.

To train a DNN that optimizes Eq. 1, we need to decide if a DNN inference output $DNN(\mathbf{x})$ is a critical error or not (*i.e.,* $App(DNN(\mathbf{x})) \neq App(\widehat{API}(\mathbf{x}))$) at the end of *every* training iteration. This decision needs to be made automatically and efficiently. For example, repeatedly running the entire ML application after every training iteration would not work, as it may significantly slow down the training procedure.

[1] A careful reader might notice that the formulation in Eq. 1 also depends on the input set. Though the input set should ideally follow the same distribution of real user inputs of the application, this distribution is hard to obtain in advance and may also vary over time and across users. Instead, we focus our discussion on training the ML model to minimize Eq. 1 with an assumed input distribution. Our evaluation (§5) will test the resulting model's performance over different input distributions.

Logical steps of ChameleonAPI: To customize and deploy the DNN for an application, ChameleonAPI takes three logical steps (Figure 3). First, ChameleonAPI extracts from an application's source code a *decision-process summary* (explained shortly), a succinct representation of the application's decision process, which will be used to determine if a DNN inference error is critical (details in §3.3). Second, ChameleonAPI converts a decision-process summary to a *loss function*, which can be directly used to train a DNN (details in §3.2). This loss function only penalizes DNN outputs that lead to critical errors with respect to a given application. Finally, the loss function will be used to train a customized DNN for this particular application's ML API invocations (§3.4).

A decision-process summary is a succinct abstraction of the application that contains enough information to determine if a DNN inference output causes a critical error or not. Specifically, it includes three pieces of information (defined in §2.3):

- *Composition of target classes:* the label list or value range of each target class;
- *Decision type:* True-False, Multi-Choice, or Multi-Select;
- *Matching order:* over the target classes, API-order or App-order, if the application makes a Multi-Choice decision.

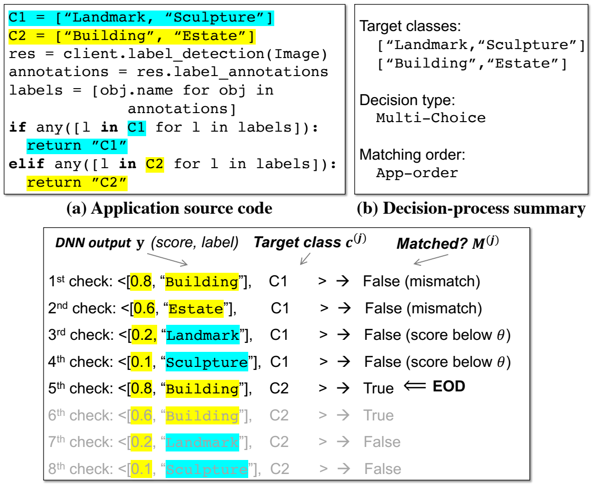
For a concrete example, the decision-process summary of the garbage classification application in Figure 2(a) contains (1) three label lists representing three target classes: `Recycle`, `Compost`, and `Donate`; (2) the Multi-Choice type of decision; and (3) the matching order of API-order.

What is changed, what is not: ChameleonAPI does *not* change the ML API or the application source code. Unlike recent work that aims to shrink the size of DNNs or speed them up [36, 37, 54], we do not change the DNN architecture (shape and input/output interface); instead, we train the DNN to minimize critical errors. That said, deploying ChameleonAPI has two requirements. First, the application developers need to run ChameleonAPI's parser script to automatically extract the decision-process summary. Second, an ML model needs to be retrained for each application, instead of serving the same model to all applications.

The remainder of this section will begin with the design of the application-specific loss function based on decision-process summary, followed by how to extract the decision-process summary from the application, and finally, how the customized ML models are used to serve ML API queries.

3.2 Application-specific loss function

Given Eq 1, ChameleonAPI trains a DNN model with a *new loss function*, which only penalizes critical errors of an application, rather than all DNN inference errors. Since decision processes vary greatly across applications (§2.4), we first explain how to conceptually capture different decision processes in a generic description, which allows us to derive the mathematical form of ChameleonAPI's loss function later.



```
C1 = ["Landmark, "Sculpture"]
C2 = ["Building", "Estate"]
res = client.label_detection(Image)
annotations = res.label_annotations
labels = [obj.name for obj in
                annotations]
if any([l in C1 for l in labels]):
  return "C1"
elif any([l in C2 for l in labels]):
  return "C2"
```

(a) Application source code

Target classes:
`["Landmark,"Sculpture"]`
`["Building","Estate"]`

Decision type:
`Multi-Choice`

Matching order:
`App-order`

(b) Decision-process summary

1st check: <[0.8, "Building"], C1 > → False (mismatch)
2nd check: <[0.6, "Estate"], C1 > → False (mismatch)
3rd check: <[0.2, "Landmark"], C1 > → False (score below θ)
4th check: <[0.1, "Sculpture"], C1 > → False (score below θ)
5th check: <[0.8, "Building"], C2 > → True ⟸ EOD
6th check: <[0.6, "Building"], C2 > → True
7th check: <[0.2, "Landmark"], C2 > → False
8th check: <[0.1, "Sculpture"], C2 > → False

(c) Generic description of the decision process
on DNN output $y = [0.1, 0.2, 0.8, 0.6]$ & score threshold $\theta = 0.3$

Figure 4: *The generic description (shown in (c)) of an application (whose source code is shown in (a) and decision-process summary in (b)) on a DNN inference output* **y**.

Generalization of decision processes: For each application in our study (§2.2), our insight is that its decision process can always be viewed as traversing a sequence of conditional *checks* until an *end-of-decision* (*EOD*) occurs:

$$1^{\text{st}} \text{ check: } < \mathbf{y}, c^{(1)} > \rightarrow M^{(1)}$$

$$\ldots$$

$$j^{\text{th}} \text{ check: } < \mathbf{y}, c^{(j)} > \rightarrow M^{(j)} \qquad \Leftarrow \textbf{EOD}$$

$$\ldots$$

where the j-th check takes as input the DNN output $\mathbf{y}$ and one of target classes $c^{(j)}$, and returns a binary $M^{(j)}$ indicating whether $\mathbf{y}^{(j)}$ *matches* the condition of $c^{(j)}$ and a binary decision whether this check happens before the EOD. The set of target classes successfully matched before the EOD will be those selected by the application.

Figure 4 shows (a) an example application, (b) the decision-process summary, and (c) the generic description for this application's decision process and a DNN output.

This generic description (*e.g.,* the traversal order of the target classes, how a match is determined in a check, and when the EOD occurs) will depend on the information in the decision-process summary and the DNN output **y**. We stress that this generic description may *not* apply to all applications, but it does apply to all applications in our study (§2.2).

Categorization of critical errors: Importantly, this generic description helps to categorize critical errors:

- *Type-1 Critical Errors:* A correct target class c is not matched before EOD, but will be so if EOD occurs later.
- *Type-2 Critical Errors:* A correct target class c is never matched, before or after the EOD.
- *Type-3 Critical Errors:* An incorrect target class c is matched before EOD.

A useful property of this categorization is that any wrong decision (a correct target class not being picked, or an incorrect target class being picked) falls in a unique category, and non-critical errors do not belong to any category. In other words, as long as the loss function penalizes the occurrences of each category, it will only capture critical errors.

ChameleonAPI's first attempt of a new loss function: To understand why it is difficult to penalize critical errors and critical errors *only*, we first consider the common practice of assigning a higher weight to the loss of a DNN output if the ground-truth of the input will lead to a selection of some target classes (*e.g.,* [26, 35, 64]). Henceforth, we refer to this basic design of loss function as ChameleonAPI$_{basic}$.

At best, ChameleonAPI$_{basic}$ might improve the DNN's *label-wise* accuracy on inputs whose ground-truth decision selects some target classes. However, as elaborated in §2.3, we also need to consider which labels belong to the same target class, the decision type, and the matching order of an application decision process in order to capture the three types of critical errors. For instance, in the garbage-classification application (Figure 1), without knowing the label lists of each target class, ChameleonAPI$_{basic}$ will give an equal penalty to a critical error of mis-classifying a `Paper` image to `Wood` and a non-critical error of mis-classifying a `Paper` image to `Shirt`. Similarly, without knowing the matching order, ChameleonAPI$_{basic}$ will equally penalize the output of [`Plastic`, `Jacket`] and [`Jacket`, `Plastic`], but only the latter leads to correct output because `Jacket` is matched first.

ChameleonAPI's loss function: ChameleonAPI leverages the categorization of critical errors to systematically derive a loss function that penalizes each type of critical error. To make it concrete, we explain ChameleonAPI's loss function of "label-based API, Multi-Choice type of decision, and App-order" (*e.g.,* Figure 4). Appendix§B will detail the loss functions of other decision processes. The loss function of such applications has three terms, each penalizing one type of critical error:

$$L(\mathbf{y}) = \overbrace{\text{Sigmoid}\left(\min\left(\max_{l\in\cup_{c<\hat{c}}G_c}\mathbf{y}[l], \max_{l\in G_{\hat{c}}}\mathbf{y}[l]\right)-\theta\right)}^{\textbf{Type-1}\text{ Critical Errors}} \qquad (3)$$

$$+\overbrace{\text{Sigmoid}\left(\theta-\max_{l\in G_{\hat{c}}}\mathbf{y}[l]\right)}^{\textbf{Type-2}\text{ Critical Errors}}+\overbrace{\sum_{c<\hat{c}}\text{Sigmoid}\left(\max_{l\in G_c}\mathbf{y}[l]-\theta\right)}^{\textbf{Type-3}\text{ Critical Errors}}$$

Here, $\mathbf{y}[l]$ denotes the score of the label l, G_c denotes the set of labels of target class c, $\hat{c}$ denotes the correct (*i.e.,* ground-truth) target class, and the sigmoid function $\text{Sigmoid}(x) = \frac{1}{1+e^x}$ will incur a higher penalty on a greater positive value.

Why does it capture the critical errors? Given this application is Multi-Choice, the EOD will occur right after the first match of a target class, *i.e.,* the first check with a c such that $\max_{l\in G_c}\mathbf{y}[l] \geq \theta$.

- A Type-1 critical error occurs, if (1) the correct target class $\hat{c}$ is matched *and* (2) it is matched after the EOD. First, the correct target class $\hat{c}$ is matched, if and only if at least one of its labels has a score above the confidence threshold, so $\max_{l\in G_{\hat{c}}}\mathbf{y}[l] \geq \theta$). Second, this match happens after the break, if and only if some target class c before $\hat{c}$ (*i.e., $c < \hat{c}$*) is matched, so $\max_{l\in G_c}\mathbf{y}[l] \geq \theta$). Put together, the first term of Eq 3 penalizes any occurrence of these conditions.
- A Type-2 critical error occurs, if no label in the correct target class $\hat{c}$ has a score high enough for $\hat{c}$ to be matched, *i.e.,* $\max_{l\in G_{\hat{c}}}\mathbf{y}[l] < \theta$, so the second term of Eq 3 penalizes any occurrence of this condition.
- A Type-3 critical error occurs, if any incorrect target class c before $\hat{c}$ (*i.e., $c < \hat{c}$*) has a label with a score high enough for c to be matched, *i.e.,* $\max_{l\in G_c}\mathbf{y}[l] - \theta$, so the third term of Eq 3 penalizes any occurrence of this condition.

To train a DNN, the loss function must be differentiable with respect to the DNN ouput $\mathbf{y}$. Eq 3 uses the max function several times. Though max is not naturally differentiable, it can be closely approximated in well-known differentiable forms provided by PyTorch's differentiable operators [56]).

3.3 Extracting applications' decision process

The current prototype of ChameleonAPI program analysis supports Python applications that make decisions based on categorical label output or floating point output of ML APIs. We first discuss how it works for ML APIs with categorical label output, like all the APIs in Table 1 except for `analyze_sentiment`. We will then discuss a variant of it that works for most use cases of `analyze_sentiment`.

Given application source code, ChameleonAPI first identifies all the invocations of ML APIs. For every invocation I in a function f, ChameleonAPI then identifies all the branches whose conditions have a data dependency upon the ML API's label output. We will refer to these branches as I-branches. If there is no such branch in f, ChameleonAPI then checks the call graph, and analyzes up to 2 levels of callers and up to 5 levels of callees of f until such a branch is identified. If no such branch is identified after this, ChameleonAPI considers the ML API invocation I to not affect application decisions and hence does not consider any optimization for it. If some I-branches are identified, ChameleonAPI records the top-level function analyzed, F, and moves on to extract the decision-process summary in following steps.

What are the target classes? ChameleonAPI figures out all the target classes and their composition in two steps.

The first step leverages symbolic execution and constraint solving to identify all the labels that belong to *any* target classes. Specifically, ChameleonAPI applies symbolic execution to function F, treating the parameters of F and the label output of I as symbolic (*i.e.,* the symbolic execution skips the ML API invocation I and directly uses I's symbolic output in the remaining execution of F)[2]. Since applications typically match only one label in API output at a time (as observed in §2.3), we set the label array returned by I to contain one element (label) and use a symbolic string to represent it. Through symbolic execution, ChameleonAPI obtains constraints for every path that involves an I-branch, solving which tells ChameleonAPI which labels need to be in the output of the ML API in order to execute each unique path, essentially all the labels that belong to any target class.

One potential concern is that a solver may only output one instead of all values that satisfy a constraint. Fortunately, the symbolic execution engine used by ChameleonAPI, NICE [31], turns Python code into an intermediate representation where each branch is in a simplest form. Take Figure 2(d) as an example, the source-code branch `if obj.name in Protein` is transformed into three branches where `obj.name` is compared with "`Hamburger`", "`Meat`", and "`Patty`" separately, allowing us to capture all three labels by solving three separate path constraints.

The second step groups these labels into target classes by comparing their respective paths: if two API output, each with one label, lead the program to follow the same execution path at the source-code level, these two labels belong to the same target class. For example, in Figure 2(d), the execution path is exactly the same when the `label_detection` API returns `["Hamburger"]`, comparing with when it returns `["Meat"]`, with all function parameters and other API output fields being the same. Consequently, we can know that label `Hamburger` and label `Meat` belong to the same target class. To figure out the path, ChameleonAPI simply executes function F using each input produced by the constraint solver and traces the source-code execution path using the Python trace module.

One final challenge is that ChameleonAPI needs to identify and exclude the path where none of the target classes are matched (*e.g.,* the "`It is others.`" path in Figure 2(a)). We achieve this by carefully setting the default solution in the constraint solver to be an empty string, which is impossible to output for any ML APIs in this paper. This way, whenever this default solution is output, ChameleonAPI knows that the corresponding path matches no target class.

What is the type of decision? When only one target class is identified, ChameleonAPI reports a True-False decision type. Otherwise, ChameleonAPI decides whether the decision type is Multi-Choice or Multi-Select by checking the source-code execution path associated with every target class label obtained above. If any execution evaluates an I-branch *after* another I-branch is already evaluated to be true, ChameleonAPI reports a Multi-Select decision type; otherwise, ChameleonAPI reports a Multi-Choice decision type.

What is the matching order over the target classes? To tell whether a Multi-Choice decision is made through API-Order like in Figure 1 or App-Order like in Figure 2(a), ChameleonAPI first identifies all the `for` loops that iterate through the label array output by the ML API and have control-dependency with I-branches, *e.g.,* the `for l in labels` in Figure 2(a) and the `for obj in response.label_annotations` in Figure 1.

ChameleonAPI then checks how many such output-iterating loops there are. If there is only one and this loop is not inside another loop, like that in Figure 1, ChameleonAPI considers the matching order to be API-Order, as the application only iterates through each output label once, with the matching order determined by the output array arranged by the ML API. Otherwise, ChameleonAPI considers the matching order to be App-Order. This is the case for the example shown in Figure 2(a), where three output-iterating loops are identified, each of which matches with one target class in an order determined by the application: the `Landmark` target class, followed by the `Building`, and finally the `Person`.

How to handle floating-point output of ML APIs? Recall in §2.3 that some ML APIs, *e.g.,*`analyze_sentiment`, have floating-point output and the application defines several value ranges to put each floating-point output into one category. To handle this type of API, ChameleonAPI needs to identify the value range of each target class, which is not supported by NICE and other popular constraint solvers. Fortunately, many applications directly compare API output with constant values in I-branches, giving ChameleonAPI a chance to infer the value range. For these applications, ChameleonAPI first extracts those constant values that are compared with API output in I-branches, *e.g.,* 0.3 and 0.6 in Figure 2(b). ChameleonAPI then forms tentative value ranges using these numbers, like -1 – 0.3, 0.3 – 0.6, and 0.6 – 1 for Figure 2(b) (-1 and 1 are the smallest and biggest possible `score` output of `analyze_sentiment` based on the API manual). To confirm these value ranges and figure out the boundary situation, ChameleonAPI then executes function F with all the boundary values, as well as some values in the middle of each range. By comparing which values lead to the same execution path, ChameleonAPI finalizes the value ranges. For the example in Figure 2(b), after executing with `score` set to -0.35, 0.3, 0.45, 0.6, and 0.8, ChameleonAPI settles down on the final value ranges to be: (-1,0.3), [0.3,0.6), and [0.6,1).

Limitation The static analysis in ChameleonAPI does not handle the iterated object of while loops, unfolded loops, and recursive functions. For complexity concerns, ChameleonAPI only checks caller and callee functions with limited levels, and hence may miss some I-branches far away from the API invocation. ChameleonAPI's ability of identifying target classes is limited by the constraint solver. ChameleonAPI assumes different source-code paths correspond to different target classes, which in theory could be wrong if the application behaves exactly the same under different execution paths.

[2] Recall that an API output contains several fields not used to influence control flow in any applications. We set them with pre-defined dummy values.

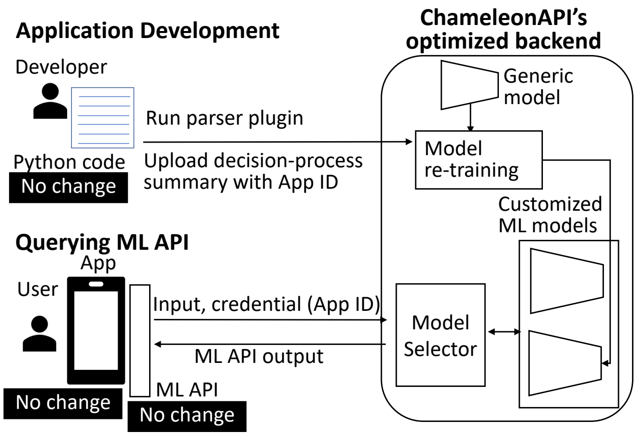


Figure 5: *Workflow of ChameleonAPI.*

3.4 Putting them together

We put these components together into a ML-as-a-Service workflow shown in Figure 5.

First, when an application (A) is developed or updated, the developers run a parser (described in §3.3) provided by ChameleonAPI on A's source code to extract the decision-process summary for A. The developers can then upload the decision-process summary to ChameleonAPI's backend together with a unique application ID[3] (which will later be used to identify queries from the same application).

ChameleonAPI's backend then uses the received decision-process summary to construct a new application-specific loss function (described in §3.2). When a DNN is trained using the new loss function, its inference results will lead to fewer critical errors (*i.e.,* incorrect application decisions) for application A. In our prototype, ChameleonAPI uses the new loss function to re-train an off-the-shelf pre-trained DNN, a common practice to save training time (see §5 for quantification). The DNN re-training uses an application-specific dataset sampled from the dataset used by the pre-trained generic DNN (see Table 2 and §4), so that each target/non-target class is selected by ground-truth decisions of the same number of inputs.

Finally, ChameleonAPI backend maintains a set of DNN models, each customized for an application and keyed by the application ID. When application A invokes an ML API at run time, the ChameleonAPI backend will use the application ID associated with the API query to identify the DNN model customized for A, run the DNN on the input, and return the inference result of the selected model to the application.

Note that, ChameleonAPI can also be used to customize ML models that run locally behind the ML APIs, instead of those in the cloud through ML service providers. In this case, developers run the ChameleonAPI parser on their application and save the parser's result into a local file. This local file will then be consumed to help re-train an off-the-shelf DNN into a customized DNN to serve the application.

	Dataset	Generic model
Image Classification	OpenImages [44]	TResNet-L [6]
Object Detection	COCO [14]	Faster-RCNN [58]
Sentiment Analysis	Amazon review [39]	BERT [18]
Text Classification	Yahoo [30]	BERT [18]
Entity Recognition	conll2003 [63]	BERT [18]

Table 2: *The ML APIs and datasets in evaluation.*

4 Implementation

Extractor of decision-process summary: The current prototype of ChameleonAPI is implemented for Python applications that use Google or Amazon ML APIs. It takes as input the application source code and returns as output the decision-process summary in the JSON format. It uses NICE symbolic execution engine [31] and CVC5 constraint solver [5] to identify target classes, and uses Python static analysis framework Pyan [47] and Jedi [24] to identify the decision type and the matching order. Particularly, it identifies the object that is iterated through by a `for`-loop through the `iter` expression in each for-loop header, which is used to distinguish Multi-Choice and Multi-Select decisions and the matching order.

ML re-training: The re-training module is implemented in PyTorch v1.10 and CUDA 11.1. It uses a decision-process summary to construct a new loss function (see §3.2), and then replaces the builtin loss function in Pytorch with the new loss function, and uses the common forward and backward propagation procedure to re-train an off-the-shelf pre-trained DNN model (explained next).

Generic models: Without access to the models and the training data used by commercial ML services, we use open-sourced pre-trained DNNs and their training datasets as a proxy, which are summarized in Table 2. These DNNs are trained on the "training" portion of their respective datasets. They are trained to achieve good accuracy over a wide range of labels, and we have confirmed that their accuracies in terms of application decisions are similar to the real ML APIs (§5.2).

Training data: We make sure that the labels included in these datasets cover the labels used in the decision processes of the applications in our study. An exception is text classification: to our best knowledge, there is no open-source dataset that covers the classes in Google's text classification API. Instead, we use the Yahoo Question topic classification dataset [30], whose classes are similar to those used in the applications.

Instead of training DNNs on all training data, most of which do not match any target classes of an application, we create a downsampled training set for ChameleonAPI and ChameleonAPI$_{basic}$. For each application, we randomly sample (without replacement) its training data such that each target class and the non-target class (not matching any target

[3] In many MLaaS offerings [2, 20], a connection between the application and the MLaaS backend is commonly created before the application issues any queries. Existing MLaaS already allows applications to specify the application ID via the connection between the application and backend.

class) is the correct decision for the same number of training inputs, which depending on applications, ranges from 12K to 40K. With such training set, ChameleonAPI$_{basic}$ will be equivalently implemented by training on the downsampled training set using the conventional loss function (*i.e.,* cross-entropy loss for classification tasks). Moreover, the downsampled training set significantly speedups DNN re-training (§5.2).

5 Evaluation

Our evaluation aims to answer following questions: How much can ChameleonAPI reduce incorrect application decisions? How long does it take ChameleonAPI to customize DNN models for applications? and Why does ChameleonAPI reduce incorrect application decisions where ChameleonAPI$_{basic}$ falls short?

5.1 Setup

Applications: We have applied ChameleonAPI on all the 77 applications summarized in Table 1. Due to space constraints, our discussion below focuses on the 57 applications that involve three popular ML tasks, image-classification, object-detection, and text-classification, and omits the remaining 20 applications that involve sentiment analysis and entity recognition. The results of the latter show similar trends of advantage from ChameleonAPI and are available in Appendix §D.

Metrics: For each scheme (explained shortly) and each application, we calculate the *incorrect decision rate* (*IDR*): the fraction of testing inputs whose application decisions do not match the correct application decisions (*i.e.,* decisions based on human-annotated ground truth).

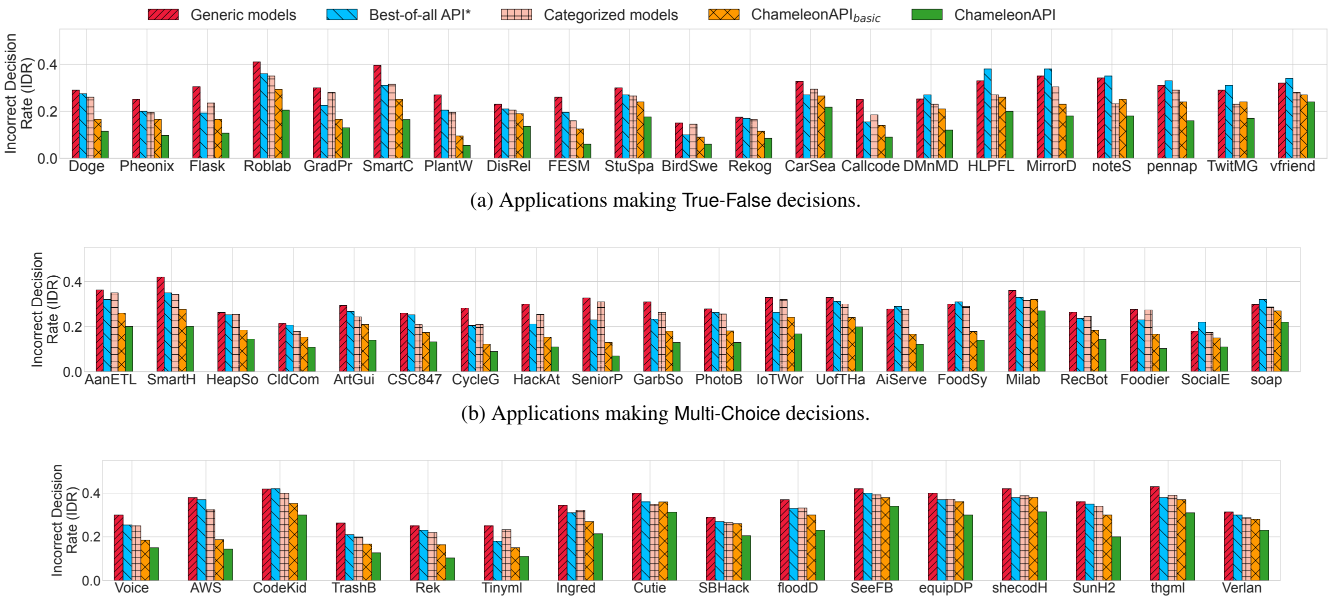
Schemes: We compare the results of these schemes:

- *Various commercial ML APIs*: the results returned by ML APIs of three service providers (Google [20], Amazon [2] and Microsoft [51]).
- *Best-of-all API**: a hypothetical method that queries ML APIs from those three service providers on each input and picks the best output based on the classic definitions of accuracy: label-wise recall for classification tasks and mean-square-error of floating-point output for sentiment analysis. This serves as an idealized reference of recent work [11,12], which tries to select the best API output with high label-wise accuracy.
- *Generic models*: the open-sourced generic model based on which the next three schemes are re-trained. They serve as a reference without customization and achieve similar accuracy as commercial APIs. Their details are explained in Section 4.
- *Categorized models*: This scheme pre-trains a number of specialized models. Each specialized model replaces the last layer of the generic model so that it outputs the confidence scores for a smaller number of labels representing a common category (e.g., "dog", "animal", "person" and a few other labels represent the "natural object" category), and is fine tuned from the generic model accordingly. A simple parser checks which labels are used by an application. If all the labels belong to one category, the corresponding model specialized for this category is used to serve API calls from this application. If the labels belong to multiple categories, multiple specialized models will be used, which we will explain more later. We set up 35 categories for image classification and 7 categories for object detection based on the Wikidata knowledge graph [68], as well as 15 categories for text classification based on the inherent hierarchy in Google text-classification output. More details of how we have designed these categories are available in the Appendix §C.

  Note that, we have designed this scheme to represent a middle-point in the design space between the generic model and the ChameleonAPI approach: on one hand, this scheme offers some application customization, but not as much as ChameleonAPI (e.g., which labels belong to the same target class, what is the decision process, and what is the matching order used by the application are all ignored); on the other hand, this scheme requires a simpler parser compared to ChameleonAPI.
- *ChameleonAPI$_{basic}$*: the model is re-trained with ChameleonAPI's training data, which concentrates on labels used by the application, but with the conventional loss function. Like Categorized models, this scheme only needs a simple parser that extracts which labels are used by the application, and does not make use of other application information that ChameleonAPI uses. Unlike Categorized models, this scheme prepares a customized model for each application, instead of relying on a small number of categorized models.
- *ChameleonAPI* (our solution): the model re-trained with our training data and loss function.

Testing data: For the same application, all schemes are tested against the same testing input set. The testing set of an application is randomly sampled from the "testing" portion of the dataset associated with the application's generic model (Table 2). We make sure that *no* testing input appears in the training data. Like the creation of training data of ChameleonAPI (§4), by default, we randomly sample the testing data such that each target class and the non-target class (not matching any target class) appear as the correct decision for the same number of testing inputs, which ranges from 1.2K to 4K. This is similar to the testing sets used in related work on ML API (*e.g.,* [11,36,37,66]). Such data downsampling is commonly used in ML [19,46]. Other than Figure 9, we will use this as the default testing dataset.

Hardware setting: We evaluate ChameleonAPI and other approaches on a GeForce RTX 3080 GPU, and an Intel(R) Xeon(R) E5-2667 v4 CPU, with 62GB memory.



(a) Applications making True-False decisions.

(b) Applications making Multi-Choice decisions.

(c) Applications making Multi-Select decisions.

Figure 6: *ChameleonAPI reduces the incorrect decision rate (IDR) on the 57 applications that use Google's or Amazon's image-classification, text-classification, and object-detection APIs.*

	True-False	Multi-Choice	Multi-Select
Google API	0.29	0.32	0.35
Microsoft API	0.30	0.33	0.32
Amazon API	0.31	0.33	0.36
Best-of-all API*	0.26	0.27	0.31
Generic models	0.29	0.30	0.34
Categorized models	0.24	0.27	0.31
ChameleonAPI$_{basic}$	0.19	0.22	0.27
ChameleonAPI	**0.13**	**0.16**	**0.21**

Table 3: *Average incorrect decision rate (IDR) among apps that make different types of decisions. The lower the better. The top half represents commercial APIs and their idealistic combinations; the bottom half represents open-source models.*

	Single-category	Multi-category
Generic models	0.32	0.28
Categorized models	0.28	0.27
ChameleonAPI$_{basic}$	0.24	0.18
ChameleonAPI	0.17	0.14

Table 4: *Average IDR among single-category and multi-category applications. The lower the better.*

5.2 Results

Overall gains: Measured by the average incorrect decision rate (IDR) across all applications, the most accurate scheme is ChameleonAPI, with an IDR of 0.16, and the least accurate scheme is Generic models, with an IDR of 0.31. In other words, ChameleonAPI successfully reduces the number of incorrect decisions of its baseline model by almost 50%. ChameleonAPI$_{basic}$ (0.22), Categorized models (0.28), and Best-of-all API* (0.28) have IDR rates in between.

The advantage of ChameleonAPI, and even ChameleonAPI$_{basic}$, over the other schemes is consistent across all three types of applications that make different types of decisions, as shown in Table 3. In fact, ChameleonAPI offers the highest accuracy by a clear margin for every single application in our evaluation, as shown in Figure 6.

To better compare the ChameleonAPI approach with Categorized models, we divide the 57 applications into two types: (1) 39 single-category applications — each application uses labels that belong to one category and hence can benefit from one specialized model in the Categorized models scheme; (2) 18 multi-category applications — each application uses labels that belong to multiple categories. For these applications, the Categorized models scheme feeds the API input to multiple specialized models and combines these models' output to form the API output. As shown in Table 4, the Categorized models scheme does offer improvement from Generic models by considering which labels belong to an application's target classes, particularly for single-category applications. However, both ChameleonAPI and ChameleonAPI$_{basic}$ perform better than Categorized models for both single-category and

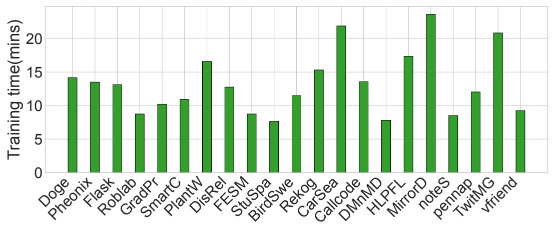


Figure 7: *Re-training time for applications in Figure 6(a).*

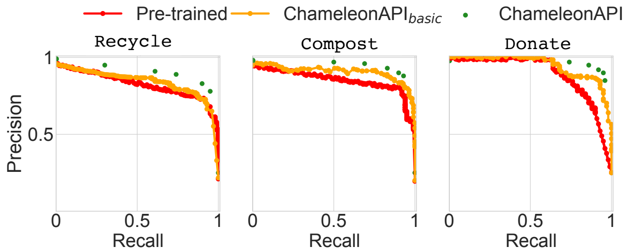

Figure 8: *Precision-recall trade-off for* `HeapsortCypher`*.*

multi-category applications—the per-application customization in ChameleonAPI and ChameleonAPI$_{basic}$ has paid off.

The above advantage of ChameleonAPI over ChameleonAPI$_{basic}$ and Categorized models shows that the static analysis used in ChameleonAPI to extract not only what labels are used by the application, but also which labels belong to the same target class, the decision type, and the matching order, as described in Section 3.3, is worthwhile.

Cost of obtaining customized models: The customization effort of ChameleonAPI includes two parts (1) extracting the decision-process summary from application source code, and (2) re-training the ML model. The first part takes a few seconds: on an Intel(R) Xeon(R) E5-2667 v4 CPU machine, our parser extracts the decision-process summary from every benchmark application within 10 seconds.

The second part takes a few minutes, much faster than training a neural network from scratch. As shown in Figure 7, re-training DNNs for the 21 applications in Figure 6(a) on a single RTX 3080 GPU takes 8 to 24 minutes. Focusing on a small portion of all possible labels (§2.4), ChameleonAPI fine-tunes pre-trained models using much less training data than the generic models and thus needs fewer iterations to converge.

Considering that a V100 GPU with similar processing GFLOPS as our RTX 3080 GPU only costs $2.38 per hour on Google Cloud [21], re-training an ML model for one application costs less than $1.

Cost of hosting customized models: For cloud providers, ChameleonAPI would incur a higher hosting cost than traditional ML APIs by serving a customized DNN for every application instead of a generic DNN for all applications.

The extra cost includes more disk space to store customized neural network models. For example, each image-classification model in ChameleonAPI uses 115 MB of disk space. So, for n applications, $115 \cdot n$ MB of disk space may be needed to store ChameleonAPI customized models.

The extra cost also involves more GPU resources. A naive design of using one GPU to exclusively serve requests to one customized neural network model will likely lead to under-utilization of GPU resources. To serve different applications' customized models on one GPU, we need to pay attention to memory working set and performance isolation issues. In our experiments on an RTX 3080 GPU, loading an image-classification model from CPU to GPU RAM takes 18 to 40 ms (inference itself takes 10 to 35 ms with a batch size of 1). Fortunately, modern GPU has sufficiently large RAMs to host several requests to different customized models simultaneously: in our experiments, the peak memory consumption of one inference request is less than 2GB. Furthermore, the majority of the model inference memory consumption comes from intermediate states, instead of the model itself. Consequently, the memory consumption of multiple inference requests on different models is similar to that on the same model.

Of course, ChameleonAPI can take advantage of recent proposals to improve GPU sharing [15, 55, 71, 73] as well as to reduce the footprint of serving multiple DNNs [33]. These techniques could be advantageously employed by ChameleonAPI to determine the optimal degree of sharing among customized DNNs, and we leave them to future work.

Finally, there is also the extra cost of needing more complex software to manage the DNN serving. For instance, ChameleonAPI needs to dynamically route each request to a GPU that serves the DNN of the application (see §3.4).

Precision-recall tradeoffs: Traditionally, for a trained ML model, it is common to vary the confidence-score thresholds in order to find the best precision-recall tradeoff of a trained model. Thus, it is important that ChameleonAPI also achieves better precision-recall tradeoffs. Figure 8 shows the precision-recall results in each target class of a particular application, by varying the detection threshold θ (defined in §3.2) of two baselines (real APIs are excluded, because we cannot change their thresholds and their IDR is not as low as ChameleonAPI$_{basic}$). ChameleonAPI's tradeoffs are better than both baselines (and we observe similar results in other applications). Note that since ChameleonAPI's loss function uses an assumed θ, we do not vary the θ when testing it; instead, we re-train five DNNs of ChameleonAPI, each with a different θ and test them with their respective thresholds.

Understanding the improvement: ChameleonAPI's unique advantage is that it factors in the decision process of an application, including not only the target classes but also the decision type and the matching order. Next, we use two case studies to further reveal the underlying tradeoffs made by ChameleonAPI to achieve its improvement on application-decision accuracy.

First, ChameleonAPI reduces errors related to different

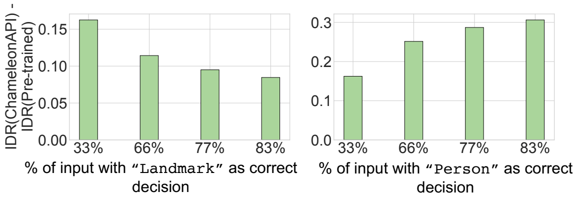

Figure 9: *How the accuracy advantage of ChameleonAPI changes with different input distribution.*

target classes differently depending on their different roles in the application decision process. This effect is particularly striking in Multi-Choice applications with the matching order of App-Order, where the first target class is always matched against API output. Thus, when the correct target class is not the first one, falsely including a label that belongs to the first target class will more likely be a critical error than other mis-classifications, because it will block the match of other target classes. To illustrate this, we consider the Multi-Choice application of `Aander-ETL`. We increase the percentage of testing inputs whose correct action is the first target class or the last target class. Figure 9 shows that increasing the portion of inputs of the last target class (`Person`) generally leads to bigger gains of ChameleonAPI, whereas increasing the portion of the first target class (`Landmark`) does the opposite. This shows the application itself already has good tolerance to mis-classification on inputs that belong to the first target class, but not to mis-classification on the inputs that belong to later target classes, which is exactly where ChameleonAPI can help.

Second, recall from §3.2 that our loss function helps to minimize critical errors, even at the cost of missing labels that do not affect application decisions (*i.e.,* non-critical errors). To show this, we define *label error rate* on an image as the fraction of the image's ground-truth labels that are missed by the DNN output (a label list). We consider `IoTWor` (explained in Table 5), which similar to `Anander-ETL` makes Multi-Choice decisions with App-Order matching order. The average label missing rate of ChameleonAPI on our testing images is 0.21, which is slightly higher than ChameleonAPI$_{basic}$'s 0.18. This means ChameleonAPI makes more label-level mistakes than ChameleonAPI$_{basic}$. However, our IDR (0.17) is 44% lower than ChameleonAPI$_{basic}$, which means ChameleonAPI makes far fewer critical errors.

6 Related Work

Due to space constraints, we discuss related papers that have not been discussed earlier in the paper.

Optimizing storage and throughput of DNN serving: Various techniques have been proposed to optimize the delay, throughput, and storage of ML models via model distillation [40, 54, 61], pruning [26] or cascading [4, 7]. This line of work explores a different design space than ChameleonAPI: they design ML models with higher inference speed or smaller model size with minimum loss in accuracy. ChameleonAPI focuses on re-training existing ML models such that the rate of incorrect decisions of a given application is reduced.

Application-side optimization: Recent work also proposes to change the applications to better leverage existing ML APIs. One line of work [11, 12, 69] invokes ML APIs from different service providers to achieve high accuracy within a query cost budget. Another line of work aims to eliminate misuse of ML APIs in applications [65, 66]. They require changes to the application source code (*e.g.,* changing the API input preparation, switching from image-classification API to object-detectin API, etc.). They are complementary to our work, because we customize the ML-API backend DNN and do not require changes on the application's source code.

Measurement work on MLaaS: For their rising popularity, ML-as-a-Service platforms have also attracted many measurement studies to understand accuracy [10], performance [70], robustness [28], and fairness [41]. However, they have so far not taken in account the ML applications that use ML APIs, and is thus different from our empirical study of ML applications in §2. Previous work that studies ML applications [65] did not look into the decision making process and how ML API errors might affect different applications differently.

Finally, a myriad of techniques have been studied to better manage and schedule GPU resources in ML training/serving systems (*e.g.,* [13, 16, 17, 22, 25, 27, 32, 42, 45, 53, 59, 60, 67, 72, 74]). They aim for different goals than ChameleonAPI, but these techniques can be used to help ChameleonAPI train and serve the application-specific ML models.

7 Conclusion

ML APIs are popular for its accessibility to application developers who do not have the expertise to design and train their own ML models. In this paper, we study how the generic ML models behind ML APIs might affect different applications' control-flow decisions in different ways, and how some ML API output errors may or may not be critical due to the application decision making logic. Guided by this study, we have designed ChameleonAPI that offers both the accuracy advantage of a custom ML model and the accessibility of the traditional ML API.

Appendix B Loss function for other decision-process summaries

True-False:

$$L(y) = \overbrace{\text{Sigmoid}(\max_{l\in G_{\hat{c}}}(\mathbf{y}) - \theta)}^{\text{Penalize } \textbf{Type-1} \text{ Critical Errors}} + \overbrace{\text{Sigmoid}(\theta - \max_{l\in G_c}(\mathbf{y}))}^{\text{Penalize } \textbf{Type-1} \text{ Critical Errors}} \tag{4}$$

Multi-Select:

$$L(y) = \overbrace{\sum_{c\in\hat{T}} \text{Sigmoid}(\theta - \max_{l\in Gc} \mathbf{y}[l])}^{\text{Penalize } \textbf{Type-1} \text{ Critical Errors}} + \overbrace{\sum_{c\in\cup_c G_c\setminus\hat{T}} \text{Sigmoid}(\max_{l\in Gc} \mathbf{y}[l] - \theta)}^{\text{Penalize } \textbf{Type-3} \text{ Critical Errors}} \tag{5}$$

Multi-Choice API-order: Here we explain why this loss function captures the critical errors:

- A Type-1 error occurs, if (1) the correct target class is matched, thus at least one of its labels has a score above the confidence threshold ($\max_{l\in G_{\hat{c}}} \mathbf{y}[l] \geq \theta$), and (2) it is matched after the EOD because all of the labels belonging to the correct target class have scores below the maximum score of labels in the incorrect target classes.
- A Type-2 error occurs if the maximum score for labels in a correct target class falls below threshold θ, thus it is never matched (before or after EOD).
- A Type-3 error occurs if any labels belonging ($\max_{l\notin G_{\hat{c}}} \mathbf{y}[l]$) to incorrect target classes appears before labels in the correct target class.

$$L(\mathbf{y}) = \overbrace{\text{Sigmoid}\left(\max_{l\in\cup_{c\neq\hat{c}}G_c} \mathbf{y}[l] - \max_{l\in G_{\hat{c}}} \mathbf{y}[l]\right)}^{\textbf{Type-1} \text{ Critical Errors}} + \overbrace{\text{Sigmoid}\left(\max_{l\in\cup_{c\neq\hat{c}}G_c} \mathbf{y}[l] - \theta\right)}^{\textbf{Type-2} \text{ Critical Errors}} + \overbrace{\sum_{c\neq\hat{c}} \text{Sigmoid}\left(\max_{l\in G_c} \mathbf{y}[l] - \max_{l\in G_{\hat{c}}} \mathbf{y}[l]\right)}^{\textbf{Type-3} \text{ Critical Errors}} \tag{6}$$

Value ranges: As for APIs that output a score $\mathbf{y}$ to describe the input, applications typically define several value ranges as target classes to make decisions, where the lower bound of the c^{th} target class is denoted as l_c and the upper bound of the c^{th} target class is denoted as u_c.

$$L(y_i) = \overbrace{\text{Sigmoid}(\mathbf{y} - u_{\hat{c}}) + \text{Sigmoid}(l_{\hat{c}} - \mathbf{y})}^{\textbf{Type-1} \text{ Critical Errors}} + \overbrace{\sum_{c\neq\hat{c}} \text{Sigmoid}(u_c - \mathbf{y}) + \text{Sigmoid}(\mathbf{y} - l_c)}^{\textbf{Type-3} \text{ Critical Errors}} \tag{7}$$

where $\hat{c}$ is the index of the correct target class. A Type-1 error occurs (*i.e.,* a correct target class is matched after EOD) when the output score $\mathbf{y}$ exceeds the upper bound of the ground-truth value range (u_c), or falls below the lower bound of the ground-truth value range (l_c). A Type-3 error occurs when the upper bound of an incorrect value range exceeds $\mathbf{y}$ *and* its lower bound falls below $\mathbf{y}$, leading it to be selected. Type-2 errors are absent in this application because all the target classes span the whole output range, thus a target class must be matched.

Appendix C Setup of Categorized models

Here, we describe in detail how we construct the label categories to support the scheme of Categorized models, which is one of the schemes in comparison with ChameleonAPI (Section 5).

Image-classification Image-classification APIs typically contains many thousands of labels without providing their categorization or hierarchy. Therefore, we create categories leveraging the Wikidata knowledge graph [68], a widely used knowledge graph database that has been referred to during the creation of many popular ML training datasets [23, 34, 44]. In this knowledge graph, each node is a named entity, covering *all* the labels used in popular image-classification APIs [2, 20, 52], and each edge represents a relationship between two entities (e.g., "subclass of", "different from", "said to be the same as").

Extracting "subclass of" edges in Wikidata knowledge graph, we get a directed acyclic graph (DAG) of label hierarchy. We believe it offers a principled foundation to create label categories based on two observations: (1) If an entity/node e is reachable from another entity/node e' through several subclass-of edges, e' is also covered by the *category* of e (e.g., entity "motor vehicle" is directly connected to "land vehicle", entity "land vehicle" is directly connected to "vehicle", so "motor vehicle" is also covered by the "vehicle" category); (2) The distance, measured in the number of subclass-of edges, between an entity/node and the DAG root indicates the specificity of the concept behind this node, with shorter distance representing coarser-grained categories. We will refer to a node that is k edges away from the root as a Level-k node.

Based on these observations, we formally define a set of categories C_k for all the image-classification labels L at a specificity level k as follows: C_k is the minimum set of Level-k nodes such that every label $l \in L$ is covered by at least one category node $c_k \in C_k$. We could categorize all the applications into single-category and multi-category applications using any level of specificity settings. In this paper, we adopt Level-2 specificity setting, since the number of single-category applications drops a lot when moving from Level-2 to Level-3, indicating Level-3 categories may be too fine-grained.

Under Level-2, we set up 35 categorized models that cover all the image-classification labels. Six of them are used by applications in our benchmark, including *natural object*, *temporal entity*, *artificial entity*, *system*, *phenomenon*, and *continuant*. With this categorization, 27 of the 40 image-classification applications are single-category, and the rest 13 applications are multi-category.

Object-detection Similar as image-classification API, every object-detection API label also corresponds to an entity node in the Wikidata knowledge graph. Therefore, we use the same methodology and the same specificity Level-2 to define categories for object detection labels.

Seven categorized models are set up to cover all object-detection labels. The object-detection labels used by 8 object-detection benchmark applications belong to 3 categories: *natural object*, *artificial entity*, and *system*. Under this setting, there will be 7 single-category applications, and 1 multi-category applications.

Text-classification The Google text-classification API [20] offers the hierarchy tree of all its labels. We simply follow their categorization and get 15 categories to covering all text-classification labels. Nine categories are used by applications in our benchmark, including *business & industrial*, *people & society*, *health*, *food & drink*, *jobs & education*, *news*, *sensitive subjects*, *adult*, and *law & government*. Under this categorization, there are 5 single-category text-classification applications, and 4 multi-category text-classification applications.

Other types of applications There are two other types of applications in our benchmark that are not suitable for designing pre-specialized models: sentiment analysis and named entity recognition.

For sentiment analysis API, the corresponding applications typically define several value-ranges and determine which range the API output (a sentiment score) falls into. Since the API output is a floating point number, there are infinite ways of defining value-ranges. Therefore, it is impracticable to create pre-categorized models.

For named entity recognition API, it only has 6 labels: *person, location, organization, number, date*, and *misc* [20]. They are already high-level categories. There is no need to create pre-categorized models for each category.

Appendix D Results of other applications

As mentioned in §5.1, the results of the 20 applications that involve sentiment analysis and entity recognition were not included in the evaluation section. Their results are shown in Figure 10 and 11. As we can see, the advantage of ChameleonAPI is consistent across these applications, similar to what we presented in§5. Note that, the scheme of Categorized models does not apply to applications that involve these two types of ML tasks, and hence is not included in Figure 10 and 11.

Abstract

This work introduces a new approach to building crash-safe file systems for persistent memory. We exploit the fact that Rust's typestate pattern allows compile-time enforcement of a specific order of operations. We introduce a novel crash-consistency mechanism, *Synchronous Soft Updates*, that boils down crash safety to enforcing ordering among updates to file-system metadata. We employ this approach to build SquirrelFS, a new file system with crash-consistency guarantees that are *checked at compile time*. SquirrelFS avoids the need for separate proofs, instead incorporating correctness guarantees into the typestate itself. Compiling SquirrelFS only takes tens of seconds; successful compilation indicates crash consistency, while an error provides a starting point for fixing the bug. We evaluate SquirrelFS against state of the art file systems such as NOVA and WineFS, and find that SquirrelFS achieves similar or better performance on a wide range of benchmarks and applications.

1 Introduction

One of the most important properties for file systems is to preserve their integrity and user data in the face of a crash or a power loss [16, 20, 28, 31, 42, 43, 51]. Unfortunately, building crash-consistent file systems is challenging; checking or ensuring crash consistency is even more so [17, 40].

There are two main approaches to building file systems today, as summarized in Table 1. First, we build file systems using low-level languages like C, and we use runtime testing to gain some confidence in the correctness of the systems [36, 37, 41, 46, 47, 59]. Note that this approach is necessarily incomplete; testing can only reveal bugs, not prove their absence. However, this approach allows rapid development, and entire testing ecosystems have sprung up around this basic approach, like the widely-used xfstests [10] and Linux Test Project [5].

A different approach to building file systems is to verify them: we write a high-level specification of correct behavior (including crash behavior) and then prove that the implementation matches the specification [17–19, 29, 53]. This approach can prove that the implementation does not have certain classes of bugs; however, it comes at a high cost. For each line of code in the implementation, we may need to write 7–13 lines of proof. Writing and maintaining proofs is time-consuming and requires specialized expertise, constraining rapid development.

Approach	Complete	Dev effort	Time to check
Testing	No	Low	Medium
Verification	Yes	High	High
This work	Yes	Medium	Low

Table 1: Comparison of different approaches to ensuring crash consistency in file systems.

In this work, we seek to find a middle ground between these two approaches. We would like to verify some aspects of file systems, but without the burden of having to write and maintain proofs. In particular, we are interested in *crash consistency*, a correctness property that is especially difficult to test for. In order to be crash consistent, systems must ensure that updates become persistent on storage media *in the correct order*; however, hardware or caching layers may reorder updates to improve performance in unanticipated ways. Exposing crash-consistency bugs thus requires one to find and reproduce these low-level orderings, which requires specialized testing software [36, 37, 41, 46, 47, 59]. Our goal is to develop lightweight approaches to statically check for crash-consistency bugs without the overhead of full verification.

We exploit two recent developments to achieve this goal (§2). First, the Rust programming language has a strong type system that supports powerful compile-time safety checks. Our work takes inspiration from Corundum [32], a Rust crate (library) that uses Rust's type system to check low-level PM safety properties. In this work, we observe that Rust's type system can also statically enforce that certain operations are carried out in a given order [27, 38]. Since the root of crash consistency is ordering updates to storage, if we can encode those ordering-based invariants in the type system, the com-

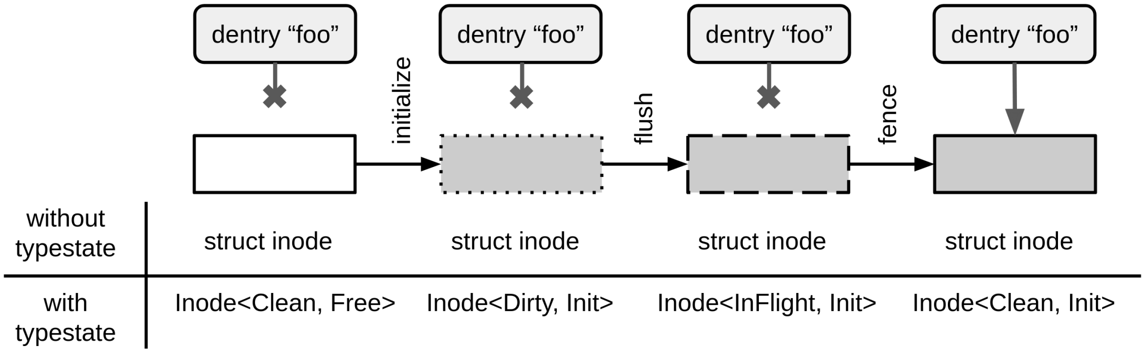

Figure 1: For a soft updates file system to be crash-consistent, directory entries should only point to fully-initialized, durable inodes. In existing file systems, all persistent inodes have the same type, regardless of whether they are durable or have been initialized. With typestate, durability and the inode’s contents are reflected in its type.

piler can ensure the invariants hold at compile time.

However, to do so, crash consistency must be derived purely from ordering-based invariants; some mechanisms such as journaling use writes to a log to obtain atomicity, which is harder to encode in the type system. Soft updates achieves crash consistency purely via ordering [43], but the traditional soft updates scheme is complex and hard to implement [13, 25].

We observe that the low latency of persistent memory [56, 59] allows file-system operations to be *synchronous*; all updates to storage media are durable by the time each operation returns [24, 34, 35, 39, 57]. We take advantage of persistent memory’s synchronous updates and byte addressability to develop a new mechanism for crash consistency we term *Synchronous Soft Updates*.

Synchronous Soft Updates builds on the classical soft updates mechanism [43], but avoids most of the complexity that prevented the widespread adoption of soft updates [13]. Two of the most complicated aspects of soft updates, dependency structures and cyclic dependency management, arise due to the need to track ordering requirements between block-sized updates across asynchronous operations. Synchronous Soft Updates eliminates these challenges entirely by using fast, fine-grained storage to back synchronous operations.

We ensure that the ordering invariants of Synchronous Soft Updates hold by using the Rust compiler. We take advantage of Rust’s support for the *typestate pattern*, an API design pattern where an object’s type reflects the operations that have been performed on it [54]. The legal order of operations is encoded in function signatures and enforced by Rust’s typechecker. For example, an uninitialized inode has a different type than an initialized one; attempting to use one where the other is expected will result in a compile-time error. Figure 1 illustrates the approach.

We implement Synchronous Soft Updates in a new file system for PM called SquirrelFS and use the typestate pattern in Rust to check that update orderings are implemented correctly. SquirrelFS provides crash-atomic metadata system calls, including `rename`; on the original soft updates, a crash during rename could result in both the source and destination existing. SquirrelFS compiles and typechecks in seconds, whereas running verification on existing storage systems takes minutes or hours. Building SquirrelFS required no modifications to the Rust language.

We evaluate SquirrelFS by comparing to a number of file systems meant for persistent memory, such as NOVA [57] and WineFS [34] (§5). We use Intel’s Optane DC Persistent Memory Module for our comparison, and find that SquirrelFS offers comparable or better performance to other PM file systems across a broad range of workloads. The current SquirrelFS prototype prioritizes simplicity of update ordering rules over performance in some areas, leading to relatively high mount times and memory utilization; however, these are not fundamental limitations of the design. We also model the design of SquirrelFS using the Alloy model-checking language [33] to gain confidence in the correctness of its Synchronous Soft Updates mechanism.

We note that SquirrelFS is not fully verified, and thus does not obtain the strong correctness guarantees of verified storage systems like FSCQ [19]. Crash-consistency bugs may still occur in SquirrelFS if their root causes are unrelated to ordering, if the ordering rules enforced by the compiler are incorrect, or if trusted code in SquirrelFS’s implementation or the Rust compiler are buggy. For example, SquirrelFS’s ordering rules guarantee that inodes are always initialized before they are linked into the file system tree, but they do not guarantee that the contents of the inode are correct. SquirrelFS’s static checks are also limited by the capabilities of the Rust compiler. For instance, the Rust compiler cannot check properties about variable-sized sets of data structures, as checking such properties is undecidable in general.

SquirrelFS offers a useful new point in the spectrum of approaches to building robust storage systems; it provides weaker guarantees than verified systems, but comes at a lower cost. As such, we hope that it proves useful for developers of storage systems that require strong guarantees, good performance, and rapid development.

In summary, this work makes the following contributions:

- Statically-checked crash consistency, an approach where high-level properties are encoded into the type system and checked at compile time (§3)
- The Synchronous Soft Updates crash-consistency mechanism for persistent-memory file systems (§3.1)
- The SQUIRRELFS prototype, along with a discussion of lessons learned during its development (§4).

SQUIRRELFS and its Alloy model are publicly available at https://github.com/utsaslab/squirrelfs.

2 Background and Motivation

2.1 Crash Consistency

A file system is *crash consistent* if it can recover to a consistent state after a power loss or a crash [16,20,51]. A consistent file system is one where all the metadata is in sync; for example, two files cannot (mistakenly) claim the same data block. Files present before the crash must exist post-crash, and the data in files must remain valid.

Crash-consistency mechanisms. Crash consistency is generally achieved using mechanisms such as journaling [28,48], copy-on-write [1,31,42], or soft updates [43]. The root of crash consistency is correctly *ordering* writes to storage [20]; for example, a data block must be initialized before a file points to it. Soft updates achieves crash consistency by carefully ordering in-place updates to storage such that all possible crash states are consistent [43]. To enforce ordering, soft updates must track updates across asynchronous operations and resolve cyclic dependencies when they arise. Though soft updates is used in FreeBSD [44], it has not been widely adopted due to its high complexity.

Ensuring crash consistency. Ensuring that a given file system achieves crash consistency is challenging. There are two main approaches. The first approach is testing, in which possible crash states of a file system are explored and checked for consistency. Obtaining these crash states requires support from tools like eXplode [59], CrashMonkey [46], Hydra [37], Chipmunk [41], or Vinter [36]. While such testing tools can find many bugs, they cannot prove overall correctness or the absence of crash-consistency bugs.

The second approach is to build verified file systems. A developer writes a high-level specification of correctness and a lower-level implementation, and proves that the implementation satisfies the specification. This approach is stronger than testing in that it can prove strong correctness properties and verify that there are no bugs. However, it comes at a high cost: the developer has to write 7–13 lines of proof for every line of code. For example, BilbyFS [12] required 13k lines of proof for 1k lines of implementation code; VeriBetrKV [29] used 45K lines of proof for 6k lines of implementation. Another verified file system, FSCQ [19], has interleaved proof and implementation code that is 10× the size of the most similar unverified system.

This heavy proof burden constrains development in a number of ways. First, building a verified system requires proof-writing expertise, which restricts the set of developers who can work on it. Second, proofs must be written in tandem with the code that they verify, which extends development time. Finally, making changes to the system requires corresponding changes to the proofs, making maintenance slow and preventing rapid updates.

Corundum [32] is a Rust crate for PM systems that, like SQUIRRELFS, uses the Rust type system to enforce certain low-level PM safety properties at compile time. For example, Corundum ensures that every update to PM occurs in a logged transaction, and prevents the storage of pointers to volatile memory in durable structures. SQUIRRELFS was inspired by Corundum and aims to enforce higher-level properties like file-system crash consistency with Rust.

2.2 The opportunity: Rust and PM

We observe an opportunity to ensure file-system crash consistency in a cheap manner.

First, we note that the Rust programming language can **statically enforce a specific order on operations** via its support for the *typestate pattern* [9,27]. Briefly, the typestate pattern enables an object's runtime state to be encoded in its type [54]. This state can be checked at compile time via typechecking, ensuring that a given operation can only occur on a specific type. Typestate information is stored in zero-sized types that incur no runtime overhead.

For example, one consistency rule enforced by soft updates is that a directory entry should never point to an uninitialized inode. Listing 1 shows how typestate is used to enforce this rule. To create a new file, we first obtain a free directory entry and inode. Initially, both objects have typestate `Free`. Then, we initialize the directory entry, transitioning its type to `Dentry<Init>`. The listing then has a bug in which the directory entry's inode number is set by `commit_dentry()` before the inode is initialized, breaking the consistency rule. The Rust compiler catches this bug because the inode's current typestate `Free` does not match the typestate `Init` expected by the function.

Since soft updates is entirely built on ordering updates to file-system objects, we can translate the required partial order into a set of types and use Rust's type checking to enforce the order. Thus, the invariants we want to maintain are translated into something the type system and compiler can enforce. We note that we are able to do this with an *unmodified* Rust compiler; the new types introduced are no different to the

```
fn new_file() {
    // Dentry<Free>
    let d = Dentry::get_free_dentry();
    // Inode<Free>
    let i = Inode::get_free_inode();
    // Dentry<Init>
    let d = d.set_name("foo");
    let d = d.commit_dentry(i);
                   ^ expected 'Inode<Init>',
                     found 'Inode<Free>'
}
```

Listing 1: The listing shows the typecheck process throwing an error when an uninitialized inode is passed to a function that expects an initialized inode.

compiler from existing types in the codebase.

However, implementing soft updates correctly remains challenging even with typestate support. With soft updates, file-system updates are applied to the page cache in DRAM, and then later written to storage in the right order. Determining the right order requires tracking complex dependencies across asynchronous operations. When a single file-system metadata object (such as an inode or a bitmap) is updated multiple times, it can lead to cyclic dependencies.

This leads to our second observation: persistent memory (PM) file systems support synchronous operations thanks to the low latency of the storage media [56, 58]. These file systems write updates directly to storage without first caching them in DRAM [24, 34, 35, 39, 57]. A **synchronous implementation** of soft updates for persistent memory **eliminates** the complexities of asynchronous dependency management, greatly simplifying the mechanism and allowing the relevant invariants to be encoded in Rust's type system.

3 SquirrelFS

We now present the design and implementation of SquirrelFS, a novel file system that uses the unmodified Rust compiler to check its crash consistency. If the compilation is successful, it indicates that the ordering-based invariants hold throughout the file system: in other words, the checking is complete. If compilation fails, the error reported by Rust is useful in figuring out which operations are out of order. Compilation takes only seconds, offering quick feedback to developers.

SquirrelFS is built on two key ideas:

- A novel crash-consistency mechanism, Synchronous Soft Updates, that achieves crash consistency purely via ordering file-system operations (§3.1)
- Using the Rust typestate pattern to encode ordering invariants into the Rust type system (§3.2)

It is important to note that we are not modifying the Rust compiler in any way. To the Rust compiler, it is no different from type-checking any other code base; we are merely using the type checking to ensure that crash consistency holds in the file system.

We now describe the key ideas in more detail.

3.1 Synchronous Soft Updates

We develop *Synchronous Soft Updates* (SSU), a novel crash-consistency mechanism. SSU is based on the traditional soft updates approach, but differs in two key aspects. First, soft updates was designed for asynchronous settings, but all operations are synchronous in SSU. Second, soft updates does not provide atomic rename; a crash during a rename of `src` to `dst` can result in both being present after a crash. SSU fixes this flaw; renames are atomic, and a crash during rename will result in either `src` or `dst` after recovery.

We now discuss why we developed SSU, its key aspects, and how renames are atomic in SSU.

Why a new mechanism? To go with our overall approach of encoding ordering-based invariants into the Rust type system, we needed a mechanism that achieves crash consistency purely via ordering file-system updates. This rules out mechanisms such as journaling and copy-on-write that use writes to a log or an extra copy to obtain atomicity. Soft updates [43] obtains crash consistency by enforcing ordering on in-place persistent updates to file-system objects; thus, it was a good match. However, traditional soft updates suffered from two problems that we needed to tackle. The first challenge was that soft updates had significant complexity arising from needing to track dependencies between asynchronous file-system operations; the presence of cyclic dependencies also requires complex roll-back and roll-forward logic. The second challenge is that soft updates does not provide atomic operations, particularly rename; atomic rename is a crucial primitive for a number of POSIX applications [50]. Thus, we need to modify soft updates to tackle both its high complexity and lack of atomic operations.

Synchronous operations. We observe that the root of complexity in soft updates (such as cyclic dependencies and structures for tracking dependencies) is *asynchrony*. A *synchronous* implementation of soft updates neatly avoids these complexities. All updates would be made durable by the end of each system call, which would eliminate the need to track cross-operation dependencies. Cyclic dependencies would no longer arise because there are no pending updates that can conflict with each other. The SoupFS [23] soft updates file system for persistent memory eliminated cyclic dependencies using fine-grained updates, but still required asynchronous dependency tracking. A synchronous implementation is necessary to overcome both sources of complexity.

A synchronous version of soft updates was not feasible until now, as running this on magnetic hard drives or even solid state drives would be prohibitively slow. However, synchronous soft updates is a good match for persistent memory (PM) due to its low latency; system calls in many existing PM file systems are already synchronous [24, 34, 35, 57].

Similar to traditional soft updates, SSU maintains crash consistency by enforcing ordering among updates to file-system objects. SSU implements the original soft updates rules [26]:

1. Never point to a structure before it has been initialized;
2. Never re-use a resource before nullifying all previous pointers to it;
3. Never reset the old pointer to a live resource before the new pointer has been set.

These rules are significantly easier to enforce in a synchronous setting, as there is no need to track dependencies across asynchronous operations. Like soft updates, SSU focuses on the integrity of file system metadata and cannot guarantee that operations on file data are atomic. SSU could be combined with journaling or copy-on-write to obtain stronger data guarantees.

Atomic rename in SSU. SSU ensures renames are atomic by cleaning up file-system state after a crash. In traditional soft updates, if there is a rename from `src` to `dst`, it is impossible to tell after a crash whether `src` or `dst` should be removed. To resolve this, SSU adds an extra field, called the *rename pointer*, to directory entries in order to persistently save enough information to complete the rename operation after a crash. The rename pointer in the destination directory entry points to the physical location of the source directory entry. The rename pointer allows the file system to follow soft updates rule 3 (never reset the old pointer before the new one has been set) while also retaining the ability to distinguish between `src` and `dst` after a crash.

Note that this is similar to what journaling-based file systems do; they write a log entry specifying `src` and `dst` so that the right clean-up action can be performed. In SSU, the information in this log entry is distributed over the source and destination inodes; taken together, they provide enough information to the file system.

Figure 2 illustrates the process. Step ❶ shows an example system state prior to the `rename` operation. In ❷, `dst`'s rename pointer (dotted line) is set to `src`. `dst` is invalid, and `src` is still valid. In ❸, we make `dst` valid; this also logically invalidates `src`. This is an atomic point; after this step, the file system will always complete the rename operation. If the file system crashes prior to this step, the rename pointer is cleared on recovery. In ❹, we physically mark `src` as invalid. In ❺, the rename pointer is cleared, and in ❻ `src` is fully deallocated. Each step either modifies metadata that is invisible to the user (e.g., deallocating an orphaned directory entry) or atomically modifies a single 8-byte value. All modifications must be durable before proceeding to the next step.

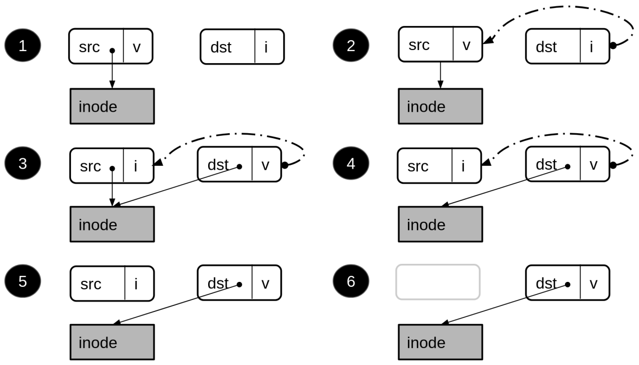

Figure 2: The figure shows the steps in atomic soft updates `rename`. The dotted lines represent rename pointers and the solid lines represent inode pointers. `src` and `dst` are directory entries. The labels "v" and "i" indicate whether a directory entry is valid or invalid.

A question that arises is how the file system finds `src` and `dst`. This is an example of how SSU is tailored for PM file systems. In PM file systems, it is common for the file system to scan persistent objects to construct indexes in DRAM; we add the rename-recovery procedure into this scan. Thus, when building volatile indexes after a crash, the file system also looks for and completes any partially completed rename operations.

3.2 Using Rust to enforce ordering

Rust's typestate pattern can be used to ensure that *a set of functions are always called in certain partial order*. A total order is not necessary, as many operations involve independent updates that can be safely reordered. As we discussed previously (§2), an object's typestate is encoded in generic type parameters in its definition, and the partial order is encoded in the function signatures of its associated functions.

We encode two states (as different type parameters) in the types of persistent objects:

- *Persistence* typestate is a representation of whether an object's most recent update(s) have been made durable. We use three persistence typestates: `Dirty`, `InFlight`, and `Clean`.
- *Operational* typestate represents the operations that have been performed on an object and is used to determine what operations can happen next.

Persistence and operational typestate are separate to capture the fact that most storage devices do not synchronously flush updates. For example, in persistent memory, updates go to

```
impl Inode<Clean, Free> {
    fn init_inode(self, ino: u64, ...)
        -> Inode<Dirty, Init> {...}
}
impl Dentry<Clean, Alloc> {
    fn commit_dentry(
        self,
        inode: Inode<Clean, Init>
    ) -> Dentry<Dirty, Committed> {...}
}
impl<S> Inode<Dirty, S> {
    fn flush(self) ->
        Inode<InFlight, S> {...}
}
impl<S> Inode<InFlight, S> {
    fn fence(self) ->
        Inode<Clean, S> {...}
}
```

Listing 2: Pseudocode implementations of file system objects with persistence and operational typestate. Typestate arguments are shown in bold.

the CPU caches first, and must be explicitly flushed to the persistent media.

Listing 2 shows implementations of several methods of persistent Inode and Dentry types with persistence and operational typestate as generic type parameters. The methods flush and fence invoke a cache line write back and store fence respectively and are generic with respect to operational typestate. These methods must be used to ensure updates are persistent before continuing; for example, commit_dentry() requires an Inode<Clean, Init> to ensure the inode's initialization cannot be transparently reordered with the directory entry updates.

This formulation of persistence typestate has several performance benefits. First, because the flush and fence methods can only be called on an object whose typestate indicates it is not yet persistent, typechecking will prevent redundant persistence operations (thereby improving performance). Second, developers can wait to flush updates until it is strictly necessary and can write additional transitions to enable multiple updates to share a single fence.

Why Rust? In order to obtain useful compiler-checked guarantees from the typestate pattern, each object must have exactly one typestate [54]. Thus, languages with unrestricted aliasing (e.g., C) cannot support the typestate pattern, as different aliases for the same value can have different types. Rust supports the pattern via its ownership type system, which ensures that each value has exactly one owner (and thus exactly one type).

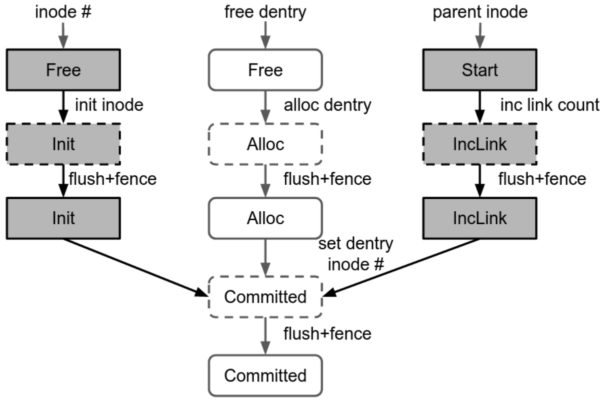

Figure 3: The figure shows the persistent updates and corresponding dependencies made during mkdir. Inodes are dark gray and directory entries are white. Each object is labeled with its operational typestate and its outline indicates whether it is clean (solid) or dirty (dotted).

3.3 Example: mkdir

We use mkdir to illustrate the typestates and dependency rules used in SSU. To be crash consistent, an SSU implementation of mkdir must ensure (1) that a structure never points to an uninitialized resource, and (2) that each inode's link count is greater than or equal to its actual number of links. Both rules prevent dangling links in the event of a crash.

Figure 3 illustrates the dependencies in a mkdir operation. During mkdir, three file-system objects are modified: an inode for the new directory, a directory entry for the new directory, and the inode of the parent directory. Note that all three can be modified at the same time in a concurrent fashion, and can share a single store fence at the end (not shown). SQUIRRELFS uses volatile allocation structures, so they are not persisted during mkdir.

The system first finds the parent inode and obtains a free directory entry in one of the parent's pages as well as a free inode. The inode is then initialized (i.e., setting its inode number, link count, timestamps), the directory entry's name is set, and the parent inode's link count is incremented.

Next, we commit the directory entry by setting its inode number. This makes the directory entry valid and connects the inode to the file system tree. Directory entry commit is dependent on inode and directory entry initialization and parent link increment. Committing the directory entry before initializing the inode can result in a directory entry pointing to a garbage inode; committing before incrementing the parent's link count can lead to dangling links.

3.4 Implementation

We implemented SQUIRRELFS in Rust with 7500 LOC. It uses bindings from the Rust for Linux project [8] to con-

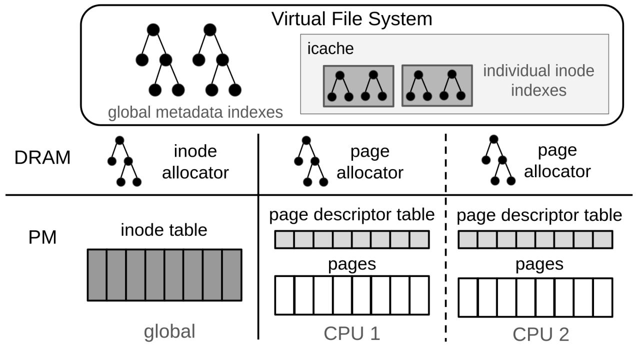

Figure 4: The figure shows the main components of SQUIRRELFS. Each CPU has its own pool of pages and private page allocator. The inode allocator is shared between all CPUs. Volatile indexes are stored in VFS data structures.

nect to the Linux Virtual File System (VFS) layer. Figure 4 shows SQUIRRELFS's architecture. We also built a model of SQUIRRELFS in the model-checking language Alloy [33] to check its design for crash consistency issues. We describe our experience developing SQUIRRELFS in §4.

Overview. The design of SQUIRRELFS combines aspects of FreeBSD's FFS [44] and PM file systems such as NOVA [57] and WineFS [35]. Like FFS, it has a simple on-storage layout, and uses soft updates. Like other PM file systems, SQUIRRELFS uses volatile index structures that are built when the file system is mounted.

SQUIRRELFS's design was primarily influenced by two factors. First, we wanted to keep dependencies as simple as possible and avoid nested persistent structures that are difficult to represent in typestate. Second, we assume the x86 PM persistence model in which only aligned updates of 8 bytes (or smaller) are crash atomic [24]. Under the x86 model, persistent addresses can be accessed via regular memory stores, but the corresponding cache line must be flushed before updates become persistent; a memory barrier like a store fence must also be invoked to correctly order stores [52]. Durable structures may also be updated via cache-bypassing non-temporal store instructions, which still require a store fence for persistence ordering. This programming model influences the structure of persistent objects and restricts the set of legal orderings.

All system calls in SQUIRRELFS are synchronous, meaning that updates to durable structures made by each system call are durable by the time the system call returns. As such, `fsync` is a no-op in SQUIRRELFS. Metadata-related operations are also crash-atomic. Data-related operations are not atomic in the current SQUIRRELFS prototype, which matches the default behavior of other PM file systems like NOVA [57]. These operations could be made atomic by using copy-on-write to update file contents.

Persistent layout. SQUIRRELFS uses a simple layout to reduce the complexity of update dependencies. SQUIRRELFS splits the storage device into four sections: the superblock, the inode table, the page descriptor table, and the data pages. The inode table is an array of all of the inodes in the system. SQUIRRELFS reserves enough space for approximately one inode for every 16KB of data (four pages), the same ratio used by the Linux Ext4 file system.

The page descriptor array contains page metadata. Rather than having inodes point to the pages they own, each page descriptor contains a backpointer to its owner (similar to NoFS [21]) and stores its own metadata (e.g., its offset in the file). This approach simplifies dependency rules for updates involving page allocation and deallocation. All remaining space after the page descriptor table is used for data and/or directory pages.

Volatile structures. SQUIRRELFS's persistent layout simplifies typestate and update dependency rules, but it is not amenable to fast lookups. Therefore, SQUIRRELFS uses indexes in DRAM to speed up lookup and read operations. Each inode in the VFS inode cache has a private index for the resources it owns; index data for uncached nodes is stored in the VFS superblock.

Like many other PM file systems, SQUIRRELFS uses volatile allocators: allocation information is not stored in a persistent manner, but rather rebuilt each time the file system is mounted. It uses a per-CPU page allocator and a single shared inode allocator (which could be converted to a per-CPU allocator to improve scalability). The allocators use free lists backed by kernel RB-trees.

SQUIRRELFS's indexes and allocators are rebuilt by scanning the file system when SQUIRRELFS is mounted. An inode, directory entry, or page descriptor is considered allocated if *any* of its bytes are non-zero. Directory entries and page descriptors are only valid if their inode numbers are set; inodes are valid only if they are reachable from the root. Thus, updates that allocate new structures and set non-inode metadata fields need not be crash-atomic.

Synchronous Soft Updates. SQUIRRELFS uses an implementation of SSU for crash consistency. As shown in Figure 3, operations that involve creation of new objects must first durably allocate and initialize resources before linking them into the file system (setting the directory entry's inode in the example) to enforce rule 1 (never point to a structure before it has been initialized). Deallocation proceeds in reverse; links are first cleared, then the object itself is deallocated by zeroing all of its bytes. SQUIRRELFS enforces rule 2 of soft updates (never re-use a resource before nullifying all previous pointers to it) by treating durable objects that are not completely zeroed out as allocated and by ensuring via typestate that pointers to the object are cleared before the object can be zeroed.

Typestate transition functions. SQUIRRELFS updates the typestate of objects via *typestate transition functions*. These functions take ownership of the original object, modify it, and return it to the caller with the new typestate. These functions are defined only on certain typestates to ensure they are called in a safe order. For example, the typestate transition function `commit_dentry()`, shown in Listing 2, is only defined for directory entries with type `Dentry<Clean, Alloc>`, and also takes ownership of an inode of type `Inode<Clean, Init>`. Calling `commit_dentry()` out of order – e.g., on a directory entry that has not yet been persistently allocated – is a potential crash-consistency bug and results in a compiler error.

Concurrency. SQUIRRELFS supports concurrent file-system operations. It relies on VFS-level locking on durable resources like inodes. This locking, together with Rust's type system, ensures that each resource has only one owner – and only one type – at any time, enabling strong typestate-based compile-time checking. SQUIRRELFS uses internal locks to protect its allocators and indexes.

Building a model with Alloy. While the typestate pattern can enforce a given operation order, it cannot verify that this order is crash consistent. To gain more confidence that SQUIRRELFS's design is crash consistent, we built a model of SQUIRRELFS in the Alloy model checking language [33].

Alloy provides a language for specifying transition systems and a model checker to explore possible sequences of states (traces) of these systems. Alloy's implementation is based on a logic of relations; each system is composed of a set of constraints that define a set of structures and the relations between them, and the model checker uses constraint solving to find traces.

In SQUIRRELFS, there is roughly a one-to-one mapping between typestate transitions in the Rust implementation and the next-state predicates in the Alloy model. Each next-state predicate specifies the states in which the transition may occur and the changes it makes to the model's state.

The model includes next-state predicates for typestate transitions and persistent updates. It also includes transitions that model crashes and recovery, which let us check SQUIRRELFS's design for crash-consistency bugs.

Each persistent structure in SQUIRRELFS is represented by a corresponding structure, also called a signature, in Alloy. The model also includes a `Volatile` signature that is used to model volatile aspects of the file system like its indexes. Each typestate is represented by a signature, and instances of persistent structures are mapped to their current typestate. Each file system operation is also represented by a signature, and relations map system calls to instances of persistent objects they are operating on as well as other volatile state (e.g., the locks held by that operation). We use this to model concurrent file-system operations.

3.5 Limitations of the approach

It is important to note that the typestate-based approach used in SQUIRRELFS is not as powerful as full verification. Fully-verified systems, such as the FSCQ file system [19], use theorem provers that can prove a wide variety of complex properties. For example, a developer could prove, if required, that the system only uses even-numbered inodes for files.

In contrast, our typestate-based approach can only check *ordering-based* invariants. Our approach could be used to verify that functions are called in a specific order; for example, our approach can ensure that a file is not linked into the file-system tree before it is allocated. However, it does not verify the implementation of each function that is called.

Thus, full verification is significantly more powerful and general, but it pays a cost in terms of complexity and development time. Our approach is more targeted and ordering-based, but allows quick feedback and incremental development.

We believe this approach is a valuable addition to the repertoire of tools we have for building correct file systems. This approach should be used alongside runtime testing and model-checking approaches.

3.6 Relevance beyond PM

While we have designed SQUIRRELFS for persistent memory, SQUIRRELFS would be relevant for any storage technology with byte-addressability and low latency. The Compute Express Link [2] standard will support attached memory devices, including PM, via the Type 3 (CXL.mem) protocol. These CXL-attached PM devices will have the same interface and persistence semantics as current NVDIMMs, though performance will be lower [14].

SQUIRRELFS, and SSU file systems in general, could be used on CXL-attached memory. As SQUIRRELFS's mount performance and memory footprint are tied to the size of the device, they may worsen with significantly larger-capacity devices. Further work will be required to optimize file systems based on our approach for such devices.

4 Experience developing SQUIRRELFS

We now describe our experience with designing, developing, and testing SQUIRRELFS. We also discuss the challenges we faced during this process.

4.1 Development process

Designing SQUIRRELFS. Our initial design closely followed that of BSD FFS [43], but most aspects eventually diverged due to differences between storage hardware and typestate considerations. We found that some data structures and crash-consistency properties were better suited for use with the typestate pattern than others. For example, we chose SquirrelFS's backpointer-based page management approach because it simplifies update dependency rules when allocating or deallocating pages. With backpointers, these operations involve a constant number of persistent updates and involve no additional durable structures. In contrast, tree or log-based approaches need extra persistent metadata and may require additional updates to balance the tree or free log space, both of which complicate dependencies and typestate management.

An important design decision we had to make was how granular typestate would be. One option was to use specific typestates to represent each fine-grained operation; e.g., have one typestate for initializing an inode's link count, another for setting its flags, etc. Another was to make each typestate more general, with transition functions potentially performing multiple persistent updates. More general typestates may sacrifice some bug-finding power, but they make the system easier to understand and develop. In SquirrelFS, we aimed to strike a balance by representing only operations that require a specific ordering with typestate. For example, when initializing an inode in SquirrelFS, the order in which the values of most fields are set is not relevant to crash consistency, as the contents of the inode are not visible until it is linked into the file system tree. Therefore, SquirrelFS uses only a single typestate (`Init`) to represent inode initialization, and another (`Committed`) to indicate when it has been added to the tree.

Parallel model and system implementation. We developed the Alloy model alongside SquirrelFS. This created a useful feedback loop in which the model supported the Rust implementation, and questions or changes to the implementation could be quickly reflected and checked in the model. We used an incremental development process, incorporating feedback from the Rust compiler and the model immediately as we implemented the system. Many transitions in the model could be translated directly into Rust typestate transitions, making the model a valuable guide for implementing file system operations. When we made mistakes translating the model into Rust, typestate checking quickly caught these issues.

Alloy also includes a graphical user interface for visualizing traces of operations on the model. This was useful for both investigating invariant violations and seeing the set of transitions that occur in a given file system operation, which could be translated directly into system call handler implementations. It also demonstrated locations where multiple updates could safely share a single store fence, which helped us avoid redundant fences.

4.2 Finding bugs

While developing SquirrelFS, we used a combination of typestate checking, model checking in Alloy, and dynamic testing to find bugs.

Typestate checking. Typestate checking in the implementation was successful at quickly catching both missing persistence primitives and higher-level ordering bugs; we provide an example of each.

- *Missing persistence primitives*. Our initial implementation of `write` was missing flush and fence calls after setting the backpointer of a newly-allocated page. This bug was immediately highlighted as an error by the compiler. Had this bug made it into the implementation, a crash could cause a file to have a size larger than the number of pages associated with it, causing errors when trying to read the file.
- *Incorrect ordering*. Our initial `rename` implementation mistakenly decremented an inode's link count before clearing the corresponding directory entry. A crash could result in a link count that is lower than the true number of links, leading to a dangling link if the inode is subsequently deleted.

Although we did not specifically check execution paths without crashes, the crash-consistency invariants encoded in typestate were general enough to detect some bugs in this code. For example, the compiler caught a bug where pages were not fully deallocated during `unlink`, which did not require a crash to manifest. Typestate-related compiler errors were relatively uncommon overall, since using the model as a guide for implementation helped us get ordering right early. However, it provided a crucial safety net to prevent subtle bugs when we did make mistakes.

Model checking with Alloy. The Alloy model found several high-level issues in SquirrelFS's design that would have otherwise been difficult to detect and time-consuming to fix, including the following examples.

- We initially believed that crash recovery would not be needed other than to fix space leaks. Alloy found an instance of the model where a crash during rename followed by deallocation of the destination directory entry could cause an invalid directory entry to reappear. Fixing this required the addition of recovery transitions.
- Early designs for SquirrelFS stored . and .. directory entries durably. We discovered via model checking that our original dependency rules for handling these directory entries during more complicated operations like `rename` were not correct. Ultimately, we decided to not store these entries, since they can be constructed at runtime using indexed information.

Testing. Neither the typestate pattern nor the Alloy model eliminated the need to test SquirrelFS. Our primary goal was to check crash-consistency, and we did not check any invariants that only impact regular, non-crash execution. We used handwritten tests and the xfstests suite [10] to test these unchecked parts of the code.

All bugs found through testing were in parts of SQUIRRELFS that were not checked by typestate or directly modeled in Alloy. Most bugs were related to updating volatile indexes or VFS inodes, e.g., failing to remove a deallocated object from an index or setting the wrong value in the VFS inode. There were also bugs in the implementations of typestate transitions, which are not themselves verified; for example, the transition that wrote new file data to a page did not always calculate the offset for non-aligned writes correctly. Implementing bug fixes was quick since we did not need to modify the typestate-restricted interface to objects and there were no proofs to update.

4.3 Challenges encountered

Challenges with typestate. It is easier to write typestate-checked code than it is to write verified code, but this comes at the cost of less powerful compile-time checking. For example, checking universally-quantified formulas (e.g., all pages in a file are allocated) is undecidable, and unlike verification-aware languages, the Rust compiler has no heuristics to attempt to solve them. As a result, we cannot ensure invariants such as "all objects in a set are in a certain typestate"; specifically, we can't encode this in typestate because the number of objects in the set is not known at compile time.

This became a problem when implementing file-system operations like `unlink`, where we would like to e.g., check that the backpointers of all pages belonging to the file are cleared before deallocating the inode. Such a check ensures that the system always follows soft updates rule 2 (never reuse a resource before nullifying all previous pointers to it); by clearing all of the page backpointers before deleting the inode, we ensure that none remain when the inode is eventually reused. However, it is impossible to check this property on arbitrary sets of pages if each page has its own typestate. We experimented with several workarounds, including forcing `write` operations to update no more than one page at a time (which was prohibitively slow and did not solve the problem for `unlink`), and storing typestate in page structures at runtime and manually adding assertions (which also impacted performance and lost the benefit of static checking). Ultimately, we decided to use a single piece of typestate to represent *ranges* of pages (e.g., all of the pages in a file or a contiguous subsection). Each typestate operation on such a range performs the operation on all pages in the range. This moved some logic into the typestate transitions, making the transition functions themselves more complicated but making page-management logic more centralized and easier to manually audit.

Challenges with Alloy. As SQUIRRELFS grew in complexity, it became harder to maintain the model and get useful feedback quickly. The model checker uses a SAT solver to check invariants, and the formulas representing a large model can take days or weeks to solve. We checked that traces with multiple concurrent operations were crash consistent, which increased the size of the problem further. To get faster feedback, we built a custom utility to run multiple independent instances of the model checker in parallel and split larger predicates into smaller, more concrete sub-checks.

It could also be difficult to determine whether a reported failure was a false positive. A particular challenge was dealing with *frame conditions*, predicates that specify what should not change in a given transition. Alloy is free to arbitrarily change any state that the current transition does not explicitly mention, so frame conditions are crucial to constrain the model to real traces. This behavior helps Alloy find corner-case bugs, but it also leads to false positives. To overcome this challenge, we built a syntax-based checker that parses the model using Alloy's API and checks that each transition explicitly mentions all mutable structures in the model. The current version of the checker cannot detect all issues, but it detected many missing conditions that would have otherwise taken hours to catch via model checking.

4.4 Typestate beyond SQUIRRELFS

Costs and benefits of typestate. We do not have equivalent verified or unverified systems to compare with SQUIRRELFS in terms of development and debugging effort; however, in the authors' experience, designing and implementing SQUIRRELFS required more effort than a typical unverified system, but far less effort than a verified storage system.[1] We believe that debugging SQUIRRELFS was faster and easier than debugging an equivalent unverified system, as following the typestate-enforced ordering rules made it easier to implement the system correctly in the first place and reduced the number of bugs overall.

Using the typestate pattern for crash consistency represents a useful new point in the tradeoff space between runtime testing and full verification. While it comes at the cost of additional development effort compared to unverified systems to determine correct ordering rules and does not gain the same correctness guarantees as verified systems, it does eliminate an entire class of crash consistency bugs that are otherwise difficult to find and fix [37,41,46]. Furthermore, as the pattern builds ordering rules directly into a system's implementation, the rules will stay up to date and continue to prevent crash-consistency bugs as the system is developed further [30,49].

Broader applicablity. As the typestate pattern is a general approach for statically checking the order of updates to data structures, it is useful in a broad variety of contexts, several of which are described below.

[1] For example, author LeBlanc recently worked on a durable log implemented in a verification-aware programming language, which took about 3 months of full-time work.

- Volatile data structures: SQUIRRELFS does not use typestate to manage updates to volatile data structures, but prior work on typestate verification has focused entirely on such use cases [11,54].

- Other types of storage systems: The typestate pattern could be used to enforce ordering invariants on durable updates in other types of storage systems (e.g., key-value stores) with different crash-consistency mechanisms. We note that crash-consistency mechanisms like journaling and copy-on-write do not achieve consistency entirely through ordering and would require auxiliary techniques to check properties like atomicity.

- Durable layout: SQUIRRELFS's on-storage layout is tailored to reduce the number of durable updates per file-system operation and to simplify ordering rules. Other layouts could also be used in typestate-checked storage systems, although the complexity of the ordering rules would increase.

- Asynchrony: The typestate pattern is compatible with asynchronous systems, although the ordering rules to enforce are much more complicated in such systems, as updates from different operations may be interleaved.

5 Evaluation

We seek to answer the following questions in our evaluation of SQUIRRELFS:

1. What is the latency of different file-system operations on SQUIRRELFS? (§5.2)
2. How does SQUIRRELFS perform on macrobenchmarks? (§5.3)
3. How does SQUIRRELFS perform on real applications? (§5.4)
4. How long does SQUIRRELFS take to mount and recover from crashes? (§5.5)
5. What compilation, memory, and CPU overheads does SQUIRRELFS incur? (§5.6)
6. Is SQUIRRELFS correct? (§5.7)

5.1 Experimental setup

We evaluate SQUIRRELFS on a two-socket, 32 core machine with 128GB of memory and one 128GB Intel Optane DC Persistent Memory Module. The evaluation machine runs Debian Bookworm and Linux 6.3.

We compare SQUIRRELFS against ext4-DAX [3], NOVA [57], and WineFS [34]. We configure all three systems to provide metadata consistency but not data consistency to match SQUIRRELFS's guarantees. We cannot compare SQUIRRELFS to SoupFS [23], the only other soft updates PM file system, as it is not open source. Due to time constraints, we were unable to compare against the recent ArckFS [60] file system. We hope to do so in the future. All reported results are the average of multiple trials. The red errors bars in Figure 5 indicate the minimum and maximum values recorded over all trials.

5.2 Microbenchmarks

We compare each system's latency by testing several file system operations: appending and reading 1KB and 16KB to a file, file creation, directory creation, renaming a directory, and unlinking a 16KB file. None of the tests call `fsync`.

The average latency over 10 trials of the tested operations are shown in Figure 5(a). The lowest latency file system in each test is either WineFS or SQUIRRELFS. Ext4-DAX has the highest latency on many operations because it interacts with the Linux kernel block layer for tasks like block allocation, which incurs additional software overhead. It achieves similar performance to the other systems on operations that do not go through the block layer (e.g., unlink). NOVA has higher latency on `mkdir` and `rename` than WineFS and SquirrelFS because operations that update multiple inodes require journaling in NOVA.

5.3 Macrobenchmarks

We evaluate SQUIRRELFS on the Filebench [4] storage benchmark suite. We run four workloads from the suite – fileserver, varmail, webserver, and webproxy – in their default configurations. Fileserver performs mostly writes with some whole file reads; varmail is half appends and half reads; webproxy appends to each file and reads from it several times; and webserver reads and occasionally appends to a log file. Figure 5(b) shows the average throughput in kops/sec for each file system on each workload. SQUIRRELFS achieves slightly better throughput than the next fastest system on fileserver and varmail (8% and 13% better, respectively) and within 10% of the fastest system on both webserver and webproxy. Fileserver and varmail perform many small appends, which SQUIRRELFS performs well on due to its lack of journaling. Webserver and webproxy are more read-heavy, which all systems perform roughly equally on. Ext4-DAX does not go through the block layer on reads and it benefits from data contiguity awareness, making its performance similar or better than the other systems on these workloads.

5.4 Applications

YCSB on RocksDB. We evaluate the four systems on RocksDB [7] using YCSB workloads [22]. We run all workloads on a 25GB database with 25M records, 25M operations, and 8 threads. All workloads are run using standard workload configurations and the default settings of YCSB, which uses

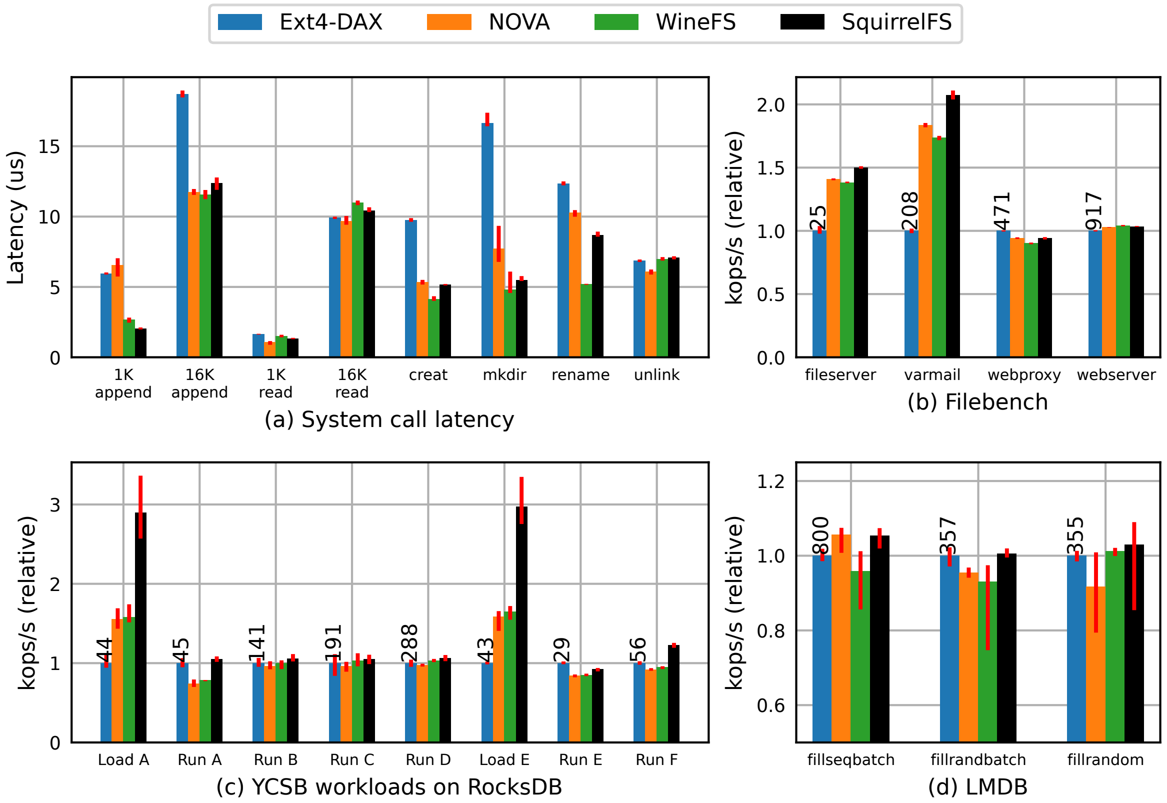

Figure 5: This figure shows the performance of the evaluated file systems on different benchmarks and applications. (a) shows absolute latency of different file system operations; (b), (c), and (d) show the relative throughput in kops/s of each system relative to Ext4-DAX on filebench, YCSB on RocksDB, and LMDB respectively.

system calls for all operations. Figure 5(c) shows throughput in kops/second relative to Ext4-DAX on each tested workload.

SQUIRRELFS outperforms the other systems on Loads A and E, which are 100% small inserts. As seen on the other benchmarks, SQUIRRELFS performs particularly well on small appends due to its lack of journaling or logging. Writes that require page allocation are particularly expensive in the other systems, as journaling/logging the new metadata incurs an additional 2-3us in NOVA and WineFS and 3-4us in Ext4-DAX. Ext4-DAX and NOVA both also journal or log metadata on every append, spending roughly 30% of each non-allocating call (approx 1-1.5us) managing journals/logs.

All file systems are within 10% of Ext4-DAX's throughput on Runs B, C, and D. All of these workloads are at least 95% small (4KB) reads, which all four systems achieve similar performance on.

SQUIRRELFS achieves the best throughput on Runs A and F, which are 50% reads and 50% updates (Run A) or read-modify-write operations (Run F). Ext4-DAX, NOVA, and WineFS all incur logging/journaling on these workloads; Ext4-DAX outperforms NOVA and WineFS because it has less journaling overhead for in-place updates and is more aware of data contiguity on reads.

Ext4-DAX achieves the best performance on Run E, which is 95% range scans and 5% inserts. Ext4-DAX's contiguity-awareness and better fragmentation-prevention mechanisms help it outperform the other systems on larger read operations.

LMDB. We also run LMDB [6], a memory-mapped database, using `db_bench`'s `fillseqbatch`, `fillrandbatch`, and `fillrand` workloads. Each experiment uses 100M keys on an empty file system. Figure 5(d) shows the throughput in kops/sec for each file system on each workload. Each file system has throughput with 12% of the other systems. Most updates are done to memory-mapped files, so differences in the performance of system calls and metadata management designs have a reduced impact.

Git. We also evaluate the performance of SQUIRRELFS by performing `git checkout` of major Linux kernel versions. The time to check out a given version in each file system is within 8% of the other systems.

5.5 Mount time

SQUIRRELFS takes longer to mount than other PM file sys-

	System state	Mount time (s)
Normal mount	mkfs	5.80
	Empty	5.51
	Full	30.50
Recovery mount	Empty	5.76
	Full	55.50

Table 2: Time in seconds to mount SQUIRRELFS file system images in differrent states. Times in the recovery mount column come from mounting a cleanly-unmounted file system that runs a recovery scan in addition to normal rebuild scans.

tems because it must rebuild volatile indices for the entire file system. Table 2 shows how long it takes to mount SQUIRRELFS on a 128GB PM device with different contents. The ≈ 5.5 seconds it takes to initialize or mount an empty system is the overhead of zeroing or scanning the metadata tables and creating volatile allocators. We also measure the time to mount a system with 100% data and inode utilization. Most of this time is spent allocating space for and managing the volatile indexes and allocators.

If SQUIRRELFS detects that it was not unmounted cleanly, it constructs additional structures to keep track of orphaned objects and the true link count of each inode. It fills in these structures during the regular rebuild scan and uses them to free orphans and correct link counts at the end of the mount process. SQUIRRELFS also checks each directory entry for non-null rename pointers and either rolls back or completes any interrupted renames. Table 2 reports the time it takes SQUIRRELFS to perform recovery scans on a cleanly-unmounted device. Mounting with recovery takes longer than a standard mount because the file system must construct orphan-tracking structures and do an extra iteration over all directories to check for rename pointers in addition to building the volatile indices and allocators.

SQUIRRELFS's mount time could be improved by parallelizing some of its rebuild and recovery logic. For example, the inode and page descriptor table scans are completely independent and could be done in parallel. The file system tree rebuild logic could also be distributed across multiple threads.

5.6 Resource usage

Compilation. SQUIRRELFS takes approximately 10 seconds to compile on our test machine, including typestate checking. This compares well to fully-verified systems; FSCQ [19] takes about 11 hours to verify, and VeriBetrKV [29] takes 1.8 hours (10 minutes when parallelized).

SQUIRRELFS also compiles faster than the other tested systems on the test machine. Table 3 shows the size of each system in lines of code and how long it takes to compile. SQUIRRELFS's more complicated typechecking does not noticeably impact its compilation time.

System	LOC	Compile time (s)
Ext4	45K	38
NOVA	16K	20
WineFS	9K	13
SQUIRRELFS	7.5K	10

Table 3: Time to compile different PM file systems as loadable kernel modules. Ext4's line count includes interleaved DAX and non-DAX code.

Memory. SQUIRRELFS maintains indexes for fast lookups of files and directory entries. Each regular file has an index mapping its inode number (8 bytes) to each of its pages and their offsets (16 bytes total). Thus, the index entries for a 1MB file use about 4KB of memory. Each directory has a similar inode to page index (without offsets), plus a mapping from directory entry names to metadata like their location on PM and inode number. The current maximum name length is 110 bytes (which makes directory entries 128 bytes) and SQUIRRELFS does not currently hash or compress names. Therefore, each directory entry takes up approximately 250 bytes in the index.

CPU. SQUIRRELFS does not start new threads in any of its operations. We leave the use of more threads for operations like freeing pages, running crash recovery, etc. to future work.

5.7 Correctness

Model checking. We check that a correctness invariant always holds in all traces of our Alloy model. We bound traces to include two operations (which may be concurrent), 10 persistent objects, and up to 30 steps. The invariant includes both sanity checks on the model as well as file system consistency checks. The sanity checks ensure, for example, that objects will never end up with conflicting typestates. The consistency checks ensure that 1) objects always have a legal link count, 2) there are no pointers to uninitialized objects, 3) freed objects do not contain pointers to other objects, and 4) there are no cycles of rename pointers and directory entries are pointed to by at most one rename pointer.

Testing. We test SQUIRRELFS using a set of handwritten tests and the xfstests [10] test suite. SQUIRRELFS currently passes all supported tests (67) from xfstests' `generic` test suite. The rest of the tests use system calls or arguments that are currently not supported by SQUIRRELFS.

Crash consistency. We used Chipmunk [41] to test SQUIRRELFS for crash-consistency bugs. We modified Chipmunk's test generators to remove several system calls that SQUIRRELFS does not currently support but otherwise ran its full suite of systematically-generated tests and fuzzed the system for approximately 24 hours. Chipmunk did not find any ordering-related crash-consistency bugs in SQUIRRELFS, providing evidence that typestate-checked SSU is an effective mechanism for preventing such bugs. Chipmunk did find four crash consistency bugs in unchecked parts of SQUIRRELFS code, three in its rebuilding of volatile data structures and one in the body of typestate transitions in which a cache line flush was issued to the wrong address. As these are not caused by incorrect update ordering, the typestate pattern did not catch them at compile time. We found that using the typestate pattern in SQUIRRELFS made locating and fixing these bugs faster and easier, as we could focus on the specific regions of code that are unchecked and are thus more likely to have bugs.

5.8 Summary

SQUIRRELFS provides comparable performance to other PM file systems, while providing strong guarantees about its crash consistency. Due to the innovative use of typestate checking, we were able to implement SSU and gain confidence in its correctness. SQUIRRELFS gains an advantage over other file systems in write-dominated workloads, since soft updates avoids writing to a log or to a second copy of the data. The design of SQUIRRELFS trades off good common-case performance for slightly longer mount times compared to other file systems; we believe this is acceptable since crashes are rare. SQUIRRELFS compiles at the same rate as other PM file systems, despite the strong type checking.

6 Related work

Rust for PM. SQUIRRELFS was inspired by Corundum [32]. Corundum builds data structures whose low-level properties are checked using Rust's type system. For example, Corundum ensures that there are no pointers to volatile memory stored in persistent memory, and that persistent state is only updated in transactions. It focuses on lower-level persistent memory programming errors and cannot prevent higher-level logical bugs. Corundum also requires *all* updates to PM to be in transactions, which is overly restrictive for many systems. In contrast to Corundum, SQUIRRELFS checks high-level file-system crash-consistency properties using type-checking without placing constraints on how the file system is used.

Soft updates for PM. Two PM file systems use soft updates for crash consistency: SoupFS [23] and ArckFS [60]. Unlike SQUIRRELFS, SoupFS is asynchronous and uses background threads to flush updates. It uses byte-addressable updates to eliminate cyclic dependencies. ArckFS is a user-space PM file system built on the Trio architecture that uses synchronous, soft-updates-esque updates for simple operations (e.g., creating a file) and undo journaling in more complicated cases. Unlike ArckFS, SQUIRRELFS uses only synchronous soft updates for its crash consistency; the novel way in which SQUIRRELFS implements atomic rename (without journaling or copy-on-write) further differentiates it from ArckFS. Both SoupFS and ArckFS are written in C, and do not use Rust's type system to check their crash consistency.

Storage systems in Rust. Bento [45] is a framework for building in-kernel file systems in Rust. The corresponding file system from the Bento project, BentoFS, was designed for block devices. Bento does not utilize the type system of Rust to check file-system properties.

ShardStore [15] is a Rust key-value store used in Amazon S3 that uses an asynchronous soft-updates-inspired crash-consistency mechanism. The rules for when something should be written to storage in ShardStore were checked with DepSynth [55], a tool for synthesizing soft updates dependency rules. Unlike ShardStore, SQUIRRELFS uses a synchronous version of soft updates, and provides higher-level primitives like atomic rename; ShardStore does not utilize the type system to perform higher-level checks.

7 Conclusion

This paper presents a new methodology for crash-consistent file system development. We propose the use of the typestate pattern in Rust to statically check crash-consistency invariants with low proof burden. We also introduce a novel crash-consistency mechanism, synchronous soft updates, that is well-suited to enforcement with the typestate pattern and that eliminates many challenges associated with the original soft updates technique. We develop SQUIRRELFS, a new file system for persistent memory that uses statically-checked synchronous soft updates for crash consistency. SQUIRRELFS achieves comparable or better performance than other PM file systems and required no language modifications or verification expertise to build. SQUIRRELFS, its Alloy model, and our Alloy utilities are available at https://github.com/utsaslab/squirrelfs.

Acknowledgments

We thank our anonymous shepherd, OSDI reviewers, and the members of SaSLab and LASR at UT Austin for their insightful comments and feedback. This work was supported by NSF CAREER #1751277, NSF CCF #2124044, and donations from Amazon, Toyota, and VMware.

Abstract

Modern network hardware is able to meet the stringent bandwidth demands of applications like GPU-accelerated AI. However, existing host network stacks offer a hard tradeoff between performance (in terms of sustained throughput when compared to network hardware capacity) and flexibility (in terms of the ability to select, customize, and extend different network protocols).

This paper explores a clean-slate approach to simultaneously offer high performance and flexibility. We present a co-design of the NIC hardware and the software stack to achieve this. The key idea in our design is the physical separation of the data path (payload transfer between network and application buffers) and the control path (header processing and transport-layer decisions). The NIC enables a high-performance zero-copy data path, independent of the placement of the application (CPU, GPU, FPGA, or other accelerators). The software stack provides a flexible control path by enabling the integration of any network protocol, executing in any environment (in the kernel, in user space, or in an accelerator).

We implement and evaluate *ZeroNIC*, a prototype that combines an FPGA-based NIC with a software stack that integrates the Linux TCP protocol. We demonstrate that *ZeroNIC* achieves RDMA-like throughput while maintaining the benefits of robust protocols like TCP under various network perturbations. For instance, *ZeroNIC* enables a single TCP flow to saturate a $100 Gbps$ link while utilizing only 17% of a single CPU core. *ZeroNIC* improves NCCL and Redis throughput by 2.66× and 3.71×, respectively, over Linux TCP on a Mellanox ConnectX-6 NIC, without requiring application modifications.

1 Introduction

Modern datacenter applications, such as artificial intelligence (AI), data analytics, and distributed storage, are increasingly reliant on moving massive amounts of data over the network. As a result, datacenter operators are deploying systems capable of hundreds of Gbps of host networking. For instance, the latest NVIDIA DGX-B200 is capable of $3.2 Tbps$ of networking – $400 Gbps$ for each of the 8 GPUs [26]. As compute, memory, and link throughput continue to scale, driven by technologies such as accelerators [5,25,49], the *end-host* network stack is rapidly becoming a dominant bottleneck for these applications [12,13,72,95]. Therefore, the problem of designing host network stacks has come to the forefront.

Existing host network stacks offer a hard tradeoff between performance (in terms of sustained throughput when compared to network hardware capacity) and flexibility (in terms of the ability to select, customize, and extend different network protocols). On the one extreme, RDMA-based host network stacks [8, 34, 38, 54] are able to achieve high performance, but provide minimal to no flexibility. With network protocols baked into the hardware, adapting the protocol to better suit the needs of emerging applications or deployments is either not feasible or requires the time-consuming process of hardware modification. As a result, existing RDMA-based deployments remain fragile due to the possibility of head-of-line blocking, deadlocks, congestion spreading, and/or host congestion [1,2,44,45,63,65,74,96]. On the other extreme, the Linux network stack provides flexibility with a variety of time-tested protocols [4,11,14,39,47,68] and mechanisms that enable the incorporation of new protocols [2,10,13]. Unfortunately, the current Linux stack falls significantly short of exploiting the high-throughput capabilities of modern network hardware [12]. Recent host network stacks [72,89] offer operating points between these two extremes, but suffer from a similar performance-flexibility tradeoff.

We present a clean-slate co-design of the host network hardware and the software stack that simultaneously achieves high performance and flexibility. Our design's key driving

*Work partially done while interning at Enfabrica.

†Affiliated with Amazon Web Services, work done while at Enfabrica.

idea is the physical separation of the data path (payload transfer between network and application buffers) and the control path (header processing and transport-layer decisions) within the host. Specifically, our NIC hardware enables a *high-performance data path* between the network and the application. The NIC splits the headers from the payload, and directly transfers the payload from/to application buffers, without requiring any intermediate data copy (*zero-copy*). Our software stack enables a *flexible control path*. Users can plug in existing transport stacks, which operate on packets (sans payloads) as before, to make decisions on when to send data (e.g., congestion and flow control) and notify applications upon completion (e.g., acknowledging in-order byte streams). The software control stack orchestrates memory management and signaling between the NIC, the transport stack, and applications. Importantly, our design is independent of the location of application buffers (CPU, GPU, FPGA, or other accelerators) or the transport protocol's execution environment (in the kernel, in user space, or even in an accelerator).

The key challenge in realizing the physical separation of data and control paths is to maintain correct semantics (in-order, exactly-once data delivery) even in presence of network perturbations (data corruption, drops, replication, reordering, etc.). Our hardware implements the bookkeeping needed to correctly transfer incoming data to their designated memory destination even in the presence of network perturbations, while our software stack coordinates across the hardware and the application layer to maintain correct protocol semantics.

We demonstrate the benefits of our approach using an end-to-end prototype, *ZeroNIC*. Our prototype combines an FPGA-based NIC connecting to CPU and GPU memory, with a software stack integrating in-kernel Linux TCP. Our prototype realizes two APIs: the *libibverbs* API [67] used by current RDMA applications and a streaming API for general-purpose socket applications. For both APIs, *ZeroNIC* supports zero-copy data transfers between the NIC and application buffers in CPU or GPU memory. We evaluate *ZeroNIC* across a variety of workloads and network conditions. *ZeroNIC* achieves RDMA-level throughput with low CPU utilization. For instance, we show that *ZeroNIC* allows a single TCP flow to saturate a $100 Gbps$ link while utilizing only 17% of a single CPU hyperthread. In comparison, the Linux host network stack on a Mellanox ConnectX-6 NIC achieves at most $50 Gbps$ for a single TCP flow at 100% CPU utilization. We also demonstrate that *ZeroNIC* enables a high-performance zero-copy data path between GPU devices, achieving 2.66× higher throughput in NCCL benchmarks [24], NVIDIA's core AI networking library. Finally, we show that *ZeroNIC* benefits from the use of robust network protocols such as the TCP implementation in Linux. *ZeroNIC* maintains its performance under drops and fairness across flows.

To the best of our knowledge, our work is the first to support both send and receive-side zero-copy for reliable protocols like TCP with no constraints (e.g., MTU alignment, API modifications). It supports accelerator devices (e.g., GPUs) and enables protocol termination anywhere (e.g., CPU or control-plane accelerators) without limiting protocol semantics.

2 Motivation and Background

Our goal is to enable high-performance host networking regardless of the data destination (host or accelerator memory) and where/how the control plane is implemented. This flexibility allows the development and tuning of network protocols that improve fabric behavior and overall network efficiency as applications evolve and systems scale.

2.1 RDMA: Performant but Inflexible

Many network-intensive applications, such as AI training using GPUs, frequently use RDMA solutions such as InfiniBand (IB) [6] or RoCE [7]. RDMA solutions bypass the OS network stack and its CPU overheads by terminating the network protocol in specialized hardware and firmware in RDMA NICs (RNICs). RNICs enable high throughput by DMAing network payloads directly from/to application buffers in CPU or GPU memory using information encoded in send/receive requests.

The disadvantage of RDMA solutions is the lack of flexibility. To achieve high throughput, RDMA solutions typically required a lossless fabric such as IB, reliant on certified (short-distance) cabling and specialized switches. Such networks were forced to adopt a restrictive topology, avoiding over-subscription and adding many redundant paths to avoid drops [21,93]. To provide a similar quality-of-service on lossy fabrics, RoCE solutions have increasingly required secondary mechanisms to eliminate drops in the face of congestion, such as priority flow control (PFC) [46] and watchdogs [8, 38]. RoCE solutions still suffer from a host of well-documented challenges, such as end-host congestion [55], major performance degradation under unavoidable network perturbations (e.g., packet drops or reorderings) [44, 103], and excessive buffer requirements [44]. Addressing these challenges is arduous because RoCE's control path is explicitly tied to the implementation of the RNIC, requiring collaboration with and intervention by RNIC vendors. For example, Microsoft required support from its RNIC vendor to address livelocks caused by go-back-0 retransmission [38].

2.2 Kernel Networking: Flexible but Slow

The Linux network stack, built around the TCP/IP protocols, runs on a vast range of commodity hardware, supports diverse topologies, and can adapt to highly-variable network conditions and failures. Its resiliency stems from the fact that developers can optimize network protocol parameters including the congestion scheme and buffer sizes for the needs of emerging applications and deployments.

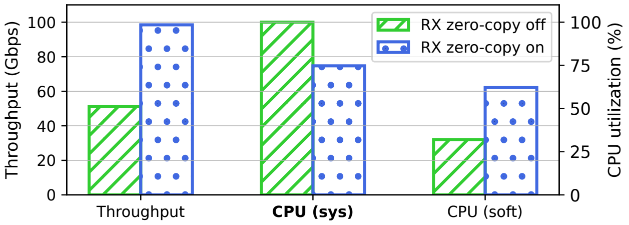

Figure 1: Throughput and receiver CPU utilization with and without receive-side (RX) emulated zero-copy. 100% means that a hyperthread is fully utilized. "CPU sys" refers to the hyperthread running protocol processing. "CPU soft" refers to the hyperthread running the application and the software interrupt handler.

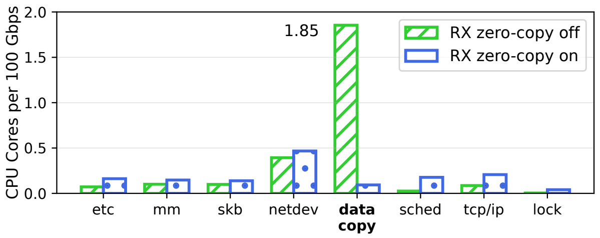

Figure 2: CPU breakdown for the TCP receiver with and without emulated RX zero-copy, normalized to the CPU utilization needed to achieve 100*Gbps* of throughput.

Unfortunately, the Linux stack cannot achieve high throughput ($\geq 100Gbps$) as single-thread CPU performance is a key bottleneck [12]. Specifically, receive-side data copies from kernel to application buffers dominate end-to-end performance, limiting a single TCP flow even after major optimizations (e.g., TSO/GRO, jumbo frames, and packet steering).

We built a proof-of-concept experiment to showcase the single-flow performance potential of removing the data copy. We modified the iperf benchmark [28] to support send-side zero-copy via the Linux sender ZC API [53]. We emulated receive-side zero-copy by truncating payloads in the kernel, avoiding the additional copy to user space [1]. We enabled TSO, GRO, and jumbo frames. We also pinned the iperf process and steered the receiver flow so that the interrupt handler (`soft`) and TCP processing (`sys`) are located in the two hyperthreads of the same physical core (sharing the L1 cache).

Figure 1 shows the sustained throughput and CPU utilization. Even with send-side zero-copy on, regular kernel networking can only achieve 50*Gbps* for a single flow. Similar to [12], we observe that CPU utilization is the bottleneck – specifically the TCP protocol processing receiver core (`sys`). Throughput cannot scale and the interrupt handling thread (`soft`) is underutilized. Figure 2 shows that the majority of CPU cycles for TCP processing are spent on data copies. Enabling receive zero-copy eliminates data copy overheads and drastically improves throughput, saturating the 100*Gbps* link. This experiment suggests that a flexible receiver zero-copy mechanism that copies data to application buffers in CPU, GPU, or storage devices can enable a wide range of protocols/stacks, including Linux TCP and other user space or hardware protocols/stacks [32, 48, 51, 72, 76, 77, 90], to meet the throughput requirements of network-intensive applications.

2.3 Towards Control & Data Path Separation

The core challenge with existing network solutions is the tight integration of the control and data paths, leading users to either integrate the data path into the kernel, sacrificing performance, or embed the control path in hardware, sacrificing flexibility. We propose the physical separation of these two paths. The data path provides robust support for zero-copy from NICs to application buffers on devices like CPUs and GPUs. The control path supports various transport protocols executing in software or hardware. This separation allows the control path to be optimized without overhauling the efficient data path.

There are many implementations of send-side (TX) zero-copy such as those in RDMA NICs, the MSG_ZEROCOPY flag in the Linux send system call [27], and the io_uring API for asynchronous I/O [18]. In contrast, existing *receive-side (RX) zero-copy* approaches are severely limited.

The challenge of page alignment. Linux includes a page-remapping mechanism for RX zero-copy in socket APIs [17, 59]. It allows the NIC to DMA the entire payload to a memory location and then remap the payload's physical address to the application buffer's virtual address at page granularity. This approach requires page-aligned payloads, making it difficult for applications to transmit arbitrary data lengths, as they can do with the socket or verbs APIs. The page-alignment requirement may also be incompatible with GPUs or flash devices [3], limiting the applicability of this approach. Moreover, page-remapping incurs high CPU overheads due to the need for TLB flushing after altering page table entries [59, 94].

The challenge of API compatibility. Several proposals facilitate RX zero-copy by altering application interfaces [9, 50, 79, 101, 102]. They require extensive changes to applications using common APIs like sockets or IB verbs, which typically rely on read/write operations from a contiguous buffer. These proposals asynchronously transfer packets from the NIC to application buffers, either as a linked list of scattered payloads or with headers and data interleaved in a buffer, which are released after being processed by the application. Hence, applications must adapt to handling non-contiguous data addresses during read operations.

The challenge of packet perturbations. Packet reordering, drops, and retransmissions disrupt the expected order of packet arrivals and complicate the correct copying of payloads into application buffers. A simple solution, employed by many

[1] Code available at https://github.com/enfabrica/iperf

RNICs, is to discard out-of-order packets and default to a go-back-N retransmission strategy, at the expense of throughput (§2.1). An alternative is to temporarily buffer out-of-order packets in the NIC until the missing packets arrive, potentially through a selective retransmission mechanism. This approach can quickly exhaust the SRAM capacity of state-of-the-art NICs [74, 96], especially in large bandwidth-delay-product (BDP) environments such as hosts with 400*Gbps*+ networking per GPU, and limits the effective rate at which data is transferred to the application.

The challenge of reliable protocols. Some systems sacrifice reliable transport semantics, directly copying incoming payloads to the next-available application buffer. This limits RX zero-copy support to unreliable protocols like UDP [15, 57]. Recent attempts to support reliable connections (RC) have constrained applicability. SRNIC [96] handles sequential and out-of-order packets via separate fast and slow data paths. IRN [74] requires the sender to explicitly define a receiver buffer identifier in the header. 1RMA [91] requires application involvement for managing ordering and handling failure recovery. Flor [62] separates the control and data paths for RDMA transports to reconcile the control path differences across different RNIC generations. However, Flor primarily supports unreliable connections (UC). To extend to reliable semantics, Flor uses an additional reliability sequence number in the RDMA work request and requires the sender and the receiver to establish a common chunk size for data transfers. Flor must dynamically tune the chunk size to tradeoff between high throughput (larger chunks) and managing congestion, drops, and retransmissions (smaller chunks).

Other related work. Nicmem [80], PayloadPark [36], and Ribosome [87] have recently explored separating the control and data paths in distinct contexts from our goals. They focus primarily on NFV (Network Function Virtualization) workloads that do not process payloads, but rather operate only on metadata to deliver packets to their next destination. To optimize resource usage such as PCIe traffic, they split packet headers and payloads and send only the header to the host. SplitRPC [56] uses a control and data path separation, but it is limited to unreliable protocols like UDP and use-cases like end-user requests/responses for AI inference. Our work tackles a broader range of applications that continuously process payloads and benefit from transport layer functionalities.

3 Performant and Flexible Host Networking

We co-design the hardware and software to *physically separate the data and control paths* in host networking, but *logically couple them after separation*. The physical separation enables a high-throughput, zero-copy data path to application buffers for payloads, and an independent control path for header processing. Figure 3 provides a high-level view of our approach. The data path connects to *any endpoint* (e.g., accelerators, storage, host memory, etc.), and the control path executes *arbitrary transport protocols* in *any execution environment* (in user or kernel space software on a CPU, in SmartNIC software or hardware, or even in a protocol accelerator), as illustrated by the two examples in Figure 4. The logical coupling allows the control path to have full control of protocol semantics, i.e., when data is correctly received or sent, how to handle events like reorderings and retransmissions, and when to notify the application – even if the transport protocol and data live in completely different devices.

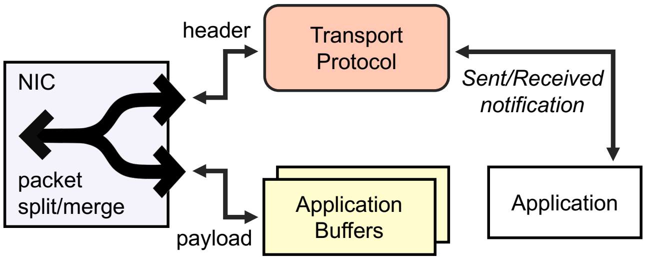

Figure 3: Host networking with physically separated control and data paths.

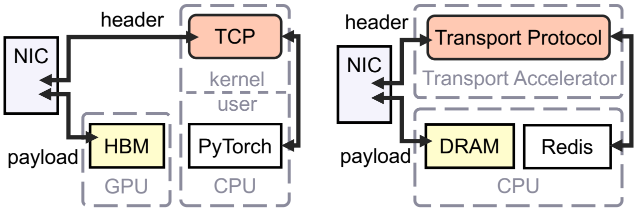

(a) Application buffers in GPU memory (HBM), protocol (in this case, TCP) in kernel space.

(b) Application buffers in CPU memory (host DRAM), protocol in a transport accelerator.

Figure 4: Examples of control and data path separation.

The key challenge in providing a zero-copy data path managed by transport protocols external to the NIC is that the NIC must decide *if, when,* and *where* to copy incoming payloads, *prior* to the transport protocol addressing out-of-order deliveries and retransmissions. Additionally, regardless of when data is copied, it should only be exposed to the application when protocol semantics allow (e.g., in-order delivery).

We begin by reviewing how packets travel throughout our network stack (§3.1). The NIC (§3.2) splits and merges headers and data to enable zero-copy data transfers directly to arbitrary devices (e.g. GPUs), even under reorderings, retransmissions, and drops. Our software stack is composed of the control stack and the provider library. The control stack (§3.3), which can execute in an arbitrary execution environment (e.g., in the kernel as a driver) is the coordinator between the NIC, an arbitrary transport protocol, and the application. The transport protocol acts only on packet headers, while the control stack proxies its actions to data in remote memory (i.e., NIC or application buffers). Our provider library implements both

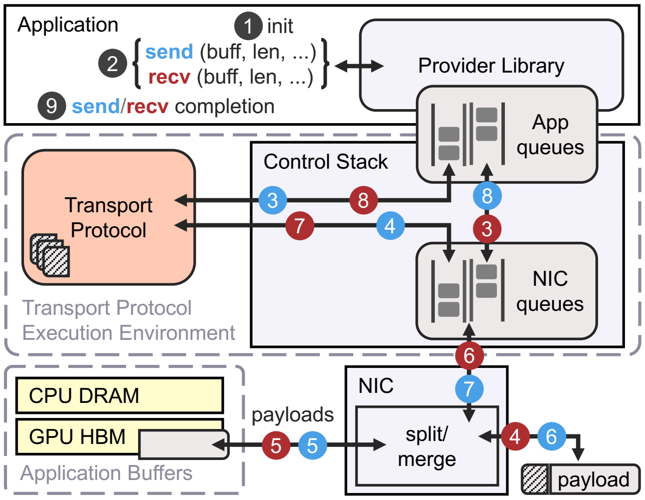

Figure 5: End-to-end send (blue) and receive (red) paths.

message and streaming APIs (§3.4) to allow an easy mapping of popular networking libraries onto our design. Finally, we discuss how we address various challenges in the host network stack such as retransmissions and compatibility with current optimizations (§3.5).

3.1 Receive and Send Path Overview

Figure 5 illustrates the receive (RX) and send (TX) paths through our stack.

Receive path. ① A receiving application begins by performing an initialization step using the provider library. As usual, this step establishes a connection and binds to a network interface. It also allocates application and NIC queues (§3.3) to coordinate between the control stack, the provider library, and the NIC hardware. The application also registers shared memory with the NIC for zero-copy transfers. These memory buffers can be anywhere in the system (e.g., GPU memory). Applications can periodically register (and deregister) shared memory space as needed. ② After initialization, the application invokes receive calls and the provider starts polling for completions. For every receive call, the provider enqueues an RX request entry into the application queue. RX request entries contain the receive call's buffer location and length. ③ The control stack steers the entry to the appropriate NIC queue. The NIC parses RX request entries to store application buffer information into dedicated hardware structures.

④ As packets arrive in the NIC from the sender, the NIC parses their headers and decides on dropping, buffering, or accepting each packet (§3.2). When a packet is accepted, the NIC splits it into the header and the payload. ⑤ The NIC identifies the payload's correct memory location in the designated device buffer and DMAs it accordingly. ⑥ The NIC creates and forwards RX header entries, composed of headers and metadata, to NIC queues leading to the control stack. ⑦

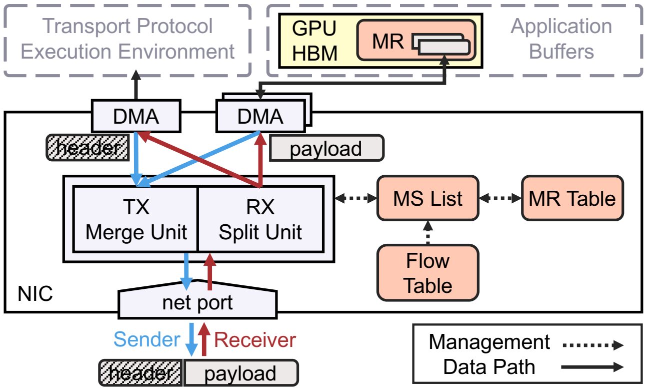

Figure 6: NIC hardware block diagram.

When the data DMA completes, the control stack forwards the headers from each RX header entry to the transport protocol. The protocol processes the header, reasoning about data acknowledgment (e.g., ACKing only in-order data). ⑧ When the protocol allows, the control stack posts a completion entry into the application queue.

Send path. The send path is also designed so that the transport protocol maintains control over data transmission. ① As with the receive path, the application begins with initialization steps that establish a connection, bind with a network device, and allocate and bind with the application and NIC queues needed for coordination. ② Upon a (non-blocking) send, the provider library enqueues a TX request entry to the application queue. The TX request entry contains the application buffer's location and length. ③ The control stack then forwards the entry to the transport protocol. ④ The transport protocol creates packet headers and allows progress according to its flow and congestion control mechanisms. When transmission is allowed, the control stack forwards the constructed header alongside the TX request entry to the NIC queue.

⑤ The NIC parses the TX request entries in-order and DMAs data from the application buffers directly into NIC memory. ⑥ The NIC then merges data with headers to form packets, optionally applying optimizations such as TSO, and transmits packets over the network. ⑦ Upon transmission, the NIC enqueues completion entries back to the NIC queue. ⑧ The control stack polls for completions and forwards them to the application queue. ⑨ Finally, the provider library polls for entries and notifies the application upon completion.

3.2 NIC Hardware Design

Figure 6 presents the NIC hardware design that implements key data structures to split (merge) packets, transfer headers and payloads to (from) the control stack and application, and track payload placement on a per-flow basis so that data can be zero-copied to their correct application buffer.

Memory management hardware data structures. The NIC

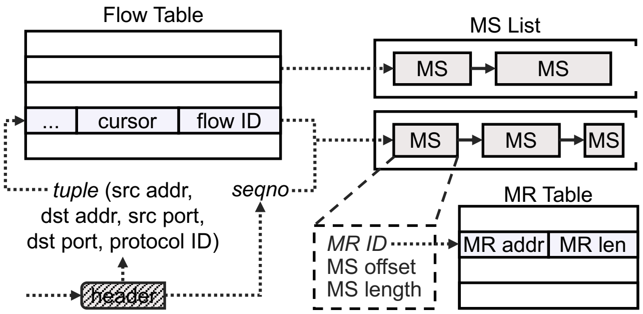

Figure 7: NIC hardware data structures.

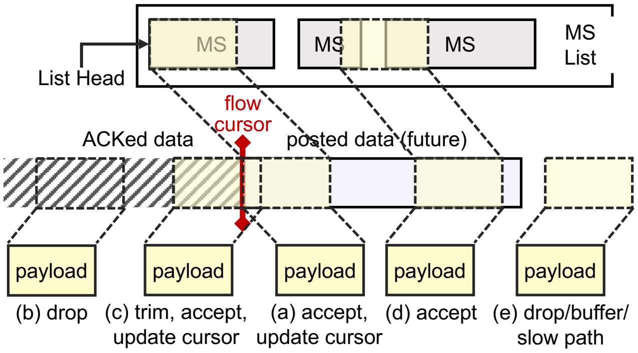

Figure 8: Flow cursor logic given packet arrival conditions.

implements the data structures shown in Figure 7 to track application buffers. At initialization, the application registers a set of *Memory Regions (MR)* using the provider library. An MR is a contiguous part of the application's virtual address space. The NIC maintains an MR Table entry for each registered MR. Virtual MR addresses are translated via an IOMMU in the NIC, which caches translations for efficiency. MRs can be anywhere in the system reachable by the IOMMU. For example, in the context of GPUs, CUDA allocates GPU memory, associates it to the PCIe address space (PCIe BAR), and maps it to host application buffers. In this case, our NIC IOMMU stores CPU to PCIe address space translations. Meanwhile, the NVIDIA driver translates between PCIe and GPU memory, as in GPUDirect.

The control stack creates a *Memory Segment (MS)* for each send and receive operation. An MS corresponds to a contiguous user buffer and is defined by its MR ID, its offset within the MR, and its length[2]. As the application makes asynchronous send and receive calls, the control stack enqueues the RX and TX MSs to the NIC into a per-flow *MS List*. The MS List is essentially a linked-list containing the application buffers involved with pending requests. Note that each flow (and thus MS List) maps to a distinct NIC queue in the control stack.

The *Flow Table* tracks flow metadata used for incoming packets. The most important fields in each *Flow Table* entry are the flow ID used to index to the flow's corresponding MS List, and the *flow cursor*. The flow cursor is the sequence number corresponding to the last in-order consumed packet in the flow. The MS List and the flow cursor are combined to make decisions over the packet's payload, as explained below.

Receiving a packet. The hardware structures described above allow the NIC to map incoming packets to application buffers for zero-copy DMA, as shown in Figure 6. We focus on the process of handling reliable protocols. Unreliable protocols simply land data in the next available MS.

The NIC parses the header of an incoming packet to construct a tuple that indexes the Flow Table (Figure 7), and obtain the corresponding MS List and flow cursor. The MS List and flow cursor are combined with the header's sequence number to derive the packet's position in the flow. The NIC then decides one of four actions: *accept*, *drop*, *buffer*, or *defer*.

We begin with Case (a) in Figure 8. In the absence of network perturbations, the arriving packet contains the next in-order unconsumed payload that the flow is expecting, i.e., the data immediately following the flow cursor. The packet is accepted: the hardware examines the top MS in the flow's MS List and uses the MS and MR information to derive the application address to DMA (zero-copy) the payload. The cursor is updated to reflect the next unconsumed position. MS boundaries and the size of the payload do not have to align. The packet's payload may consume a fraction of the MS or may need to span into the next MS in the list. Fully consumed MSs are retired when the flow cursor passes them.

Case (b) receives a packet with a sequence number that suggests all the bytes in the payload have been previously received and ACKed according to the flow cursor. This may be due to a re-transmission when an ACK is lost or delayed. This packet is dropped and no further action is taken. Case (c) receives a packet that includes some bytes that are previously ACKed and some new bytes. The hardware drops the repeated part and accepts the rest of the packet as in Case (a).

Case (d) receives a packet beyond the flow cursor (i.e., with a hole). This may be the result of packet reordering or a drop of an earlier packet. The hardware will walk the MS List, and by accumulating MS lengths, it will identify the right segment for the data. The data will be accepted and DMAed to the proper application buffer address. Even if future MSs are fully filled, they will not be retired until the cursor passes them. The control stack periodically sends the latest acknowledged byte to the NIC to update the cursor.

Finally, under rare conditions, a packet may not match any MS (Case (e)). This may be the result of excessive drops or the receiver posting buffers at a slow pace. We can drop the packet, buffer it in NIC memory and retry later, or defer the packet to a non-zero-copy path. We implemented the last option (defer) in our prototype system (§4). We also use this approach if a packet arrives for a flow that has no Flow Table

[2] For simplicity of presentation, we assume contiguous Memory Segments, although MSs may map to more complex data structures.

entry (i.e., the table has reached its capacity limits).

When a packet is accepted, it is passed to the Split/Merge unit shown in Figure 6, which splits the packet into header and payload. A DMA engine copies payload data directly to application memory (e.g., in CPU user space or GPU device memory). Another DMA engine then forwards headers to the control path address space (e.g., in CPU kernel memory).

Note that the NIC lands data in application memory before any transport processing happens. It also allows the overwrite of future data if a packet is transmitted multiple times since their MSs are not retired. However, correctness is maintained because the application is notified when it is safe to use its buffer by the control path, after protocol processing is done.

Sending a packet. The send hardware path is simple, as packets are sent in the order of requests. Upon receiving a header from the control stack, MSs enter the MS List and are handled by hardware in FIFO order. A DMA engine copies the payload directly from the corresponding application buffer. The Split/Merge unit merges the header and payload to form a packet, which is transmitted over the network.

Hardware requirements for scalability. Maintaining per-flow state raises scalability concerns. Our design supports 10K high-performance flows with ~10MB of NIC memory.

Most proposed structures have a low memory footprint. To support 10K flows, the Flow Table and MR Table require ~700KB and ~100KB respectively, to store all necessary metadata. MS Lists are the most resource-intensive structures. To support long, potentially out-of-order, packet runs with low memory footprint, our NIC does not buffer payloads. Instead, the NIC DMAs future payloads to their correct memory destination by finding the correct MS. For maximum efficiency, we allocate a minimum number of MS List entries per flow to keep the flow pipeline humming, and pull additional MS List entries as needed (a CIR/PIR – committed/peak information rate system) [43].

For example, a large bandwidth-delay-product (BDP) of $100Gbps \cdot 0.2ms = 2.5MB$ would require $\frac{2.5MB}{4KB} = 625$ MSs. Instead of allocating 625 entries for all 10K MS Lists ($10K \cdot 625 \cdot 8B = 50MB$), we allocate a minimum of 128 committed entries to each MS List, while supporting thousands of peak entries (e.g. 8K) that are allocated to flows on demand from a large entry backing store (e.g. 1M entries). For 10K high-performance flows, the total buffer requirement is $\max(1M \cdot 8B, 10K \cdot 128 \cdot 8B) = 9.77MB$. Downsizing MS Lists adds the additional requirement to buffer RX NIC requests during the lifetime of their respective MSs. Besides supporting thousands of zero-copy flows, our design additionally supports non-zero-copy flows that do not occupy the newly proposed data structures.

The required hardware resources for our NIC are significantly lower than those of most RNICs [96]. Modern SmartNICs also require several processor cores, tens of MBs of processor caches, and external memory like DDR, LPDDR, or HBM that can handle payload buffering for high BDPs.

3.3 Control Stack Design

The goal of the control stack is to enable an arbitrary transport protocol with our zero-copy data path, while maintaining efficiency and correctness. The control stack does so by separating and defining a clean interface between three components: *a) the application, b) the transport protocol,* and *c) the NIC*. The control stack maintains connections between each application and the NIC using two sets of queues.

Application queues. The control stack is co-located with the transport protocol [3], *application queues* are allocated in shared memory between the control stack and the application, and connect the provider library with the control stack. Each set of application queues contains a send queue, a receive queue, and their respective completion queues. TX and RX requests are enqueued by the provider library into the send and receive queues, respectively, while the control stack notifies applications upon completions via the completion queue.

NIC queues. The control stack also establishes a set of *NIC queues* for TX and RX requests, incoming RX header entries, and completions. NIC queues connect the control stack to the NIC. They are implemented in the control stack and are accessed by the NIC via DMA. In the send direction, the control stack enqueues MSs and headers to the NIC, constructed from TX requests enabled by the transport protocol. In the receive direction, the control stack sends MSs from RX requests to the NIC. As they are consumed by incoming data, the corresponding headers are split from incoming packets to form RX header entries directed to the control stack.

Supporting arbitrary transport protocols. Current solutions that leverage a single queue pair to provide zero-copy functionality struggle to support protocols not executing in either end of the queue (in the NIC or in user space). In contrast, our control stack uses two separate sets of queues to interpose the transport protocol between the application and NIC. The control stack polls the application send queue for requests and the NIC queue for receive-path headers and invokes the transport protocol to generate send-path headers and acknowledgments, respectively. The control stack can support arbitrary transport protocols by translating application requests to the respective transport API (e.g., TCP sockets).

Enhancing efficiency. In addition to eliminating data copies, the control stack benefits from reduced system call and interrupt overheads when submitting work and receiving completions. Specifically, polling on application queues avoids system calls, resulting in performance benefits similar to mechanisms such as `io_uring` [18]. Since the control stack is co-located with the transport protocol, it directly invokes it without system calls. Similarly, the control stack polls the NIC for completions and headers, avoiding software interrupts. To address applications with sparse communication, mechanisms such as combining polling and doorbells can also be applied.

[3] We assume the control stack executes as a kernel module; §6 discusses supporting transport protocols external to the kernel (e.g., in user space).

Maintaining correctness. Finally, the control stack maintains correctness by logically coupling the physically separated control and data paths. On the sender side, the control stack invokes the protocol's flow and congestion control to enqueue control entries in the NIC and to trigger data DMAs. This is equivalent to the congestion control algorithm acting on headers physically accompanied by their data. On the receiver side, payloads are separated from their headers in the NIC and DMAed directly to application buffers. RX header entries sent to the control stack incorporate information (e.g. sequence number) to bind to their corresponding data. Data becomes visible to the user upon consulting the protocol's acknowledgment policy (e.g., in-order delivery). Thus, the transport protocol maintains ownership of the data without ever touching the data itself, allowing us to reap all the benefits of current transport protocols (robustness, fairness, etc.).

3.4 API Design

The primary goal of our API is to allow current applications (more precisely, current networking libraries) to use our network stack with minimal effort. Current applications use either *message-based* or *streaming* semantics. Message semantics (e.g., RDMA verbs) require the network stack to deliver messages corresponding to contiguous memory buffers. A message size is well-defined by the side initializing communication (one- or two- sided). Streaming interfaces (e.g., sockets) allow senders to continuously transmit byte streams of arbitrary length. The receiver can keep invoking receive calls to consume data in the stream as the network stack progressively signals reception on a byte-stream basis. The stream memory layout can be irregular (non-contiguous) and different on the sender and receiver sides. Our design explicitly supports *both* message-based and streaming semantics. We implement the *libibverbs* API [67] and a socket-like interface.

Supporting message interfaces. Most high-performance applications rely on message semantics [24, 33, 37, 71, 73]. We support their transparent interoperability by implementing the libibverbs API. We dynamically link the libibverbs `verbs_context_ops` to our provider library. The provider in turn connects to our control stack and exposes our application queues to the user as `struct ibv_qp`.

Supporting streaming interfaces. Our design also supports streaming applications by exposing a socket-like API, with slight modifications to support our software stack. The application performs initialization similar to *libibverbs* (find a device, allocate a protection domain for memory regions, and initialize queues). Connection is established via the ordinary socket API (not requiring our fast data path). The above structures are wrapped in a `struct comm_ctx`. `send` and `recv` calls are asynchronous and extended with an argument containing the `comm_ctx`. To relieve the responsibility of registering and de-registering memory regions from the application, our `send` and `recv` calls post their buffer argument as an MR on their invocation. MRs can reside within any endpoint.

3.5 Addressing Challenges

Retransmissions. Section 3.2 explains how the NIC chooses the correct MSs, including when packets are retransmitted. However, in the presence of potential retransmissions, an already consumed MS may need to be reused multiple times. Both TX and RX sides post buffers that ultimately create MSs which must therefore be carefully retired or replenished.

On the sender side, the control stack clones the socket buffer (containing only metadata), before sending it to the transport stack and keeps it alive until the protocol receives an acknowledgment. If the transport decides on retransmitting the packet, the socket buffer is cloned again. The hardware will create the same MS and the retransmission will be accommodated. On the receiver side, the NIC only retires MSs directly following the flow cursor (§3.2), allowing overwrites of future retransmitted data. Permitting overwrites simplifies our retransmission handling logic, especially when arriving packets contain both new and previously delivered data.

Multiple flows. Multiplexing flows in the same NIC queues or MS Lists creates significant complexity in tracking which flow is served on each access. We bypass this issue by assigning NIC queues on a per-flow basis. Before binding with a NIC queue, the control stack creates a flow entry rule in the NIC Flow Table. The unique *flow ID* is used to index NIC queues and MS Lists, ensuring exclusivity. Hence, zero-copy flows are limited to the number of queues supported by the NIC. Despite this issue, we support large enough flow counts with moderate resource requirements (§3.2).

Associating messages with application buffers. Our design supports message semantics with a streaming protocol underneath. In contrast to streams, messages do not have to fully consume a user buffer before using the next one. Thus, there is no clear signal to determine if an incoming packet is the continuation of the currently served message (and MS) or refers to the next message (and MS). We address this issue by adding a message sequence number within the packet transport header (e.g. in the "options" field for TCP). Combined with the stream sequence number, we can point to the correct MS and retire previous MSs that can be consumed even if they were not fully filled.

Compatibility with offload mechanisms. Popular offload optimizations such as GRO/LRO (receiver) and TSO (sender) are compatible with our design. The control stack can transparently support software offload mechanisms like GRO; consecutive headers will be merged into a single socket buffer while their payloads have already been DMAed to consecutive Memory Segments. The user is notified about the latest in-order data, as usual. Similarly for LRO, headers are combined in the NIC after they are split from their payloads. For TSO, to support headers corresponding to more than an MSS (maximum segment size), the NIC segments them into smaller headers. The MS in the send request will now serve for multiple DMAs, one for each segmented header.

4 Implementation

We implemented *ZeroNIC*, an end-to-end prototype of our proposed design. *ZeroNIC* consists of an FPGA-based NIC that implements the key hardware functionality (§3.2), a software control stack that uses TCP as the transport protocol (§3.3), and a provider library exposing the API (§3.4).

NIC. We built a 100*Gbps* Ethernet NIC prototype using a commodity Xilinx Virtex UltraScale+ FPGA [97]. The NIC has three x16 PCIe 3.0 links that connect to an x86 CPU socket and two NVIDIA GPUs (Quadro RTX 4000). In essence, our NIC also acts as a switch between the CPU and the GPUs.

The NIC-to-CPU link is controlled by the QDMA IP [99] from Xilinx that presents the NIC as an endpoint device to the CPU. The CPU is the PCIe root port device. The QDMA block allows for DMA transfers in both directions at full PCIe bandwidth (100*Gbps*). Each NIC-to-GPU link is controlled by the Xilinx XDMA IP [98] that presents the NIC as the root port device to the GPU. The GPU is a PCIe endpoint device. Unfortunately, under this configuration the XDMA block supports a limited number of outstanding PCIe transactions. This imposes a hardware limit on the sustained PCIe bandwidth for DMA transfers between the NIC and the GPU. When moving data from the GPU to the FPGA (GPU is the sender), the maximum PCIe bandwidth is 85.0*Gbps*. When moving data from the FPGA to the NIC (GPU is the receiver), the maximum PCIe bandwidth is 38.6*Gbps*. This limitation of our FPGA system and IP blocks is not fundamental to our design. An ASIC implementation of our NIC would saturate available bandwidth for transfers to GPUs.

Our NIC implements a split/merge unit for the 100*Gbps* Ethernet port. We use context-addressable memories to implement the MR Table and the Flow Table that is addressed by the 5-tuple from the TCP/IP header (source and destination addresses and ports, and protocol ID). The split-merge unit connects to the PCIe ports. The *ZeroNIC* design is modular and can be extended to support multiple 100*Gbps* Ethernet ports using replicated split/merge units. It can also support more root-ports in order to connect more than two GPUs.

Control Stack. We implemented the control stack as a Linux kernel driver, which binds the provider library with the NIC. The driver directly invokes the *unmodified Linux kernel TCP stack* for protocol processing, translating application requests and NIC queue entries into Linux TCP socket calls. While our design supports arbitrary protocols and execution locations, we select the kernel TCP protocol for the first prototype as it is robust, but challenging to make performant (see §2.2). Application queues live in shared memory between the kernel and provider library. NIC queues live in the kernel's virtual network device. Both are implemented as ring buffers of user-configurable sized entries.

Table 1: Evaluation system setup.

System	TCP / RoCE Baselines	*ZeroNIC*
NIC	Mellanox ConnectX-6	Prototype built on Xilinx Virtex UltraScale+
Topology	2-node direct-conn 100G eth	2-node direct-conn 100G eth (38.6G max for GPU)
Protocol	TCP bbr / RoCEv2 RC	TCP bbr
Setup	TCP: TSO, LRO, 9K MTU RoCE: 4K MTU	TSO, GRO, 9K MTU (always TCP)
CPU	32 core AMD EPYC 7502 L1,L2,L3: 2MB,16MB,128MB	32 core AMD EPYC 7502 L1,L2,L3: 2MB,16MB,128MB

5 Evaluation

We evaluate the efficiency of our host networking approach using the *ZeroNIC* prototype, with the Linux kernel's TCP transport in our control stack. We compare the performance of *ZeroNIC* against two popular baselines: a TCP baseline that uses the Linux network stack without our high-performance data path, and a RoCE baseline that terminates the transport protocol in the NIC. Both baselines use a Mellanox ConnectX-6 NIC. We summarize the specific configurations of these systems in Table 1. All *ZeroNIC* measurements utilize large-segment offloading (TSO and GRO) and jumbo frames, unless otherwise specified. We do not require MTUs to be page-aligned.

5.1 *ZeroNIC* Throughput Evaluation

***ZeroNIC* provides RDMA-level throughput to application buffers in CPU memory at low CPU utilization.** Table 2 shows the throughput achieved by *ZeroNIC* for a single flow between a sender and a receiver application using CPU memory. We compare against the Mellanox RoCE baseline (MLX RoCE), as well as against kernel TCP using the Mellanox NIC (MLX TCP) with and without send-side zero-copy (TX ZC on/off). We enabled send-side zero-copy for Mellanox TCP as discussed in §2.2. For *ZeroNIC* and Mellanox TCP, we pin the protocol processing thread, and either the queue polling (for *ZeroNIC*) or the software interrupt handling (for Mellanox TCP) thread to hyperthreads in the same physical core to maximize cache locality.

Table 2 breaks down the receiver-side CPU utilization between the kernel (`sys`) and other CPU cycles (`usr/soft`). `sys` includes protocol processing and the *ZeroNIC* driver, while `usr/soft` includes the *ZeroNIC* provider library, interrupts, and the application itself. Note that 100% CPU utilization means that *a single CPU hyperthread* (2 per core) is fully utilized. RoCE offloads protocol processing to the RNIC and

Table 2: Throughput and receiver-side CPU utilization for CPU-to-CPU transfers. "CPU sys" refers to the hyperthread running protocol processing and *ZeroNIC*'s driver. "CPU usr/soft" refers to the hyperthread running the application, software interrupt handler, and *ZeroNIC*'s provider library.

System	Throughput (Gbps)	CPU sys (%)	CPU usr/soft (%)	Estimated max Tput
MLX TCP TX ZC off	43.89 ± 1.35	94.15 ± 3.45	29.55 ± 2.62	46.61
MLX TCP TX ZC on	50.63 ± 0.55	100.0 ± 0.00	32.36 ± 0.80	50.63
MLX RoCE	98.03 ± 0.00	N/A	9.58 ± 0.81	N/A
ZeroNIC	96.37 ± 0.60	17.20 ± 1.96	33.50 ± 1.11	560.29

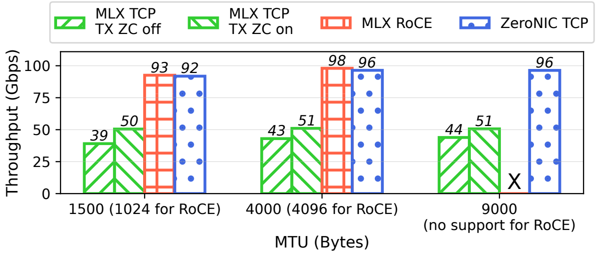

Figure 9: Achieved throughput across multiple MTU sizes. RoCE only supports power-of-two MTU sizes up to 4096B.
