lands data directly into application buffers. Thus, we do not observe `sys` CPU utilization. For *ZeroNIC* and RoCE, the throughput benchmark polls for completions. We do not include cycles spent on the polling loop for *ZeroNIC* and RoCE, as cycles spent polling do not limit throughput (e.g. the RoCE application hyperthread shows as 100% utilized).

We observe that Mellanox TCP is constrained by CPU utilization, despite the optimizations used (TSO, LRO, 9K MTU). The Linux TCP stack uses a single thread for protocol processing for each flow. With send-side zero-copy disabled, the sender-side protocol processing thread saturates (not shown), while the receiver thread almost reaches full utilization at 43*Gbps*. Enabling sender zero-copy exposes the receive-side bottleneck as the receiver thread saturates at 50*Gbps*.

ZeroNIC copies RX data directly to user space application buffers, eliminating the CPU cycles spent on data copy as shown in Figure 2. This reduces the protocol processing thread's CPU utilization from 100% at 50.63*Gbps* to 17.20% at 96.37*Gbps*. *ZeroNIC* also eliminates the majority of system calls via the control stack's polling architecture (§3.3), achieving an even lower `usr/soft` utilization than what baseline TCP is projected to need at 100*Gbps* (§3.3, Figure 1). This allows *ZeroNIC* to reach a throughput comparable to RoCE. However, *ZeroNIC* maintains the flexibility of the Linux stack, while RoCE implements its entire control path in the RNIC.

Table 3: Achieved throughput and receiver-side CPU utilization for communication across different CPU/GPU endpoints.

System	Throughput (Gbps)	CPU sys (%)	CPU usr/soft (%)	Estimated max Tput
ZeroNIC CPU-CPU	96.37 ± 0.60	17.20 ± 1.96	33.50 ± 1.11	560.29
ZeroNIC CPU-GPU	84.78 ± 0.41 [4]	16.31 ± 0.54	36.33 ± 2.21	519.80
ZeroNIC GPU-GPU	38.59 ± 0.07 [4]	9.12 ± 0.21	32.50 ± 2.07	423.14

ZeroNIC is now bound by the link capacity. Given additional or faster links, *ZeroNIC* can scale beyond 100*Gbps*. The last column in Table 2 estimates the maximum throughput that *ZeroNIC* can achieve with the kernel TCP stack, by scaling the protocol processing thread (`sys`) to saturate CPU utilization (indeed, as we will see in Table 3, the `usr/soft` thread has minor variations for different peak bandwidth settings). *ZeroNIC* is projected to scale to > 500*Gbps* for a single flow of the kernel TCP stack. This is a 11× higher throughput than the current TCP network stack achieves for a single flow using the Mellanox NIC.

Finally, Figure 9 demonstrates that *ZeroNIC*'s benefits hold across various MTU sizes. For smaller MTUs (1500 or 1024 bytes), throughput on both *ZeroNIC* and RoCE slightly reduces due to higher packets-per-second DMA overheads.

***ZeroNIC* enables high-throughput data transfers directly to device (GPU) memory.** *ZeroNIC* is able to extend zero-copy benefits to arbitrary endpoints, including GPUs. Hence, *ZeroNIC* can directly transfer data from and to GPU HBM, bypassing the host CPU memory, similar to GPUDirect [22]. Table 3 presents *ZeroNIC*'s single-flow throughput for CPU-to-CPU, CPU-to-GPU, and GPU-to-GPU communication. In all cases, the control path uses the Linux TCP stack. *ZeroNIC* is able to saturate the bandwidth supported by the hardware on all paths, given the prototype IP limitations discussed in Section 4: ~100*Gbps* for CPU-to-CPU, 85*Gbps* for CPU-to-GPU, and 38.6*Gbps* for GPU-to-GPU transfers.

To validate that the *ZeroNIC* design scales to higher throughput in the absence of prototype limitations, Table 3 also reports CPU utilization. As in Table 2, we split CPU utilization between protocol processing and driver (`sys`) and other cycles (`usr/soft`). As we can see by comparing the CPU-to-CPU and GPU-to-GPU results, the `usr/soft` CPU cycles do not strongly scale with maximum throughput. The limiting factor for higher throughput for a single flow would be the protocol processing overheads of the kernel's TCP

[4] This is the maximum throughput supported by our hardware prototype due to FPGA IP limitations (Section 4).

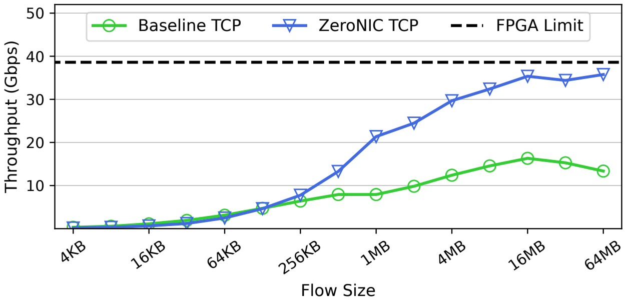

Figure 10: NCCL throughput using *ZeroNIC* across different flow sizes.

stack. Hence, we calculate the maximum throughput *ZeroNIC* can reach when the kernel thread saturates (100% utilization) to be above 400*Gbps* for CPU-to-CPU, CPU-to-GPU, and GPU-to-GPU flows, This means that *ZeroNIC* can replace the RoCE back-end network in GPU-based AI clusters that is used to communicate activations and gradients during AI training [75]. A *ZeroNIC*-based system with 8 GPUs would require 8 CPU hyperthreads to support a total of 3.2*Tbps* of GPU-to-GPU networking, while gaining the benefits of using any network protocol, such as the robustness of TCP.

5.2 End-to-End Workloads

ZeroNIC supports popular APIs (§ 3.4) that enable application integration *without modifications*, simply by linking against our provider library. We demonstrate this using three important workloads; NCCL benchmarks, PyTorch, and Redis.

NCCL. NCCL [24] is the dominant communication library for distributed AI using GPUs. It implements and optimizes collective communication primitives that are commonly used in AI training and multi-GPU inference. Different phases of inter-node collective communication (all-reduce in data parallelism, all-to-all in expert parallelism, point-to-point in pipeline parallelism, etc.) use tens of megabytes as their collective bucket size [58, 64, 85]. The number of flows scales with the number of nodes (N). For example, NCCL's tree algorithm, the predominant inter-node collective implementation algorithm, creates $2\log N$ flows per node [19]. Exposed communication increases with system size [88], making network performance critical, especially as cluster sizes increase beyond 10,000 GPUs and 1,000 nodes [20]. Improving NCCL performance directly reduces exposed communication, leading to faster AI training and inference [41, 70, 82, 100].

We ran the broadcast NCCL benchmark [23]. For 2 nodes, broadcast sends the full collective size unidirectionally between two *ZeroNIC* GPU servers. Since broadcast is the core primitive used to build other collectives, improved broadcast throughput directly translates to higher collective throughput in general. We compare *ZeroNIC* to a baseline TCP implementation which uses the *ZeroNIC* NIC hardware, but always forwards the entire packet directly to the unmodified Linux network stack (no zero-copy).

Table 4: Average training epoch latency (in seconds) for different PyTorch distributed data parallel models using RoCE GPUDirect and *ZeroNIC*.

System	ResNet50	ResNet101	ResNet152
MLX RoCE	3.52 ± 0.04	6.12 ± 0.07	8.80 ± 0.04
ZeroNIC	3.57 ± 0.02	6.22 ± 0.08	8.83 ± 0.08

Figure 10 shows the throughput achieved by NCCL as we vary the collective size. For small sizes, *ZeroNIC* and the baseline deliver the same throughput. The throughput bottleneck for small collectives is actually NCCL itself. It implements a higher-level protocol with significant processing overheads that cannot saturate the link with a single flow for small collectives, regardless of whether RDMA or TCP is used. As the collective size increases, the bottleneck becomes packet processing in the TCP stack. For the baseline TCP (no zero-copy), NCCL saturates at ~16*Gbps* for flows beyond 16*MB*. For large collective sizes, *ZeroNIC* manages to hit the maximum throughput allowed by our FPGA prototype, 2.66× higher than the baseline. If the FPGA limitation is removed, *ZeroNIC* will saturate the Ethernet link. These results show that the *ZeroNIC* data path is especially powerful for devices such as GPUs. It eliminates two data copies: a copy from the kernel buffer to the application buffer and a copy from the CPU-based application buffer to a GPU buffer.

PyTorch. PyTorch [78] is the most popular AI framework. For distributed training, PyTorch implements various parallelization strategies, leveraging communication backends such as NCCL. For example, in data parallelism, training data is partitioned while each node holds a full copy of the model. During each iteration's backward pass, all model gradients are averaged across all ranks using the all-reduce collective.

We trained different sizes of ResNet [42] using PyTorch's distributed data parallelism [81] with NCCL. We compared the average training epoch latency on two *ZeroNIC* nodes using TCP, against two Mellanox nodes using RoCE with GPUDirect [22]. Our baselines, ResNet50, ResNet101, and ResNet152 are composed of 25.6, 45.5, and 60.2 million parameters, and require synchronizing 51.2, 91.0, and 120.4 MBs worth of gradients in every iteration, respectively. Each epoch is composed of 100 iterations. Table 4 shows that *ZeroNIC* achieves GPUDirect-level performance, within 2% of RoCE's latency.

As NCCL supports the IB verbs API, we ran both the PyTorch and NCCL experiments on *ZeroNIC* without any application/library modifications. These results demonstrate that our design can be effortlessly used in AI clusters that rely on high performance, while maintaining the flexibility and robustness of the Linux network stack.

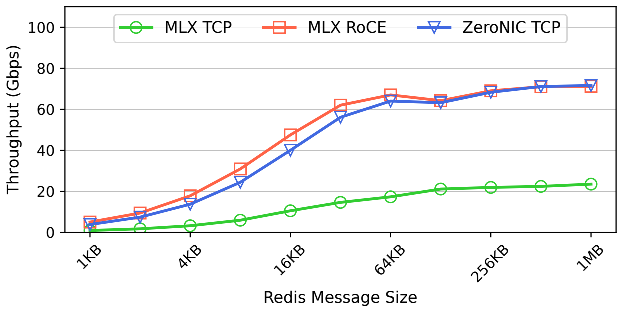

Figure 11: Redis throughput across different payload sizes.

Redis. Redis [83] is an in-memory key-value database widely used for in-memory caching. Redis' performance is crucial for a wide range of data-intensive web-scale applications. We used Redis with the *libibverbs* API, and we evaluated its throughput on *ZeroNIC* against Mellanox RoCE (MLX RoCE) and kernel TCP using the Mellanox NIC (MLX TCP). We ran the *redis-benchmark* [84] using the `SET` operation and varied the payload size from 1*KB* to 1*MB*. We used a total of 4 clients with 10 outstanding requests per client in order to saturate the Redis server thread.

Figure 11 illustrates that *ZeroNIC* achieves end-to-end performance on par with RoCE, averaging 89% of RoCE's throughput across all the payload sizes. Compared to Mellanox TCP, *ZeroNIC* achieved a 3.71× higher throughput on average, benefiting from the lower CPU overheads. For instance, for the 16*KB* message size, 71% of CPU cycles are consumed by networking stack overhead for Mellanox TCP. In contrast, both *ZeroNIC* and Mellanox with RoCE allow for nearly 99% of the cycles to be dedicated to application-level processing.

5.3 *ZeroNIC* Robustness Evaluation

While *ZeroNIC* achieves high throughput, it *also* gains the robustness offered by transport protocols such as TCP. To demonstrate the benefits of a flexible control path, we evaluate *ZeroNIC* under various network perturbations and conditions.

***ZeroNIC* supports interleaved packets across multiple zero-copy and non-zero-copy flows.** To evaluate *ZeroNIC*'s ability to handle and scale to multiple flows, we performed an incast experiment combining 2MB zero-copy flows, and 64KB bidirectional short flows that used the unmodified non-zero-copy socket API. The receiver *ZeroNIC* server used a single core (two hyperthreads) to perform application and network processing for all zero-copy flows.

Figure 12 shows (a) the throughput and CPU utilization for the long flows and (b) the p50 latency for the short flows. *ZeroNIC* is able to steer interleaved incoming packets to their correct NIC queues, avoiding flow collision. It maintains fairness across all flows, evenly distributing bandwidth of up to 8 zero-copy flows, the FPGA's hardware limit. Meanwhile, total CPU utilization (protocol processing, driver, provider, and application) remains approximately constant, and the aggregate throughput across flows saturates the available bandwidth. Overall, *ZeroNIC* achieves high throughput with roughly constant CPU resource demands as the flow count scales. This result, together with our moderate hardware memory requirements to support thousands of high-performance flows (§3.2), validates our design's scalability. Additionally, regardless of the number of high-performance flows, *ZeroNIC* can still concurrently support non-zero-copy flows. Figure 12b shows that their latency is not affected by the number of long flows.

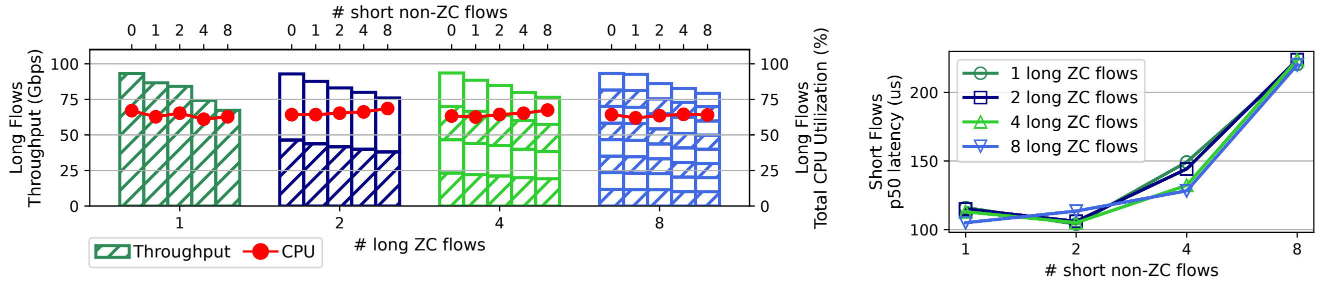
***ZeroNIC* extends the drop-resistance of TCP to GPU-direct data paths.** A primary motivation for physically separating the control and data paths is to combine zero-copy performance with a mature network transport. This experiment examines packet losses, which is a significant problem for RDMA solutions, like RoCE, that were designed assuming a lossless fabric (§2.1). We injected packet drops by adding probabilistic filtering rules at the RX side for both *ZeroNIC* and the Mellanox TCP baseline with TX zero-copy. We could not replicate this experiment for RoCE because none of our available drop rules [35, 66, 92] could intercept RDMA traffic.

Figure 13 shows the throughput of a single GPU-to-GPU flow as we raised the probabilistic drop rate from 0.1% to 10% for the two systems. As expected, both TCP-based systems perform well at low drop rates. *ZeroNIC* maintains near-full throughput even at 1% drops, taking advantage of TCP's mechanisms for drop resistance (retransmitting minimal data). RoCE is known to collapse to near-zero throughput at 1% drops due to the use of go-back-N for retransmissions [69, 103].

Adding drop resistance to GPU-to-GPU traffic is particularly important for AI clusters. It removes the pressure to design a perfect congestion control mechanism and to oversize switch buffers. It also allows switch chips to be configured to use cut-though switching instead of store-and-forward switching. The latter is forced by the need for forward-error-correction (FEC) in order to reduce noise-induced packet losses to zero.

6 Discussion

Zero-copy is critical but is not a panacea. We demonstrated that a data path with both receive and send-side zero-copy improves host networking even with mature network protocols. However, as network links scale to 800*Gbps* and beyond for workloads like artificial intelligence, the control path will become the next bottleneck. Recent proposals to reduce packet processing overheads include hardware offload [40, 60], system call mitigation [18, 31], extending segmentation offload [16, 29, 52], and cache-aligned reorganization [61]. To improve metadata I/O between the NIC and software, systems like Enso [86] and PacketMill [30] introduce optimizations



(a) Long flow (zero-copy) throughput and CPU utilization under collision with short flows.

(b) Short flow (non-zero-copy) p50 latency.

Figure 12: Robustness experiment with long (zero-copy) and short (non-zero-copy) CPU-to-CPU flows colliding in *ZeroNIC*.

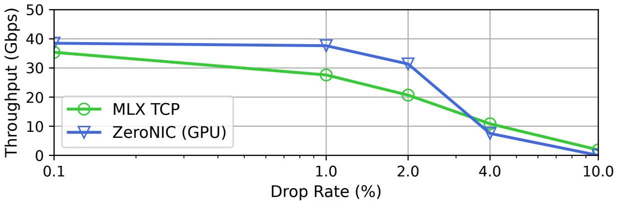


Figure 13: Throughput under instrumented drops in *ZeroNIC* (GPU-to-GPU) and Mellanox TCP (CPU-to-CPU).

for the efficient use of PCIe bandwidth. Our design is well-positioned to help with and benefit from this evolution.

Our design enables an agile evolution of the data and control path. Our design creates a triangle between the NIC, data path devices, and control path devices with well-defined interfaces and responsibilities. This allows the fast and largely independent evolution and optimization of control and data path devices. For example, a host architect can quickly swap GPUs for other AI accelerators without re-implementing or re-optimizing the network data path or the control path.

Control path flexibility is equally important. Achieving the right balance of features and resources integrated in the NIC is difficult. Unlike RNICs that jointly implement the control and data paths in inflexible hardware or opaque firmware, our NIC design implements only a necessary subset of features to support remotely executed control paths. Via our design, a system architect may use a different network protocol in order to improve fabric performance (high utilization, reduced drops, reduced hot spots, etc.) or use a specialized hardware component for faster header processing (CPU with specialized cores, FPGAs, or specialized accelerator). Our design facilitates changes in the control path of the triangle without necessitating changes in the performant data path or the application layer.

The bounds of the maximum bandwidth and minimum latency of communication between the elements of the triangle are set by the link specifications that connect them. Our prototype uses PCIe links and inherits PCIe's bandwidth and latency profiles. As higher throughput and/or lower latency links, such as CXL and NVLink, gain acceptance in industry, our design will benefit from their characteristics.

7 Conclusion

Current end-host network stacks inherently couple the control and data path, resulting in implicit trade-offs between the flexibility and performance of network solutions. In this paper, we showed that a physical separation of the data and control paths allows host network stacks to achieve *both* flexibility and performance. To this end, we presented a co-designed hardware and software stack, which enables a zero-copy receive and send data path between the NIC and any device memory, controlled by any arbitrary transport protocol. We showcased *ZeroNIC*, a prototype that combines an FPGA-based NIC and the TCP stack in the Linux kernel as the transport protocol. Our prototype saturates available network bandwidth on CPU and GPU benchmarks. It improves TCP-based NCCL and Redis throughput by 2.66× and 3.71×, respectively, over Linux TCP on a Mellanox ConnectX-6, all while maintaining the robustness of the TCP transport.

Acknowledgments

We are grateful to the anonymous reviewers and to our shepherd, Aurojit Panda, whose comments have greatly helped improve this paper. We would also like to acknowledge the contributions of Antonis Michaloliakos, Grigori Inozemtsev, George Prekas, and many others at Enfabrica who have played a vital role in this endeavor. *Stony Brook University, †Purdue University, ‡Virginia Tech

Abstract

This paper introduces INTOS, an embedded operating system and language support for multi-threaded intermittent computing on a battery-less energy-harvesting platform. INTOS simplifies programming with a traditional “thread” and a “transaction” with automatic undo-logging of persistent objects in non-volatile memory. While INTOS allows the use of volatile memory for performance and energy efficiency, conventional transactions do not ensure crash consistency of volatile register and memory states. To address this challenge, INTOS proposes a novel *replay-and-bypass* approach, eliminating the need for users to checkpoint volatile states. Upon power restoration, INTOS recovers non-volatile states by undoing the updates of power-interrupted transactions. To reconstruct volatile states, INTOS restarts each thread bypassing committed transactions and system calls by returning recorded results without re-execution. INTOS seeks to build a persistent, full-fledged embedded OS, supporting priority-based preemptive multithreading while ensuring crash consistency even if power failure occurs during a system call or while some threads are blocked. Experiments on a commodity platform MSP430FR5994 show that when subjected to an extreme power failure frequency of 1 ms, INTOS demonstrated 1.24x lower latency and 1.29x less energy consumption than prior work leveraging idempotent processing. This trend turns out to be more pronounced on Apollo 4 Blue Plus.

1 Introduction

Instead of using a battery, energy-harvesting systems [24, 30, 40, 54, 57] capture necessary energy from ambient sources (*e.g.,* solar [27], radio frequency [35]) and leverage a small capacitor as energy storage. The ability to offer sustainable and long-term deployment without the need for battery replacements has unlocked a diverse range of emerging applications such as body implants [29], wearables [61], wildlife tracking [67], road monitoring [26], and satellites [5].

Since the capacitor undergoes cycles of depletion and recharge, program execution on an energy-harvesting system is inherently *intermittent*, involving repetitive power interruptions and resumptions. The nature of intermittent computing necessitates crash consistency to guarantee correct resumption throughout frequent power cycles.

An operating system (OS) offers essential services to application developers (users), including multi-threading, queues, semaphores, events, and timers, to assist in creating feature-rich applications. To illustrate, widely-used embedded OSes like FreeRTOS [3] have streamlined the development of diverse embedded applications. Unfortunately, this level of OS-/runtime support is absent in intermittent computing environments. For instance, ImmortalThreads [65] offers a tiny runtime supporting (pseudo) threads with cooperative scheduling; however, its capabilities are limited. It lacks a wait-list for blocking threads. Its event loop is based on polling, wasting microcontroller (MCU) cycles. Many task-based solutions such as Ink [64] and CatNap [52] do not support threads.

There arises a growing need for a more robust OS tailored specifically for intermittent computing. Advancements in hardware technologies, such as ultra-low power microcontrollers like TI’s MSP430FR [6] and ARM’s Cortex-M4 [2], as well as non-volatile memory (NVM) like FRAM [12] and MRAM [10], have empowered intermittent applications to perform more computations. Emerging intermittent applications are becoming increasingly complex, incorporating features like multi-threading, communication, synchronization, and responsiveness to events. We started witnessing machine and deep learning tasks [16, 28, 39, 48] on energy-harvesting platforms. Despite these advancements, users are compelled to manage this complexity without adequate OS support.

Unfortunately, the current crash consistency solutions are hard to adopt or result in inefficient designs when applied to the development of persistent embedded OS kernels. Some approaches [22, 31, 49, 52, 53, 56, 64] require users to decompose applications into a task graph, demanding each task to inherently possess failure-atomicity and idempotence. This poses considerable challenges for programmers [38, 65]. Breaking down a kernel system call, such as creating a thread or blocking on a full queue, into tasks is not trivial. Other compiler-based solutions [15, 18, 19, 37, 47, 50, 55, 62] automatically divide programs (*e.g.,* into idempotent regions) and incorporate checkpoints, requiring little to no user annotations. Thus, they may be used to build a persistent OS. Yet, many (except Chinchilla [50]) assume execution solely on NVM, overlooking potential advantages offered by volatile memory.

This paper introduces INTOS, a new persistent full-fledged embedded OS accompanied by language support for multithreaded intermittent computing (§4). To ease intermittent application programming, INTOS offers a traditional "thread" along with a priority-based preemptive scheduler. INTOS also allows users to define a standard "transaction" with automatic undo-logging to ensure the crash consistency of persistent objects residing in NVM, akin to a widely adopted Intel's Persistent Memory Programming Kit (PMDK) [7]. INTOS places program stacks, encompassing local variables and function frames, in volatile memory to improve performance and energy efficiency. However, their crash consistency in the event of a power failure is not safeguarded by transactions. The absence of volatile states (*e.g.,* stacks) makes it impossible to simply resume from the beginning of a transaction.

To address this challenge, INTOS proposes a new *replay-and-bypass* approach (§5). Upon power restoration, INTOS recovers non-volatile states by undoing the updates of power-interrupted transactions. To reconstruct volatile states, it then restarts each thread from the beginning while bypassing committed transactions and system calls by returning recorded results without re-execution. This approach is grounded in the insight that reconstructing the volatile states with replay-and-bypass is more energy-efficient, compared to alternatives checkpointing volatile states to NVM—since NVM writes are the most energy-consuming in the instruction set architecture.

In particular, INTOS provides a programming model based on Rust, leveraging Rust's type system to enforce various programming rules (§6). These rules are designed to ensure crash consistency: *e.g.,* the prohibition of modifications to persistent objects outside of transactions. The adaptability of this programming model has been showcased through the successful implementation of the INTOS kernel, featuring multithreading, queues, semaphores, events, and timers.

We evaluate INTOS with three single-threaded and eight multi-threaded applications, including those ported from RIoTBench [58], an IoT/Edge stream processing benchmark for real city sensing and fitness sensing data, on MSP430FR5994 [6] and Apollo 4 Blue Plus [1]. We compare INTOS with Ratchet [62] where compiler-based idempotent processing is applied in both the INTOS kernel and application. On the MSP430FR platform without power failures, INTOS exhibited 1.65x lower latency and 1.85x less energy, compared to Ratchet. Even when subjected to an extreme power failure frequency of 1 ms, INTOS demonstrated 1.24x lower latency and 1.29x less energy overhead. This trend became more pronounced on the Apollo 4 platform.

This paper makes the following contributions:

- To the best of our knowledge, INTOS is the first persistent embedded OS that supports priority-based preemptive multithreading and other core features, tailored for intermittent computing with frequent power failures.
- INTOS combines transactional programming with a new replay-and-bypass recovery mechanism to ensure whole-system crash consistency, encompassing both volatile and non-volatile memory states at both user and kernel levels.
- INTOS introduces a Rust-based programming model ensuring crash consistency through the proposed transactions and replay-and-bypass recovery mechanisms.
- INTOS is to our best knowledge the first intermittent system that is evaluated with multithreaded applications.

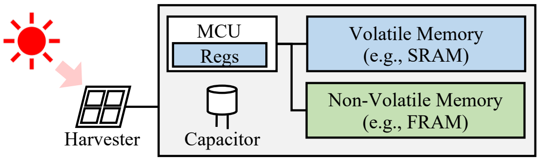

Figure 1: An architecture of energy harvesting platforms (*e.g.,* MSP430FR). Registers and SRAM (blue boxes) are volatile.

2 Background

This section briefly discusses intermittent computing, embedded OS, and transactions.

2.1 Intermittent Computing

Execution on an energy-harvesting platform is *intermittent*, *i.e.,* it abruptly halts upon the depletion of the capacitor and resumes after recharging, typically to the full capacitance. This implies that the program is often power-interrupted, and therefore intermittent computing requires to ensure crash consistency for correct recovery across frequent power cycles.

Figure 1 depicts an architecture of energy harvesting platforms available in TI MSP430 [6] or Ambiq Apollo 4 [1]. The energy harvester gathers ambient energy (*e.g.,* solar, RF) and stores it in a capacitor. Capacitor sizes typically vary from a few to several hundred microfarads (µF). For reference, WISP [57] uses 47 µF. The computing components include an ultra-low power microcontroller (MCU) along with both volatile memory (*e.g.,* SRAM) and non-volatile memory (*e.g.,* FRAM [12] or MRAM [10]). For instance, the MSP430FR5994 features a 16 MHz MCU with 8KB SRAM and 256KB FRAM. Registers and SRAM states (blue boxes) are lost upon a power outage. Previous solutions (§3) have suggested diverse approaches to maintaining the crash consistency of data stored in registers, volatile memory, and non-volatile memory across a power cycle.

Table 1: A comparison of the main features of IntOS with prior intermittent computing solutions.

2.2 Embedded Operating Systems

Embedded OSs [3,13,14,25,41,42] are a specialized software layer that provides essential services for the target embedded system. They empower users (application developers) to create applications with rich features using a conventional thread-based programming model, even within resource-constrained environments. For instance, FreeRTOS [3], widely recognized as one of the most adopted, supports (1) multi-threading with a priority-based preemptive scheduler; (2) synchronization (*e.g.,* semaphores) and communication (*e.g.,* queues) among threads; (3) dynamic memory allocation; and (4) software timers. An embedded OS is intimately linked with the application code and is typically included as part of the firmware image. Existing embedded OS kernels are not designed to be crash-consistent and do not support intermittent computing.

2.3 Transactions for Non-volatile Memory

Transactions stand out as a widely adopted programming model for NVM, as demonstrated by Intel's PMDK [7] for Optane memory [4]. Users can allocate a persistent object using a non-volatile memory allocator. A transaction employs undo logging (or redo logging) to ensure failure-atomicity (the "all-or-nothing" semantic) for operations executed during the transaction. Transactional programming has demonstrated success in the development of complex software such as persistent memchached [9] and redis [8].

3 Related Work

This section initially emphasizes the absence of essential OS features in prior solutions (Table 1) and then delves into the challenges associated with applying existing crash consistency solutions to design persistent OS services.

No OS exists for intermittent computing. As highlighted in the middle five columns of Table 1, current intermittent processing runtimes lack essential features present in modern embedded OSes. ImmortalThreads [65], for example, introduces (pseudo) multithreading with "non-blocking" spin-locks and event buffers. Spinning results in inefficient utilization of MCU cycles. To support "blocking" semaphores, queues, event groups, and software timers in intermittent computing, an OS/runtime should maintain a run-queue, wait-queues, and other relevant kernel metadata in a crash-consistent manner. ImmortalThreads (its runtime) does not offer them.

We believe ImmortalThreads can be extended to implement such missing kernel features using its micro-continuation approach. However, we expect ImmortalThreads would suffer from two fundamental problems. First, ImmortalThreads would incur high performance overhead. Unlike those hardware-based roll-forward solutions [17,21,36,51,66] that detect impending power failure and save registers to resume from the failure point, ImmortalThreads does not (cannot) sense the dying voltage. Thus, it ends up persisting a program counter in every store instruction to enable roll-forward recovery (micro-continuation). Second, micro-continuation only works for non-volatile memory and excludes volatile SRAM available in commodity energy harvesting systems, thereby losing a great opportunity to enable more energy-efficient intermittent computing. JustDo logging [34], from which the micro-continuation idea is inspired, also requires the entire memory hierarchy to be fully persistent. We discuss ImmortalThreads' potential high overhead later in §10.

On the other hand, Ink [64], Coati [56], and Catnap [52] offers partial support for task-based event-driven runtimes, yet they do not accommodate threads and demand a task-based programming model, which we explain next.

Manual task decomposition adds programming burden. For crash consistency, several prior solutions [22,31,49,52,53,56,64] require users to decompose an application into a graph of "tasks". Each task is compelled to inherently guarantee failure atomicity and idempotence in the face of a power failure, leading to considerable programming challenges and design complexities. Some runtime systems employ a cooperative scheduler to execute multiple tasks. However, the manual task decomposition shifts the responsibility of ensuring crash consistency onto users. This has been demonstrated to be a significant burden for programmers [38, 65]. For example, breaking down a kernel system call, such as creating a thread or blocking on a full queue, into tasks is far from trivial.

Within the task-based model, several new features have been introduced. For example, Alpaca [49] suggests task privatization, creating a volatile copy of shared non-volatile variables before entering each task. A task's local computation can run on volatile memory. Upon task completion, updates to shared variables are committed to NVM in a double-buffered manner. Chain [22] abstracts inter-task variable passing with the use of a persistent queue; Ink [64] and Coati [56] support event-driven programming; and CatNap [52] adaptively schedules tasks based on task priority, energy consumption, current energy level, and charging rate.

Automatic checkpointing often does not consider volatile memory. Several works [15, 19, 37, 47, 50, 55, 62] have introduced compiler support to automatically partition a program into multiple regions and insert checkpointing at the boundaries of these regions. Users require little to no annotations, so they can be used to build persistent OS services. Our evaluation (§10) includes a comparison against Ratchet [62] idempotent processing. However, many compiler-based solutions assume a program execution solely on non-volatile memory, foregoing the potential performance and energy efficiency benefits that volatile memory could provide. Experiments with MSP430FR5994 (§10.1) show that executing our 11 benchmarks entirely in non-volatile memory (FRAM) results in 1.11x latency and 1.16x energy overheads compared to running them entirely in volatile memory (SRAM). In this context, only live-in (volatile) registers necessitate checkpointing at a region boundary. A notable exception is Chinchilla [50] which maintains volatile and non-volatile stacks, yet it still involves frequent checkpoints of stacks to NVM.

Ratchet [62] divides a program into idempotent regions [23, 43, 45, 46] with no write-after-read dependencies within a region. Chinchilla [50] selectively skips certain checkpoints based on energy conditions. WARio [37] reduces the number of idempotent regions by reordering instructions and incorporating a loop optimization. Differently, HarvOS [15] partitions a program into regions where the energy required to complete that region is less than the energy buffer size. RockClimb [19] checks the energy level at the region boundary and only proceeds if there is sufficient energy. On the other hand, TICS [38] and ImmortalThreads [65] leverage a compiler for checkpoint instrumentation without region partitioning. TICS employs stack segmentation, where only a working stack (and registers) is checkpointed in NVM via a two-phase commit. ImmortalThreads introduces micro continuation, which checkpoints every memory update, ensuring the idempotence of the execution until the next checkpoint (store).

Other issues Prior works also address data timeliness [31, 38, 52, 64], event-driven programming model [38, 52, 56, 64], and others. Surbatovich et al. [59, 60] use Rust's type systems for data freshness checking and crash consistency. Hardwawre support [20, 32, 36, 44, 63, 68] also exists.

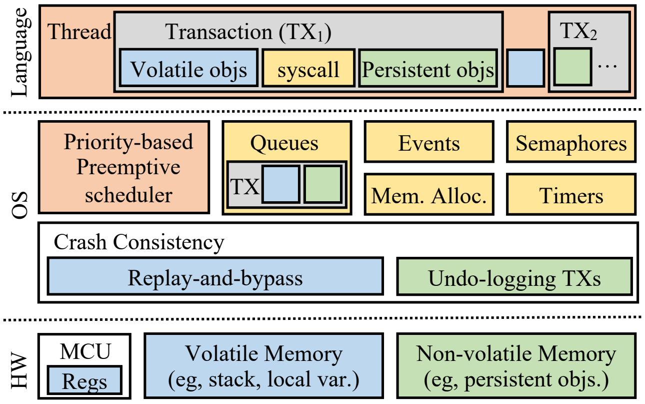

Figure 2: Overview of INTOS

4 Overview of INTOS

Figure 2 shows an overview of INTOS, embedded OS and language support for multi-threaded intermittent computing.

4.1 Multithreading and Transactions

Threads To ease the aforementioned programming burden and keep the same embedded application programming model, INTOS supports a traditional stackful "thread" as a programming unit and a schedulable entity, similar to commodity embedded OSes (*e.g.,* FreeRTOS[1]). Users can generate multiple threads through the system call `sys_create_thread` (Table 2). These threads run concurrently. Users can assign different priorities for threads. The INTOS scheduler employs a priority-based preemptive scheduling policy, a widely adopted approach for real-time capabilities. More discussion on INTOS's real-time capability will follow in §8.

Transactions To facilitate the utilization of both volatile and non-volatile memories while simplifying crash-consistent programming, INTOS offers a conventional "transaction" with automatic undo-logging to ensure crash-atomicity of persistent objects. Program stacks, encompassing local variables and function frames, reside in volatile memory. Users can either annotate a persistent variable (*e.g.,* globals) or employ the `sys_palloc` system call to create a persistent object in non-volatile memory. Both volatile and persistent objects can be used inside a transaction. Users do not need manual undo-logging. INTOS's transactions ensure that updates on persistent objects (not volatile ones) within a transaction are crash-atomic via automatic undo-logging. INTOS leverages Rust to identify the first writable dereference. As persistent objects share a base class or trait in Rust, the logging logic is integrated into the dereference operation within the class/trait. This approach mirrors PMDK's undo-logging support for its

[1] FreeRTOS employs the term "task", but it is technically a preemptive thread. For clarity and to distinguish it from the (cooperative) task in manual task decomposition works (§3), we will refer to it as a (preemptive) thread.

C++ programs. In §7.3, we discuss an undo logging optimization that logs old values only if there is a write-after-read dependency in a transaction.

Language The Rust type system in IntOS guarantees that persistent objects are not modified outside transactions (§6). Conversely, volatile states, such as local variables in program stacks, can be utilized both outside and inside transactions.

Challenges IntOS allows users to employ volatile variables for computing, yet IntOS transactions do not protect them. Consequently, the states of program stacks are susceptible to loss upon a power failure. A program cannot resume from the beginning of the failed transaction due to the absence of stack (and register) states. One solution could involve abstaining from the use of volatile memory, a proposition we oppose for energy efficiency reasons. Another approach might be to checkpoint volatile states to NVM at the onset of each transaction, but this would be expensive.

4.2 Replay-and-Bypass

To address the above challenge, IntOS proposes a novel *replay-and-bypass* approach (§5) to guarantee whole-system crash consistency across a power cycle. IntOS eliminates the need for users to checkpoint or create customized crash consistency solutions for volatile register and memory states. Upon power restoration, IntOS first recovers non-volatile states by undoing uncommitted transactions. Then, the thread is restarted from the beginning, safely resuming with empty registers and stack states. Throughout the execution, committed transactions and system calls are replayed and bypassed by returning the recorded results without re-execution – resulting in a more energy-efficient recovery process. Volatile states are reconstructed, enabling the program to resume beyond the point of power failure.

4.3 Persistent Embedded OS

System Calls IntOS provides comprehensive multithreading features (Table 2), comparable to those found in FreeRTOS. For instance, threads can communicate and/or synchronize with each other using the `sys_queue_*` and `sys_semaphore_*` system calls. A thread might block, for instance, if a queue is either empty or full. Multiple threads may access a shared persistent object by obtaining its reference (inside a transaction). Later in §6, we delve into how IntOS's programming model ensures the obligatory use of a mutex for synchronization via Rust's strong type system.

Kernel Crash Consistency Similar to user threads, IntOS kernel codes, including system calls, utilize volatile and non-volatile memories. The IntOS kernel employs the same undo-logging transactions to ensure crash consistency of persistent kernel objects that undergo updates during system calls. Table 2 lists the number of transactions and examples of persistent kernel data safeguarded by kernel-level transactions. Later in §7.2, we also discuss that the kernel uses optimized transactions (without undo-logging) for frequently used linked lists operations (*e.g.,* `ready-list`, `wait-list`). Using the same replay-and-bypass, IntOS provides a crash consistency guarantee even if a power failure occurs in the midst of a system call and some threads are blocked.

Features	System calls	TXs	Persistent kernel objects
Threads	sys_create_thread	2	ready_list, thread_cnt, heap
	sys_thread_delay	1	delay_list
Queues	sys_queue_create	1	heap
	sys_queue_send_back	2	queue and its waitlist
	sys_queue_receive	2	queue and its waitlist
Events	sys_event_group_create	1	heap
	sys_event_group_wait	3	event_grp and its waitlist
	sys_event_group_set	3	event_grp and its waitlist
Semaphores	sys_create_semaphore	1	heap
	sys_semaphore_take	2	semaphore and its waitlist
	sys_semaphore_give	2	semaphore and its waitlist
Dyn. memory	sys_palloc	1	heap
	sys_pfree	1	heap
Timers	sys_timer_create	1	heap
	sys_start_timer	2	timer_cmd_q and its waitlit
	sys_reset_timer	2	timer_cmd_q and its waitlist

Table 2: IntOS supports full-fledged embedded OS features, akin to FreeRTOS [3]. Some system calls are not listed.

Energy efficient execution Designing an OS and language support for intermittent computing requires more than merely ensuring crash consistency. Both (fail-free) execution and recovery should be energy-efficient. IntOS provides energy-efficient execution by: (1) Utilizing both volatile and non-volatile memories; (2) Avoiding the checkpointing of volatile states; (3) Optimizing undo-logging for non-volatile states (§7.3); (4) Offering blocking/waiting system calls, such as semaphores and events, in contrast to existing approaches like ImmortalThreads [65], which requires spinning and wastes MCU cycles; (5) In the absence of events, with a blocking mechanism, allowing the MCU to enter a deep sleep mode where only a subset of interrupts are monitored.

Energy efficient recovery IntOS offers energy-efficient recovery by: (1) Utilizing replay-and-bypass recovery to avoid redundant execution (§5); (2) Undoing only the non-volatile state relevant to the high-priority thread that will resume during recovery (§5.2); (3) Introducing loop optimization (§7.1).

4.4 IntOS Program Example

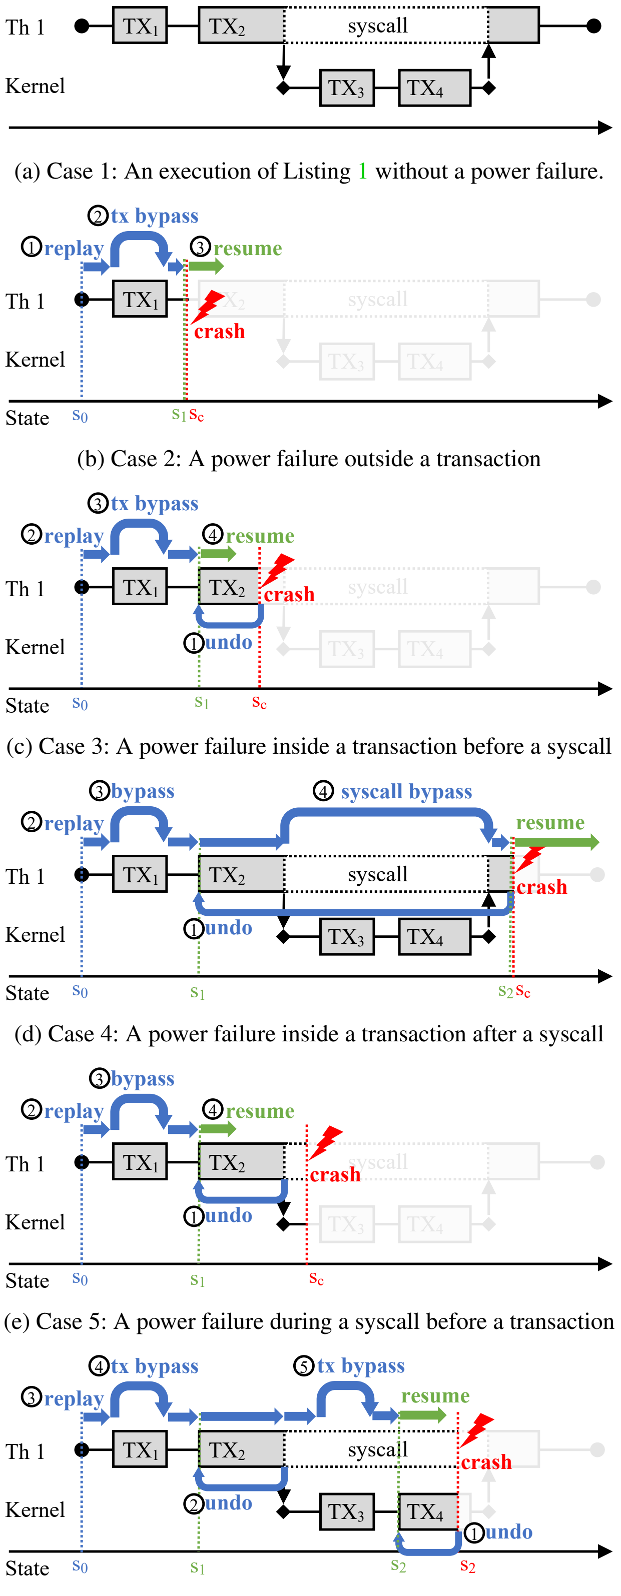
The example presented in Listing 1 illustrates the `recognize` program with two transactions. In this example, a queue is created to enable message passing between two threads, like a Linux pipe. A thread (`recognize`) is reading data from the sensor and sending the data to another thread (not shown) for processing using the queue. `PBox` is a smart pointer for a

```
1  fn recognize(model: PBox<Model>) {
2    let (q,stats) = transaction::run(|j, t| {
3      // syscall to create a queue
4      let q=sys_queue_create::<Result>(Q_SZ, t).unwrap();
5      // syscall to create a persistent object
6      let stats = PBox::new(Stats::new(), t);
7      ...
8      return (q,stats)
9    });
10   transaction::run(|j, t| {
11     // obtain read only ref, no logging
12     let mdl_ref = model.as_ref(j);
13     // syscall to perform I/O
14     let reading = sys_read(SENSOR_0);
15     // data processing in volatile buffer
16     let mut window = [AccelReading::new(); 3];
17     init_window(&readings);
18     transform(&mut window, j);
19     let feature = featurize(&window);
20     let class = classify(&feature, mdl_ref);
21     // obtain mutable ref, auto. undo logging
22     let mut stats_ref = stats.as_mut(j);
23     stats_ref.cnt[class] += 1;
24     // syscall to send result
25     sys_queue_send_back(q, class, WAIT_TIME, t);
26   });
27   ...
28 }
```

Listing 1: An example INTOS program with transactions.

persistent object. Users can enclose a program region with the transaction construct, `transaction::run(|j,t|{ ... })`, where `j` represents the journal object and `t` is the system call token. The journal object enforces restrictions, ensuring that persistent smart pointers like `PBox` cannot be dereferenced outside a transaction, while the system call token restricts system calls to occur exclusively within a transaction. Further details on this will be provided in §6.

The first transaction (Lines 2-9) involves creating a queue with a size of `Q_SZ`. This queue contains objects of type `Result`, and a persistent object (`stats`) that holds counts (`cnt`) for each class/result. The transaction returns them after some processing. The second transaction (Lines 10-26) reads an ML model using a read-only reference. This eliminates the need for undo-logging. Following I/O, it conducts data processing (Lines 16-20) such as filtering, normalization, and classification, notably on a volatile buffer. This strategy enhances performance and energy efficiency compared to conducting all intermediate computations on a non-volatile buffer. Subsequently, the transaction obtains a mutable reference to a persistent object (`stat`), created, and passed from the first transaction, and updates it. As this is the first write after getting a mutable reference, INTOS automatically applies undo logging. Finally, the transaction makes a system call `sys_queue_send_back` to place the result into the queue, maintained by INTOS. Another thread (not shown) can then receive the result from the queue for subsequent processing.



(a) Case 1: An execution of Listing 1 without a power failure.

(b) Case 2: A power failure outside a transaction

(c) Case 3: A power failure inside a transaction before a syscall

(d) Case 4: A power failure inside a transaction after a syscall

(e) Case 5: A power failure during a syscall before a transaction

(f) Case 6: A power failure during a syscall inside a transaction

Figure 3: Replay-with-bypass recovery examples

5 Replay-and-Bypass Recovery

The following two sections demonstrate INTOS's replay-and-bypass approach. along with examples.

5.1 Single Thread Crash Consistency

Let's illustrate INTOS's *replay-and-bypass* recovery mechanism using the `recognize` example in Listing 1, which involves two user-level transactions, $\texttt{TX}_1$ and $\texttt{TX}_2$. Figure 3a depicts an execution of `recognize` without a power failure. For simplicity, the system calls in the first transaction $\texttt{TX}_1$ are omitted, and only the system call `sys_queue_send_back` (Line 23) made by $\texttt{TX}_2$ is highlighted. Assume that the system call includes two kernel-level transactions, $\texttt{TX}_3$ and $\texttt{TX}_4$.

In Figure 3b, we consider a scenario where $\texttt{TX}_1$ has been committed, and then a power failure occurs before $\texttt{TX}_2$ starts (outside transactions). Upon power recovery, INTOS initiates a *replay* of the thread from the beginning (step ①), restarting with empty registers and stack state $\texttt{s}_0$. INTOS's type system (§6) ensures that no non-volatile states are updated outside the transaction. Volatile states are *reconstructed* during replay. Since the non-volatile states at $\texttt{s}_\texttt{c}$ (before the power failure) already incorporate the effects of the committed transaction $\texttt{TX}_1$, re-executing $\texttt{TX}_1$ would be incorrect and non-idempotent. Therefore, INTOS *bypasses* the transaction $\texttt{TX}_1$ (step ②), simply returning the logged return value without re-execution. No system calls are made during bypass, and no kernel-level recovery is required. INTOS ensures that the program reaches the same state $\texttt{s}_1$ as $\texttt{s}_\texttt{c}$, from which it can safely resume.

Now, let's consider a power failure inside a transaction. In Figure 3c, a power failure occurs inside a user-level transaction before a syscall. INTOS's undo-logging transaction ensures the failure-atomicity of non-volatile states changed within the transaction. Upon power recovery, INTOS applies undo-logging (step ①) to roll back the (user-level) non-volatile states from $\texttt{s}_\texttt{c}$ to $\texttt{s}_1$, the state before the transaction begins. Next, INTOS starts a replay from the beginning state $\texttt{s}_0$ (step ②). The committed transaction $\texttt{TX}_1$ is bypassed (step ③), and INTOS reconstructs all volatile states along the way, making the state $\texttt{s}_1$ (after replay) equivalent to $\texttt{s}_\texttt{c}$ (before the failure).

Figure 3d illustrates the actions to be taken if a power failure occurs after a syscall completes (inside a user-level transaction). As usual, INTOS applies undo-logging (step ①) and initiates a replay (step ②). The committed transaction $\texttt{TX}_1$ is bypassed (step ③). Notably, in this scenario, while replaying transaction $\texttt{TX}_2$, INTOS also bypasses the completed system call (step ④). Consequently, INTOS avoids the need to alter kernel states — any changes to kernel-side non-volatile states made during the original system call (before a power outage) can remain unchanged. The INTOS kernel caches the return value of a system call upon its completion (before a power failure). Then it simply returns the cached value during replay. From the user thread's perspective, a system call can be considered as a nested black-box transaction.

Now, let's delve into scenarios where a power failure occurs during a system call. As mentioned earlier, INTOS utilizes transactions ($\texttt{TX}_3$ and $\texttt{TX}_4$) to safeguard kernel-side nonvolatile data. If a crash occurs before (or outside) a kernel-side transaction, as depicted in Figure 3e, the situation is straightforward and aligns with the case presented in Figure 3c. There is no need to undo anything in the kernel. INTOS simply undoes the user-level transaction that invoked the system call (①) and initiates the replay-and-bypass recovery mechanism.

On the other hand, if a crash occurs inside a kernel-side transaction, as illustrated in Figure 3f, INTOS must first undo transaction $\texttt{TX}_4$ (step ①) to roll back the kernel-side state to $\texttt{s}_2$, followed by undoing transaction $\texttt{TX}_2$ (step ②) to roll back the user-side state to $\texttt{s}_1$. INTOS then employs a replay from initial $\texttt{s}_0$ (step ③), bypassing the committed transactions on the user side, $\texttt{TX}_1$ (step ④), and on the kernel side, $\texttt{TX}_3$ (step ⑤). Note that INTOS rolls back the kernel-side transaction first (before any aborted user-level transaction). This has correctness implications in multi-thread scenarios, which will be discussed in the subsequent section.

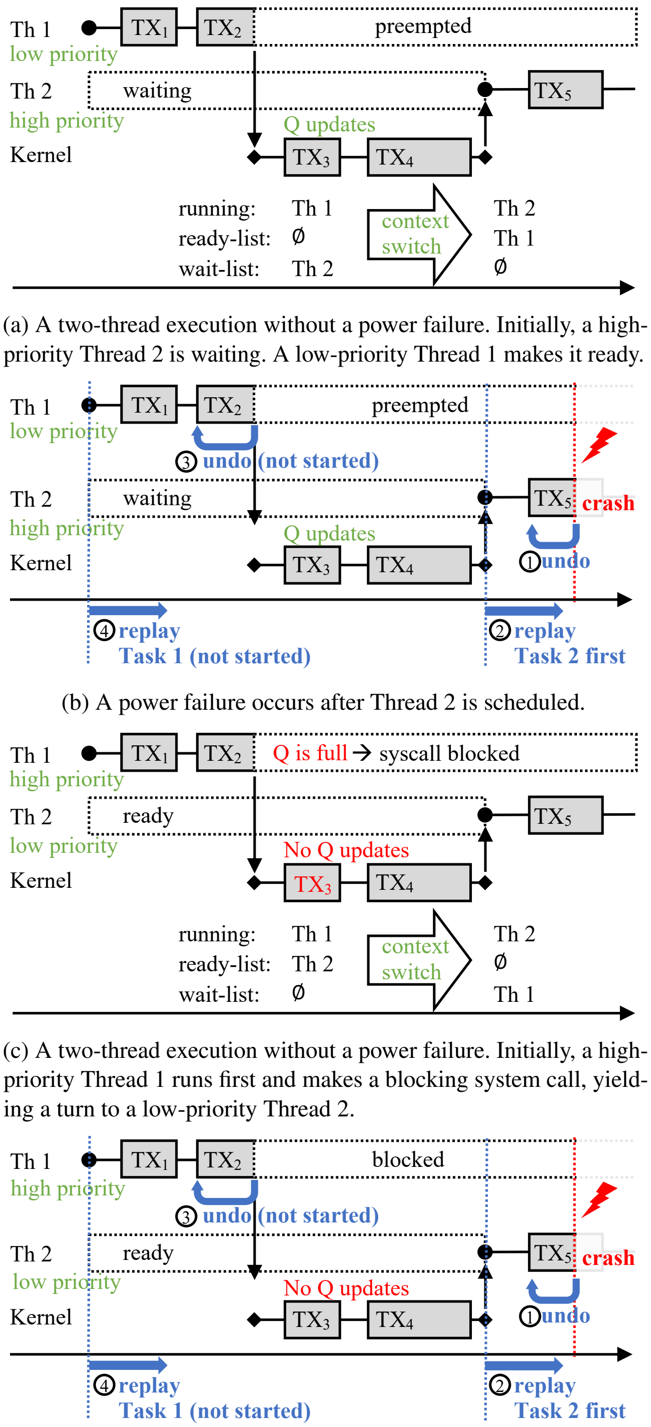
5.2 Multi-Threads Crash Consistency

Next, we discuss INTOS's approach to ensuring crash consistency for multiple threads. Specifically, INTOS employs priority-based recovery and resumption. Upon power restoration, INTOS always recovers and replays the thread with the highest priority among those ready.

Figure 4a illustrates a two-thread execution without a power failure. Initially, high-priority Thread 2 waits, for example, on a queue. A low-priority Thread 1 uses `sys_queue_send_back` to enqueue data, allowing Thread 1 enabled (its waiting condition is satisfied). During the system call, the kernel-side transaction $\texttt{TX}_3$ updates the kernel queue object in NVM. As Thread 1 is awakened and has a higher priority, the INTOS scheduler preempts Thread 1 and context-switches to Thread 2 by modifying thread-related persistent linked lists, such as `ready-list` and `wait-list`, in transaction $\texttt{TX}_4$. It is a common pattern for a system call to update a system call-specific kernel data structure (*e.g.,* queue) in one transaction and to modify schedule-related linked lists in another transaction. After the context switch, Thread 2 runs, and Thread 1 remains on the `ready-list`, awaiting its turn.

Let's first consider a simple power failure case. If power is lost during the system call (*e.g.,* during $\texttt{TX}_3$ or $\texttt{TX}_4$ or between them), it constitutes a single-thread scenario. The recovery protocol remains the same as the case presented in Figure 3f.

Suppose a power outage occurs while running Thread 2 (after the context switch) as depicted in Figure 4b. This makes a multi-thread scenario: Threads 1 and 2 are runnable. Upon power restoration, INTOS recovers and runs Thread 2 — the thread that was running and experienced a power failure. The priority-based scheduler always schedules the thread with



(a) A two-thread execution without a power failure. Initially, a high-priority Thread 2 is waiting. A low-priority Thread 1 makes it ready.

(b) A power failure occurs after Thread 2 is scheduled.

(c) A two-thread execution without a power failure. Initially, a high-priority Thread 1 runs first and makes a blocking system call, yielding a turn to a low-priority Thread 2.

(d) A power failure occurs after Thread 2 is scheduled.

Figure 4: Multi-threads recovery examples

the highest priority among ready threads. Thus, recovering the failed thread implies that when power becomes available, INTOS runs the ready thread with the highest priority. In this example, it is Thread 2. INTOS roll-backs transaction TX$_5$ (step ①) and replays Thread 2 (step ②). On the other hand, INTOS does not eagerly undo transaction TX$_2$ (step ③). Hard-won energy should not be wasted. A system may not possess enough energy to run Thread 1 (after Thread 2). High-priority ready Thread 2 takes precedence over undoing the transaction TX$_2$ of Thread 1. Sometime later, when Thread 1 is scheduled, INTOS then rolls back transaction TX$_2$ on demand (step ③) and replays Thread 1 (step ④).

When managing multiple threads, a blocking system call warrants detailed discussion. Figure 4c depicts another two-thread execution without a power failure, distinct from Figure 4a. In this scenario, Thread 1 possesses high priority, and even though Thread 2 is ready, it is not scheduled. Suppose the queue is already full. Assuming the queue is already full, when Thread 1 employs the `sys_queue_send_back` system call to enqueue data, it discovers the queue lacks space and becomes blocked. Subsequently, the scheduler moves Thread 1 to the `wait_list` in transaction TX$_4$. In this scenario, it is crucial to note that TX$_3$ is indeed a null transaction, making no updates to the queue. An essential invariant established by the INTOS kernel is that a blocking system call, if it actually blocks, does not alter the state of system call-specific persistent objects (*e.g.,* queue). The system call is not considered complete, and no result is cached for bypassing. The impact of a blocking call is confined to schedule-related linked lists in TX$_4$. Given that a blocking system call has no substantive effect on kernel states, it is safe to proceed with the same recovery and replay of the ready thread with high priority — Thread 2 in this example. Any processing for the blocked threads, such as Thread 1, can be deferred, as illustrated in Figure 4d. When Thread 1 is later scheduled for recovery and replay, it will re-invoke the system call as if it had not been issued previously. In the INTOS implementation, those system calls that may block always first check for a blocking condition to uphold this invariant.

6 INTOS Programming Model

INTOS's programming model upholds five rules designed to guarantee crash consistency.

Rule 1: Persistent objects should not be accessed (both write and read) outside the transaction and their update inside the transaction must be logged. Modifications on persistent objects outside transactions are untracked. Therefore, any update to persistent objects should be confined within transactions. INTOS also prohibits the reading of persistent objects outside transactions to prevent potential divergence in program control flow during replay. When restarting, non-volatile memory states are not rolled back to the thread's outset. For example, in the scenario illustrated in Figure 3c, replay begins with non-volatile memory states still reflecting the state s$_1$ after TX$_1$. Consequently, control flow outside transactions should not rely on persistent objects. To precisely identify a subset of persistent object reads that may influence control flows, one can perform static analysis and selectively prevent them. INTOS, for simplicity, conservatively enforces the restriction of no reads (and writes) outside transactions. This approach does not overly constrain programmability since it is natural to assume that persistent objects are primarily used within transactions. Furthermore, INTOS permits a transaction to acquire references to persistent objects that were created or modified by another transaction and subsequently update them arbitrarily within the executing transaction, as demonstrated in Listing 1 (Lines 6, 22-23).

Rule 2: References/Pointers to persistent objects should not escape a transaction as a return value. Rule 2 further enforces Rule 1. Allowing the return of references would potentially enable users to directly modify persistent objects without proper logging. Mutable references should be acquired and dereferenced exclusively within a transaction, as exemplified in Listing 1 (Lines 22-23).

Rule 3: Persistent objects should not contain references to volatile objects. Volatile objects are susceptible to data loss during power failures. Storing their references in persistent objects is thus unsafe.

Rule 4: System calls (excluding Locks) should only be made within transactions. There is, in theory, no fundamental restriction against using a system call outside a transaction for crash consistency. Yet, INTOS mandates adherence to this rule to constrain the length of system call replay and bound memory resources. After a transaction concludes, there is no necessity to replay any system call within that transaction. As a result, the upper limit for system calls to be replayed is determined by the number of system calls in the last uncommitted transaction. INTOS can safely free the system call replay metadata for committed transactions.

Rule 5: Locks should not be used inside transactions. A critical section, defined by locks, should be larger than a transaction. Suppose two concurrent transactions, `TX`$_1$ and `TX`$_2$, utilize a lock when accessing a shared object `X` within transactions. `TX`$_1$ acquires the lock, updates `X`, releases the lock, but remains uncommitted. The concurrent `TX`$_2$ acquires the lock, reads `X`, performs some computation, releases the lock, and eventually commits. If a power failure occurs at this point while `TX`$_1$ remains uncommitted, a data consistency issue arises. This occurs because our transaction lacks “isolation” among concurrent transactions. Rule 5 is enforced to avoid this problem. Ultra-low power intermittent computing systems hardly use multi-cores. Introducing a more intricate yet efficient solution, such as tracking data dependencies between transactions and aborting one if a conflict is detected, doesn’t appear necessary in this context.

Enforcement INTOS employs Rust’s robust type system to uphold the aforementioned rules, akin to [33] that statically prevents common persistent memory programming errors within the realm of server-side (non-energy-harvesting) persistent memory programming. Rules 1-3 resemble those in [33], with INTOS extending Rule 1 to disallow reading persistent objects outside transactions to avoid potential control flow divergence during replay. Rules 4-5 are distinctive to INTOS. The implementation utilizes Rust’s traits.

7 Optimization

INTOS employs three performance optimizations.

7.1 Loop Optimization

Threads in embedded systems often involve loops, such as event loops handling sensor readings or loops with numerous iterations, as seen in matrix multiplication for neural network machine learning threads. Consider a thread with a loop where the loop body comprises T transactions, and a power crash occurs on the N-th iteration. While INTOS’s replay-and-bypass approach can bypass $(N-1)*T$ transactions (in addition to any committed transaction in the last iteration), the overall replay window’s length could potentially be excessively long, leading to substantial energy consumption during replay.

To address this common scenario, INTOS introduces the new `nv_for_loop!` macro, extending the loop construct in Rust to utilize a non-volatile variable as the iteration counter. With the non-volatile iteration counter, INTOS can infer completed iterations (committed transactions therein) during replay, enabling a safe and efficient fast-forward to the last iteration without executing the bypass logics.

INTOS’s Rust language enforces the absence of loop-carried dependent volatile states to safely employ `nv_for_loop!` optimization as it skips iterations during recovery. Users are still able to employ volatile variables within a loop body, provided there is no loop-carried dependency.

7.2 Linked List Optimization

The INTOS kernel extensively utilizes doubly-linked lists to manage threads and scheduling states. Nearly every system call involves the manipulation of these linked lists. Notably, we have identified optimization opportunities, recognizing that linked list updates within the kernel occur within a critical section, eliminating the need to account for arbitrary interleaving. Additionally, there are no intermediate volatile hardware buffers (such as store buffer or cache) between registers and non-volatile memory. Consequently, any store instruction promptly persists as it retires from the pipeline. With these factors combined, we can scrutinize the crash non-volatile state, reason through intermediate linked list update steps, and precisely identify the power failure point.

INTOS presents *crash state analysis*-based roll-forward recovery optimization for linked list transactions. There is no undo-logging. Instead, INTOS records an operation log including the type (*e.g.,* insert) and the node (data) — only one per operation. During recovery, INTOS analyzes the crash

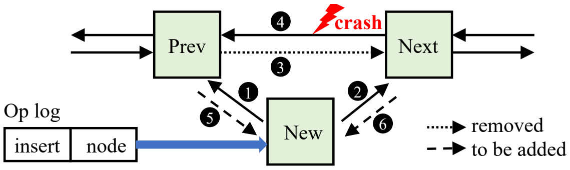


Figure 5: Crash state analysis to roll forward a list insertion

state remaining in NVM to infer the steps that have been completed. Then, it rolls forward the rest of the operation.

Consider an insertion transaction, illustrated in Figure 5. The process of list insertion involves six ordered steps. Initially, we link the node to its previous and next node (step ❶ - ❷). Then, the backward/forward link between the next node and the previous node is removed (step ❸ - ❹). Finally, we insert the new forward/backward link between the previous/next node and the new node (step ❺ - ❻). Suppose a power crash occurs before step ❹. During recovery, the operational log is first retrieved to determine the operation type and the node involved. It is discovered that the link from the new node to the previous/next node already exists, indicating that steps ❶ - ❷ are completed. It is also found that the forward link from the previous to the next node is removed, but the backward link remains intact. This observation suggests that the crash occurred before step ❹ was completed. IntOS can roll forward the operation by executing steps ❹ - ❻.

7.3 Undo-Logging Optimization

The default IntOS transactions automatically perform undo-logging on every first write (after acquiring a mutable reference), as in Listing 1 (Lines 22-23). IntOS introduces another smart pointer type, `Ptr<T>`, providing an option to leverage Rust's type system for the static detection of write-after-read (WAR) dependencies. A transaction utilizing `Ptr<T>` logs an old value only if there is a WAR dependency in the transaction, resulting in fewer logs. Within a transaction, users should dereference a persistent object pointer to obtain a reference. `Ptr<T>` does not provide users with a raw reference and imposes restrictions on the access interface, such as `r.read()` and `r.write()`. Consequently, utilizing `Ptr<T>` involves some additional coding efforts.

8 Discussion

Transactions for Partial vs. Whole System Persistence A crucial distinction between PMDK [7] (`libpmemobj`) and IntOS transactions lies in their persistence guarantees. `libpmemobj` supports "partial" system persistence, only ensuring the recoverability of non-volatile objects within transactions. Thus resuming program execution often requires user-defined custom crash-recovery logic to achieve consistent whole system states including volatile ones. In contrast, IntOS offers "whole" system persistence through the proposed replay-and-bypass mechanism, guaranteeing the recovery of both persistent and volatile states.

Transaction Length To ensure forward progress, IntOS mandates that a transaction must be able to complete with a fully charged capacitor. IntOS handles only one ready, highest-priority thread at a time and employs replay-and-bypass mechanisms to skip committed transactions and system calls, ensuring progress as long as one transaction successfully passes each power cycle. IntOS asks users to ensure this property via profiling. Bounding the size of a program region is a common requirement for many intermittent computing systems (*e.g.,* an idempotent region, a failure atomic section, and a transaction in IntOS) to ensure stagnation-free execution. Consequently, previous solutions including Choi et al. [19] have proposed various dynamic (profiling) and static program analysis techniques considering the worst-case behaviors. IntOS's kernel transactions are intentionally designed to be brief, considering this constraint. Our evaluation (§10) reports the maximum number of cycles per transaction in tested applications is short enough.

Energy-aware Scheduler If hardware provides a capability to monitor the remaining energy in the capacitor, one can design an energy-aware scheduler in IntOS: *e.g.,* not scheduling a thread if it is soon to stop.

Real-time Capabilities IntOS provides real-time capabilities comparable to FreeRTOS as long as the power is on. Yet, IntOS does not provide (hard) real-time guarantees due to the non-deterministic energy nature inherent in intermittent computing, rendering such assurances impossible.

Rust Rust is chosen for static correctness guarantees. Users can use C or other languages, provided they adhere to the programming rules (§6). It is feasible to statically link C programs with the Rust IntOS kernel since the contract/interface between the kernel and a user program is well-defined. Using C would require complex static program analysis to verify adherence to the programming rules. Additional static analysis should be employed for automatic undo-logging.

9 Implementation

We implement IntOS using the Rust programming language, leveraging its strong static type system to uphold IntOS's programming model (§6) with performance comparable to C. The initial implementation of the IntOS kernel mirrors FreeRTOS, having been ported to Rust and extended with transaction and crash consistency support. User threads are also crafted in Rust. Presently, IntOS extends support to two architectures: ARM Cortex-M4 and MSP430. The overall IntOS implementation, excluding testing and benchmark code, encompasses approximately 9900 lines of Rust code. We elaborate on some details below:

Multithreading The INTOS kernel allocates essential data structures, such as the thread control blocks, inter-thread communication objects (*e.g.,* queue, semaphore), and scheduling lists (*e.g.,* ready-list, wait-list) in non-volatile memory. Table 2 (last column) lists some examples.

Replay Tables To support *replay-and-bypass* recovery, INTOS maintains three per-thread replay tables that cache the return values of user-level transactions, kernel-level transactions, and system calls. For each table, the `tail` pointer indicates the last completed transaction or syscall, and the `current` pointer points to the presently executing one. The transaction `tail` pointer contains the commit flag, transaction id, and the pointer to the replay table.

Log Sizes The logged results of system calls generated within a transaction are garbage-collected upon the completion of each transaction, thereby bounding the maximum length of system call logs. Upon the completion of a task, all transaction logs associated with that task can be cleaned. We assume that a task entails a finite number of transactions, which is typically valid given that embedded application tasks often serve as short event handlers. An exception arises with tasks executing transactions within a loop, potentially leading to unbounded logs. This scenario is addressed by the `nv_for_loop!` optimization (§7.1). Transaction result logs from completed (old) loop iterations can be safely discarded, thus capping the transaction log size per loop iteration.

10 Evaluation

We evaluate the performance of INTOS on two platforms: MSP430FR5994 [6] and Apollo 4 Blue Plus [1]. MSP430FR5994 features 256KB of non-volatile FRAM and 8KB of volatile SRAM. We configured its MCU to operate at 16MHz. The Apollo 4 Blue Plus is equipped with an ARM Cortex-M4 processor. It has 384KB of TCM (faster SRAM), 2MB of SRAM, and 2MB of non-volatile MRAM.

The benchmark suite comprises 11 applications. The first group encompasses three single-thread applications (BC, AR, MLP), utilized in previous studies [22,38,49,50,53,56,64,65]. The second group comprises four multithreaded applications (KV, SEN, EM, MQ) designed to evaluate the performance of INTOS's OS features, including locks (semaphores), timers, events, and queues, respectively. The final macro-benchmark group comprises four multithreaded applications (ETL, PRED, STATS, TRAIN), adapted from RIoT-Bench [58]. Table 3 provides the application name, description, the number of threads, transactions, and system calls. The last three columns will be discussed later.

We compare the following four configurations:

- **SRAM (not crash consistent, baseline)**: A vanilla application and INTOS kernel without crash consistency support (*i.e.,* no undo-logging, no replay-and-bypass) operate on volatile SRAM. All the data is in SRAM, while the code is stored on FRAM due to space limitations. In the event of a power outage, both register and SRAM memory states are lost. This configuration serves as the baseline.

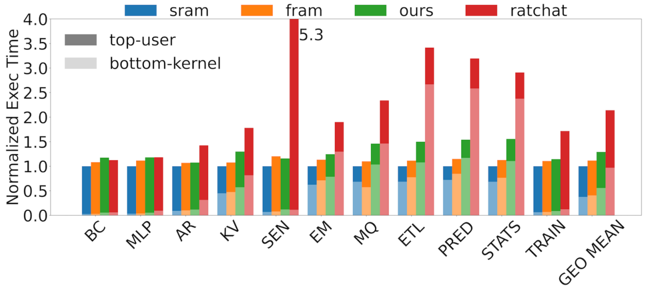

Figure 6: Latency overhead without power failure on MSP430

- **FRAM (not crash consistent)**: A vanilla application and INTOS kernel without crash consistency support (*i.e.,* no undo-logging, no replay-and-bypass) runs on non-volatile FRAM. All data resides in FRAM. Volatile registers remain susceptible to loss. This setup underscores the limitations of not utilizing SRAM and establishes the lower bound for existing compiler-based checkpointing solutions assuming no volatile memory (§3).
- **INTOS (crash consistent)**: This configuration represents our approach using both SRAM and FRAM. It uses INTOS's transaction undo-logging and replay-and-bypass recovery to ensure whole-system crash consistency.
- **Ratchet (crash consistent)**: Ratchet [62] represents a state-of-the-art compiler-based idempotent processing solution that uses non-volatile FRAM only. We used Ratchet compiler to transform a vanilla application and INTOS kernel to idempotent regions — with neither undo-logging nor replay-and-bypass.

It is worth noting that we were unable to compare INTOS with ImmortalThreads [65] due to the incomplete nature of the publicly available code. It offers only the essential logic for micro-continuations and lacks OS/runtime features required by the tested benchmarks (*e.g.,* blocking queues). It was originally evaluated with four simple single-threaded Bitcount (BC), Cuckoo Filter (CF), Activity Recognition (AR), and DNN, which do not involve any application-OS interactions. Thus, conducting a fair comparison becomes impractical without ImmortalThreads' supplementary runtime support. Nonetheless, as discussed in §3, we expect its micro-continuation would suffer from high runtime overhead. For example, ImmortalThreads reports (See [65] Table 4 and Figure 7) that AR incurs 237% overhead with no failure and 300% with 5ms-period power failure. In contrast, we later show that in INTOS, AR experiences 8% and 15% overheads, respectively (See Figure 6 and Figure 8).

App	Description	Threads	TXs	Syscalls	Max Cycles/TX	LoC	Add&Mod
BC	Count the number of 1s in an integer using multiple algorithms	1	8	1	10676	181	32
MLP	Multi-layer perception with two fully connected layers	1	4	2	3488	155	30
AR	Train an activity recognition model and analyze the activities	1	3	3	12060	301	33
KV	Two threads perform concurrent operations on KV Store with locks	2	9	23	6276	325	102
SEN	Periodic Sensing using software timers	2	3	4	6420	107	15
EM	One thread monitors events and notifies other threads with event groups	3	6	12	2592	113	29
MQ	One thread distribute messages to other threads using queues	4	6	13	2532	166	51
ETL	Extract, Transform and Load dataflow in RIoTBench [58] (*e.g.,* range filter, bloom filter, interpolation, join, annotation, kv store)	5	10	23	3580	709	148
PRED	Predictive analysis dataflow in RIoTBench [58] (*e.g.,* average, kalman filter, distinct count, sliding linear reg., kv store)	5	9	26	3808	440	58
STATS	Statistic summerization dataflow in RIoTBench [58] (*e.g.,* decision tree, multivar linear reg., average, error estimation, kv store)	5	11	27	4884	413	46
TRAIN	Model training dataflow in RIoTBench [58] (*e.g.,* multivar linear reg. training, decision tree training)	4	20	28	9472	511	132

Table 3: Description for Benchmarks and Statistics

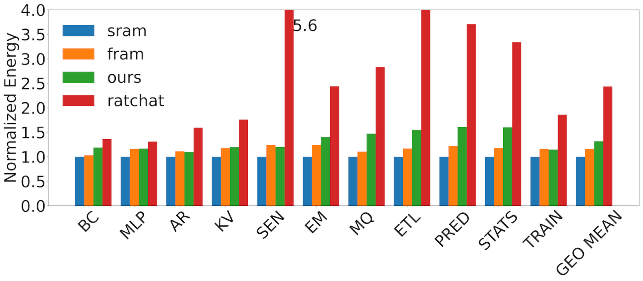

Figure 7: Energy overhead without power failure on MSP430

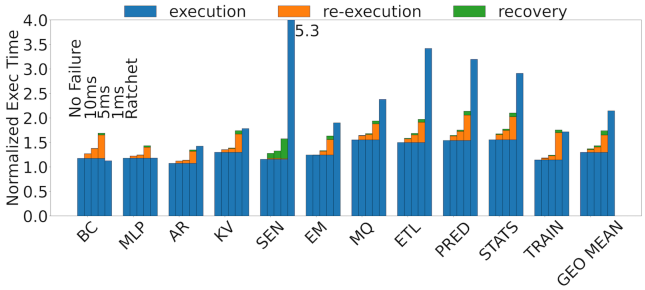

Figure 8: Latency overhead with power failure on MSP430

10.1 Without Power Failures on MSP430

We first measure the performance and energy overhead without power failure on MSP430FR5994.

Figure 6 illustrates the latency overhead of four configurations, normalized to the SRAM baseline. Each bar provides a breakdown between user-level (top, solid color) and kernel-level (bottom, light color) execution times. On a geometric mean, FRAM (the second bar) shows 1.11x latency overhead compared to SRAM. This highlights the performance loss when SRAM is not utilized, as in existing compiler-based checkpointing solutions. This serves as the lower bound for the latency overhead imposed by such tools. Specifically, Ratchet (the last bar) incurs a latency overhead ranging from 1.12x to 5.30x, with a geometric mean of 2.14x. Ratchet's performance is highly dependent on the precision of static analysis and application characteristics.

Contrastingly, INTOS (the third bar) demonstrates substantially lower latency overhead, ranging from 1.07x to 1.55x, with a geometric mean of 1.29x. This showcases the advantages of placing the stack and performing computations on local variables in SRAM while storing persistent objects in FRAM. Notably, for AR, SEN, and TRAIN, INTOS demonstrates comparable or superior performance to FRAM, even considering INTOS's transaction logging overhead.

Regarding the breakdown between user and kernel levels, simple single-thread BC, MLP, and AR predominantly operate in the user level, while multi-threaded RIoTBench's ETL, PRED, STATS, and TRAIN frequently utilize system calls for queues, mutexes, etc. The SEN application conducts periodic sensing using software timers. It displays a small kernel (syscall) time, as the kernel's timer handler indeed runs as a thread and is thus counted as user time.

Figure 7 illustrates the energy overhead of four configurations, normalized to the SRAM-only baseline. We measured the energy consumption for MSP430FR5994 using TI's EnergyTrace tool [11]. The observed trend aligns generally with the latency overhead discussed earlier. The FRAM setting incurs 1.16x (geometric mean) more energy consumption compared to the SRAM setting. The energy consumption gap between INTOS and Ratchet widens, with INTOS consuming 1.31x more energy on a geometric mean relative to the baseline, while Ratchet consumes 2.43x more energy. Notably, across various applications, including MLP, AR, KV, SEN, and TRAIN, INTOS exhibits comparable or superior performance to the FRAM-only setup, even when factoring in INTOS's transaction overhead.

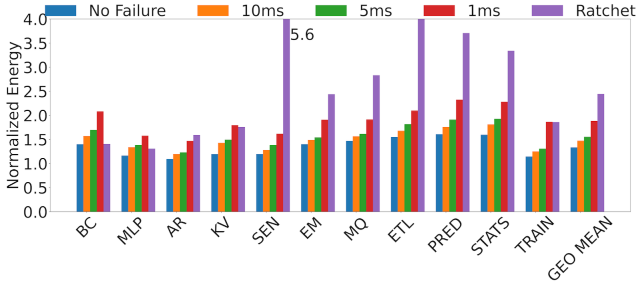

Figure 9: Energy overhead with power failure on MSP430

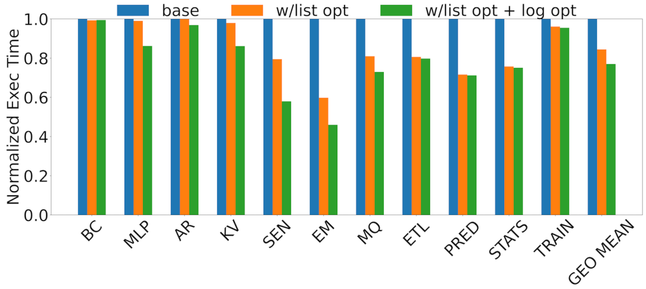

Figure 10: Latency with/without optimizations on MSP430

10.2 With Power Failures on MSP430

In this section, we investigate the latency and energy overhead of INTOS and Ratchet under frequent power failures. We inject controlled power failure at regular intervals of 10ms, 5ms, and 1ms using a soft reset, following the methodology employed in previous works [37,38,49,62,64,65]. Intermittent computing devices continue operation until the energy stored in the capacitor is depleted, subsequently restarting after the capacitor is fully recharged. In cases where the capacitor can recharge during the run, it results in extended run time for the power cycle. Employing a regular power failure interval represents the worst-case scenario, where the capacitor cannot be effectively charged during execution.

To determine and justify the power failure interval, we ran our benchmarks and used EnergyTrace to measure the average power consumption of MSP430FR5994 and the number of MCU cycles spent for each time interval. We considered the maximum power consumption (among applications) and calculated the corresponding capacitor size under a 3V voltage. To sustain continuous operation for 1ms, where MSP430 MCU can run for about 16,000 cycles, the capacitor size required is approximately 4 µF, which is ten times smaller than a typical capacitor size (*e.g.,* WISP [57] utilizes 47 µF). Thus, the 1ms interval represents an extreme case.

INTOS requires each transaction to be completed with a fully charged capacitor to guarantee forward progress. The third last column in Table 3 displays the maximum number of cycles per user transaction in tested applications, indicating that an application can be implemented with a (relatively) short transaction. Should a longer transaction be desired, INTOS might necessitate a larger capacitor.

Figure 8 depicts the latency overhead under power failures on MSP430. Moving from left to right, the bars represent the latency overhead of INTOS in a no-failure scenario, with failure intervals of 10ms, 5ms, 1ms, and Ratchet – all of which are normalized to the SRAM setting (baseline). Note that as an idempotent processing solution, Ratchet exhibits negligible latency difference between with and without power failures. Across different applications, we observed 30-900 power outages with the 1ms failure interval, and 3-60 power failures with the 10ms interval. As anticipated, the latency overhead of INTOS increases with the frequency of power failures. On a geometric mean, INTOS exhibits latency overheads of 1.37x, 1.43x, and 1.73x for 10ms, 5ms, and 1ms intervals, respectively. INTOS's recovery mechanism involves restoring volatile states (while bypassing numerous committed transactions and system calls), making its latency sensitive to the failure frequency. However, for the 10ms, 5ms, and even in the extreme 1ms failure intervals, INTOS demonstrates significantly better performance than Ratchet, particularly when considering realistic complex applications like RIoTBench's ETL, PRED, and STATS, while excluding trivial single-thread applications like BC and MLP.

The figure also provides a breakdown of the latency overhead between re-execution (orange bar) and recovery (green bar). Re-execution overhead involves rerunning an interrupted program region, representing wasted computation, while bypassing committed transactions and system calls. Recovery overhead is incurred by applying undo logging to roll back a failed transaction and executing other basic recovery checking codes. The results indicate that INTOS's latency overhead is predominantly attributed to re-execution overhead. SEN is unique in that it uses software timers, so in most cases, it has no task to run but simply checks for recovery.

Figure 9 illustrates the energy overhead under the same power failure experiments on MSP430. The energy overhead follows a similar trend as the latency overhead. INTOS consistently demonstrates a lower energy profile than Ratchet across all failure intervals, especially when considering realistic applications ETL, PRED, and STATS. On a geometric mean, INTOS exhibits energy overheads of 1.47x, 1.55x, and 1.88x for 10ms, 5ms, and 1ms intervals, respectively. In comparison, Ratchet incurs an energy overhead of 2.43x.

10.3 Optimization Effectiveness on MSP430

This section investigated the impact of linked list optimization (§7.2) and undo logging optimization (§7.3). Each optimization was individually enabled, and the execution time was measured. The results, normalized to INTOS with no optimizations (the first bar), are presented in Figure 10. The second bar illustrates the outcomes with only the list optimization enabled, while the last bar represents the results with both

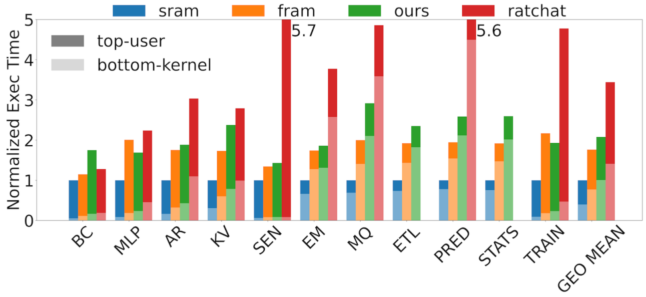

Figure 11: Latency without power failures on Apollo 4

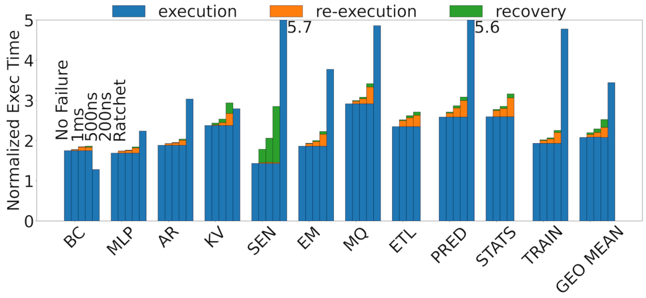

Figure 12: Latency with power failures on Apollo 4

optimizations in use. For applications with frequent system call usage, the list optimization significantly enhances performance, with improvements exceeding 40%. However, for simpler single-thread BC, MLP, and AR, which only utilize memory allocation syscalls, there was marginal improvement. The effectiveness of the undo-logging optimization is highly dependent on application characteristics. MLP, KV, SEN, EM, and MQ have a small fraction of stores with write-after-read dependencies. Thus the undo logging optimization demonstrates substantial improvements.

10.4 Experiments with Apollo 4

Now, we transition our experiment to the Apollo 4 Blue Plus, equipped with an ARM Cortex-M4 MCU, 384KB of TCM (faster SRAM), 2MB of SRAM, and 2MB of non-volatile MRAM. However, it is important to acknowledge that the MRAM in Apollo is presently only byte-readable and not byte-writable. To overcome this constraint, we simulate the execution environment by utilizing (fast) TCM as volatile memory and designating the (slow) SRAM as non-volatile memory. In our experiment, the SRAM is approximately 2-3 times slower than TCM for sequential access, which is bigger than the FRAM-SRAM gap in MSP430. The (simulated) Apollo 4 experiment has two purposes. First, it demonstrates that INTOS can support different MCU architectures: MSP430 and ARM Cortex-M4. Second, it illustrates a scenario in which the latency disparity between volatile and non-volatile memories is more pronounced. The board does not have an on-board debugger probe that allows us to measure the energy, so this experiment focuses on latency comparison.

Figure 11 shows the latency overhead of Apollo 4 Blus Plus without a power failure, normalized to the TCM-only baseline. The ETL and STATS bars are missing for Ratchet because the programs instrumented by Ratchet crashes. With the higher gap between volatile and non-volatile memories (simulated by TCM and SRAM), the result shows higher latency overheads than the MSP430 experiments (Figure 6). INTOS and Ratchet incur 2.07x and 3.44x latency overhead, respectively, where Ratchet is more penalized by slow non-volatile memory.

Figure 12 shows the latency overhead when considering power failure intervals of 1ms, 500ns, and 200 ns. The intervals are set to be much smaller than those of MSP430 as ARM Cortex-M4 in Apollo 4 runs at a much higher clock frequency. 200 ns allows around 19,000 cycle executions. The trend again remains the same. Even in the extreme case of 200 ns failure interval, INTOS incurs 2.52x latency overhead (compared to SRAM). INTOS is 1.37x less than Ratchet.

10.5 INTOS Programming Overhead

The INTOS programming model asks users to allocate persistent objects in NVM and define transactions to ensure crash consistency of updates on persistent objects. Quantifying programming overhead is challenging, but as a proxy, Table 3 presents the lines of source code (LOC) for each application and the added/modified LOC for persistent object allocation and transaction codes. Examining four realistic RIoTBench applications, the table reveals that the extent of modification varies from 11% (STATS: 46/413) to 26% (TRAIN: 132/511) of the source code. Although these percentages may seem large, it is important to note that these changes pertain to persistent object allocation and transaction codes, aspects that we believe are well-understood and manageable.

11 Conclusion

INTOS is a persistent embedded OS and language support for multi-threaded intermittent computing. INTOS uses transactions to ensure the crash consistency of non-volatile objects. Instead of checkpointing volatile states, INTOS proposes a replay-and-bypass recovery mechanism, reconstructing volatile states without re-executing committed transactions and system calls. Evaluation with MSP430FR and Apollo 4 shows that INTOS exhibits lower latency and energy costs compared to compiler-based idempotent processing.

A Artifact Appendix

Abstract

IntOS is an intermittent multithreaded embedded RTOS based on FreeRTOS for research. It features transactions with replay and bypasses to enable cheap crash consistency. The kernel and user applications are all written in the Rust programming language. The Rust type system is used to enforce safe programming rules defined by the framework to guarantee crash consistency and Persistent Memory safety. Currently, we support three platforms: QEMU, Apollo 4 Blue Plus, MSP430FR5994.

Scope

This artifact contains code to build the crash-safe INTOS kernel and benchmark/user app to run on intermittent computing platforms(e.g. MSP430FR5994). Users can use the artifact to reproduce the results in the paper. For evaluation of functionality, please just follow the instructions for QEMU. This artifact is for research purposes only.

Contents

The artifact contains Rust written kernel, user library code, and the benchmarks used in the paper. The general kernel code is under the `src/` directory. The user library is in `src/user`. Benchmarking code is under `src/benchmarks`. Platform/Architecture-related code is in `src/arch` and `src/board` directory. A simple demo app is hosted under `src/app`.

Hosting

The artifact is hosted in https://github.com/yiluwusbu/IntOS. The branch is master and the commit version is a916c16

Requirements

The OS we use is Ubuntu 22.04. For evaluating the functionality and debugging, QEMU(for ARM) is sufficient. For evaluating the performance, you need to get the MSP430FR5994 or Apollo 4 Blue Plus development board.

Run with Docker

We provide a docker image for users to run the system with QEMU. If you use docker, please skip the dependency/-toolchain installation sections. To build the docker image, run:

```
docker build -t rtosdev .
```

Then, run the docker:

```
docker run -v $(pwd):/repo -it rtosdev bash
```

Install System Dependency

```
sudo apt install curl wget p7zip-full
libncurses5 libncursesw5 build-essential
qemu-system-arm
```

Install Rust Toolchain

```
curl --proto '=https' -tlsv1.2 -sSf
https://sh.rustup.rs | sh -s -- -y
```

Set the compiler version:

```
rustup toolchain add nightly-2022-04-01
```

Install MSP430 Toolchain

Download and install the msp430-gcc toolchain from TI's website. For detailed commands, see README.md in the github repo.

Install ARM Toolchain

Install JLink flasher/debugger and the ARM gcc toolchains:

1. Download the Segger JLink tools (v7.92) on your platform from their website

2. Download ARM (arm-none-eabi) toolchain (version 12.3.Rel1) from the official ARM website

Compile INTOS

You can compile the OS and benchmarks/example applications using the provided Python script:

```
./compile.py --board [qemu|apollo4bp|msp430fr5994]
--bench [app name] [--run (for qemu)]
```

Example:

```
./compile.py --board qemu --bench bc --run
```

Configuration Parameters

To list all the available benchmarks and custom compilation flags, you can run:

```
./compile.py -h
```

Table 3 describes the benchmarks we use in this work. To enable timer daemon, you can pass `--timer_daemon`

Power Failure Injection

To inject soft power failure to the system at a given frequency, you can use the following command:

```
./compile.py --board [board name] --bench [app
name] --fail --pf_freq [frequency: e.g. 1ms]
[--run (for qemu)]
```

Example:

```
./compile.py --board qemu --bench bc --fail
--pf_freq 1ms --run
```

Run Demo App

We give a simple example of two tasks communicating using a Queue (i.e. IPC). The full code can be found in the `app/demo.rs` file.

To run the demo:

```
./compile.py --board qemu --app demo --run
```

Flash and Run App on MSP430FR5994

You can install the TI's Uniflash or CCSTUDIO IDE to flash the application binary (located under target/msp430-none-elf/release/) onto the board.

The application/OS will print debug/perf related information through the UART interface to the host machine. The default Baud Rate is 115200. To view the printed message, you can use any Serial Monitor tools to view the printed message. For example, on Linux/Win, you can install the Serial Monitor Plugin. Termite is another handy tool you can use.

Flash and Run App on Apollo4 Blue Plus

Use GDB and JLink to load and run the application.

1. In one terminal, run `JLinkGDBServer -if SWD -device AMA4B2KP-KXR`

2. In another terminal run `arm-none-eabi-gdb -x apollo.gdb <path/to/binary>`

After the binary is loaded onto the board, enter ’c’ to run. The application will print message to the gdb interface and port 2333 (TCP/IP) .

Data-flow Availability: Achieving Timing Assurance on Autonomous Systems

Ao Li Ning Zhang
Washington University in St. Louis

Abstract

Due to the continuous interaction with the physical world, autonomous cyber-physical systems (CPS) require both functional and temporal correctness. Despite recent advances in the theoretical foundation of real-time computing, leveraging these results efficiently in modern CPS platforms often requires domain expertise, and presents non-trivial challenges to many developers.

To understand the practical challenges in building real-time software, we conducted a survey of 189 software issues from 7 representative CPS open-source projects. Through this exercise, we found that most bugs are due to misalignment in time between cyber and physical states. This inspires us to abstract three key temporal properties: freshness, consistency, and stability. Using a newly developed concept, Data-flow Availability (DFA), which aims to capture temporal/availability expectation of data flow, we show how these essential properties can be represented as timing constraints on data flows. To realize the timing assurance from DFA, we designed and implemented Kairos, which automatically detects and mitigates timing constraint violations. To detect violations, Kairos translates the policy definition from the API-based annotations into run-time program instrumentation. To mitigate the violations, it provides an infrastructure to bridge semantic gaps between schedulers at different abstraction layers to allow for coordinated efforts. End-to-end evaluation on three real-world CPS platforms shows that Kairos improves timing predictability and safety while introducing a minimal 2.8% run-time overhead.

1 Introduction

Recent advances in artificial intelligence and robotics have promoted the integration of various autonomous cyber-physical systems into society, including self-driving cars [94], drones [31], and home-service robots [32]. Unlike conventional systems, CPS has to sense the physical world, compute for the appropriate control actions, and actuate on the physical world in a timely manner. Therefore, the assurance of temporal properties in autonomous CPS is fundamental to the correctness of the system.

System Challenges in Real-time Cyber-physical Systems. Recognizing its importance, the real-time systems community has devoted significant effort to ensuring the timeliness of computation. However, despite the rich literature on the theoretical foundation of real-time computing, such as schedulability analysis [70], mixed-criticality scheduling [43], and compositional scheduling [51, 83], leveraging these results in the development of CPS software remains quite challenging for non-experts. Furthermore, recent advances in multi-core execution and multi-modal sensing also make the problem challenging even for experts, with plenty of open research questions that are actively being investigated [66, 70]. A recent industrial survey [29] (Question 23) also indicates that only a small fraction (9.38%) of systems are designed with commercial schedulability analysis tools.

Understanding Timing Problems in Real-world CPS. To gain a better understanding of system challenges in CPS, we draw inspiration from the recent survey on concurrency bugs [64, 67], and conducted a systematic study of the 189 timing bugs in 7 mainstream open-source CPS software projects. Our goal is to understand the categories of timing bugs in CPS applications, the root causes of each bug category, as well as the challenges developers face in preventing them. We found that most of the timing bugs are caused by misalignment in time between cyber states and physical states. Therefore, building on top of the cyber-physical control loop abstraction, we extracted three most essential temporal properties: freshness, consistency, and stability. Furthermore, we found that many existing mitigations implemented manual checks for data timestamps, inspiring us to model the problem from a data-flow perspective.

Our solution - Data-flow Availability. Motivated by the findings from the timing bug study, we propose Data-flow Availability, a new concept that achieves timing assurance in autonomous systems. Building on the observation that data flow drives cyber-physical control loops in modern CPS, we

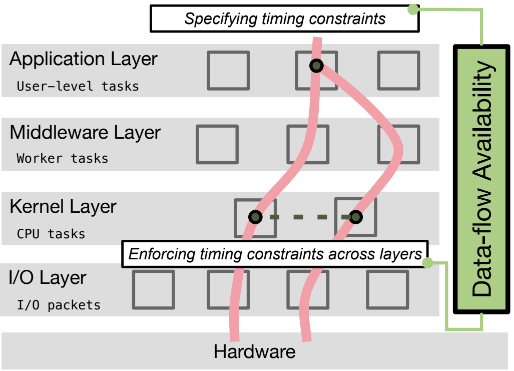

Figure 1: Data-flow Availability in the system stack.

augment data flow with a new temporal dimension, resulting in *Timed Data-flow Graph* (TDFG). Conceptually, each variable (that captures cyber or physical state) would have a time attribute (tag), and information flow among them has to respect the expectation of the software. Therefore, temporal policy is encoded as timing constraints on the edges of the graph.

To realize the concept of data-flow availability in system, we design and develop Kairos, a programming model to enable the automatic detection and mitigation of timing constraint violations. Kairos consists of a DFA-embedding tool for detection of timing constraint violation at run-time and a cross-layer scheduling system for mitigation (as shown in Figure 1). Using the DFA-embedding tool, developers can either manually annotate the source code with APIs provided by Kairos or use the provided dynamic profiler to specify the expected temporal properties. A compiler extension then takes the temporal expectation, expressed as data-flow constraints, and automatically instruments the software to detect timing constraint violations at run-time. However, detection alone does not provide timing assurance. Upon timing constraint violations, actions have to be taken to recover the system. To do so, Kairos builds on the concept of schedulable entity path to construct an association of schedulable entities in different abstraction layers of the operating system for a cyber-physical data flow. This bridges the semantic gap between the abstraction layers, and allows for more effective coordination of schedulers in the system for violation mitigation.

Prototype and Evaluation. To understand the effectiveness of DFA in mitigating the timing bugs, we analytically studied how existing bug fixes can be implemented using Kairos, and found that among the 189 bugs, 111 of them can be mitigated by Kairos. To understand the performance characteristics of Kairos, we built a prototype of Kairos, and evaluated it on three real-world robotic platforms: Autoware [36], Jackal UGV [59], and Turtlebot3 [89], each with distinct workloads and computing power requirements. On these three platforms, we show how TDFG can be constructed and used in Kairos to mitigate the existing timing issues. At runtime, Kairos introduces an average overhead of 2.8% and shows manageable performance under scalability analysis. Under high system overload, Kairos shows a faster and more stable response time in reacting to timing violations compared to other state-of-the-art systems – ROS [80], ERDOS [55], and ghOSt [57]. Furthermore, the end-to-end evaluation shows that Kairos can improve safety under high system overload.

Contributions. We make the following contributions [1]:

- Formulation of Data-flow Availability, a new concept for achieving timing assurance from a data-flow perspective.
- Design and implementation of Kairos, a proof-of-concept realization of DFA. Kairos detects timing violations by embedding a temporal property monitor within the application and mitigates these violations through a cross-layer scheduling infrastructure.
- Evaluation of DFA and Kairos across three real-world robotic platforms, each with distinct workloads and operational domains.

2 Background

Real-time Cyber-physical Systems. A unique characteristic of autonomous cyber-physical systems is their tight connection to physical world processes. Cyber-physical systems software often builds on top of the abstraction of a cyber-physical control loop, which continuously senses the physical world, calculates the appropriate control actions, and then actuates on the system to reach the desired state. The implementation of this control loop is often realized using multiple tasks (processes), where each is modeled as either periodic or sporadic tasks in the real-time models.

Timeliness Abstraction in Cyber-physical Systems. Due to their cyber-physical nature, the correctness of autonomous systems depends on both functional correctness and temporal correctness. To achieve this, real-time schedulability analysis [77] is conducted on each system based on the real-time task models. Meeting deadlines is often considered the most important requirement in real-time systems. Using the task parameters from the schedulability analysis, the scheduler of the system enforces temporal isolation among the tasks, ensuring no task misses its deadline. Based on the ability to tolerate deadline misses, systems can be hard, firm, or soft real-time. Due to various practical challenges, such as difficulty in determining a real-time task model, the efficiency of the processor to achieve system guarantees, and accurate estimation of worst case execution time, many deployed real-time systems are soft real-time systems, according to a recent

[1] The source code, as well as the extended version of this work with additional analysis and experiments is available at https://dataflow-availability.github.io/.

industry survey [29]. Furthermore, timing constraints can manifest in properties other than deadline misses, including but not limited to task response time, execution time, release jitter, and response jitter.

Timeliness Implementation in Cyber-physical Systems. Modern autonomous systems generally involve multiple abstraction layers, as shown in Figure 1. Besides the typical userspace and kernel-space layers, modern CPS software also utilizes middleware, such as the robotic operating system (ROS) [68, 80] to ease programming. Some CPS software even implements their own userspace scheduler within the application, resulting in time management across multiple layers of abstractions. This presents unique challenges for developers in achieving alignment of cyber events with physical world events. Furthermore, there is often a combination of time-driven [33] or event-driven [80] tasks.

3 Real-world Timing Bug Study

Motivation. Real-time theory suggests modeling individual computations as individual tasks. However, developing a real-time task model for modern complex data-driven CPS can be quite challenging for non-experts. Further, the formulation of highly efficient task models often requires deep domain expertise in real-time scheduling. A recent industrial survey [29] (Question 23) also indicates that only a small fraction (9.38%) of systems are designed with commercial schedulability analysis tools. Inspired by existing studies on concurrency bugs [64, 67] that had offered key insights to the community, we conducted a systematic study of timing bugs in 7 open-source robotic software. The goal is to gain a better understanding of the underlying practical challenge faced by developers. As such, the focus of the study is on *timing bugs*, where the bug is caused by non-deterministic timing of data flow within the cyber-physical system.

Methodology. The seven selected open-source GitHub robotic software projects are Autoware [53], MoveIt [2], Google Cartographer [56], Baidu Apollo [37], ORB-SLAM2/3 [3, 4], ROS Navigation [5], and ROS2 rcl [7]. These projects were selected because they represent important subsystems in modern cyber-physical control loops, including perception, localization, planning, and control. Furthermore, they have also been widely adopted [1, 35, 52, 75]. To collect the bugs, a set of keywords (e.g., 'timing', 'sched', 'timestamp', 'temporal', etc.) was used to filter the issues, resulting in a list of 189 bugs.

Summary of Systemization. As shown in Table 1, we find that two categories of root causes account for the majority (169 out of 189) of the collected timing bugs: insufficient specification and enforcement of timing constraints. The rest are design flaws and hardware problems.

Table 1: Timing Bugs in Real-world Applications

Projects	# bugs	Timing Constraint Specification			Timing Constraint Enforcement		Others
		Missing Constraint	False Specification		Missing Constraint	False Enforcement	
			Expressibility	Parameter			
Cartographer [47]	34	14	12	1	1	4	2
Apollo [37]	49	11	23	2	3	0	10
MoveIt [2]	23	4	7	2	2	5	3
ORB-SLAM [4]	6	1	1	0	1	2	1
Autoware [53]	16	6	5	0	1	0	4
Navigation [5]	15	3	3	1	2	4	2
ROS rcl [7]	46	3	3	1	3	35	1
Total	189	42	54	7	13	50	23
Scope of This Work		✓	✓	✓	✓		

3.1 Timing Specification Bugs

The most common cause of timing assurance failure is incorrect specification of timing constraints (103/189 bugs). As discussed earlier, though real-time theory provides a sound foundation for assuring timing behavior, there remains a gap in transitioning the theory into practice for developers without expertise in real-time computing. Without the formal guarantees provided by real-time theory tools (such as schedulability analysis), current practice adopted by developers to mitigate this involves developers tagging data with timestamps when data is created or transferred, and then using these timestamps to check the data's validity (e.g., freshness) when it is used. This data-centric approach to timestamp checking for specifying timing constraints is ubiquitous in the codebases we investigated. For example, Autoware and Google Cartographer use timestamp checks in over 340 and 110 places, respectively, to determine the execution logic. Additionally, state-of-the-art middleware such as ROS [80], ROS2 [68], and ERDOS [55] also incorporate built-in timestamps on data transferred between tasks.

3.1.1 Missing Time Constraints (What to Check)

Figuring out where and how to add the timestamp checks manually is quite challenging due to the complex dependency among data from different tasks [8, 12, 14, 17, 19–21, 23, 50, 54]. Naively, one can simply add timing checks on all instructions. However, that will introduce prohibitive overhead to the system, leading to adverse physical outcomes.

Implication - It is essential to understand not only which program statements need to be checked but also which aspects of temporal properties should be verified, in order to minimize the performance impact of the protection.

To further dive into the root cause of the problem in a principled approach, we went back to the basic abstraction of a cyber-physical control loop to ask the question of what properties are these timing bugs violating. Through the lens of physical world impact, three key properties arise during the analysis of the timing violations.

Freshness - *describes the latency between the occurrence of a physical phenomenon and the consumption of its cyber rep-*

resentation. While data should be as fresh as possible, there will always be some delay due to sensing and computation.

The key is to ensure that the freshness of the particular data is acceptable by the control implementation. Figure 2 shows an example from Cartographer-Pull-153. Cartographer [47] uses a queue to manage and process sensor data streams from multiple sources in a coordinated, time-ordered manner. It then uses the data to construct a robot's trajectory for localization. The code snippet checks if the incoming data is older than the start time of the current trajectory and discards the outdated data if it is.

```
void OrderedMultiQueue::Dispatch() {
  // We take a peek at the time after next data. If it
  // is not beyond 'common_start_time' we drop it
  std::unique_ptr<Data> next_data = next_q->queue.Pop();
  if (next_q->queue.Peek()->time > common_start_time) {
    last_dispatched_time_ = next_data->time;
    next->callback(std::move(next_data));
  }
  // else: drop the data
```

Figure 2: Freshness check where outdated data is dropped. Simplified code snippet from Cartographer-Pull-153.

Consistency - *describes the temporal alignment of the physical world observations in the data flows converging at a specific statement of the program. Ideally, the physical events captured by these cyber states should be as synchronized as possible.*

Figure 3 shows an example from ROS Navigation [5] (Navigation-Pull-1121), where the control task retrieves the robot pose using the tf_ buffer, which maintains historical poses. In the original code (highlighted in red in line 1), it directly uses the latest pose. However, since the tf_ buffer is dynamically updated by other tasks, the timestamp of the current map used by the control task (time) might be older than the latest pose in tf_. This could result in using a pose that is ahead of the current map in time, causing motion planning to produce incorrect paths. To fix this, the code highlighted in green (in line 3) adopts a timestamp-based check that compares the timestamp of tf_ with the control task's timestamp. If time is not newer than the latest in tf_, the lookupTransform() function is called to interpolate the pose that temporally aligns with the current map.

```
 1 tf_.transform(robot_pose, global_pose, global_frame);
 2  // check if curr_time is less than latest update time of tf_
 3 if (tf_.canTransform(global_frame, robot_base_frame, curr_time)) {
 4   // if so, transfomr at the time point of curr_time
 5   transform = tf_.lookupTransform(global_frame,
 6                                   robot_base_frame,
 7                                   current_time);
 8   tf2::doTransform(robot_pose, global_pose, transform);
 9 } else {
10   // use the latest otherwise
11   tf_.transform(robot_pose, global_pose, global_frame_);
12 }
```

Figure 3: Consistency check detecting temporal alignment between the data from two tasks (Navigation-Pull-1121).

Stability - *describes the variation in freshness. This is similar to the concept of jitter in the real-time and control domains, and ideally jitter should be minimized.*

Many control algorithms and systems are designed to have an implicit assumption of not only the boundary of the freshness but also its variation (often relatively small) from loop to loop. In essence, it is about the consistency of data flow in the temporal dimension, as compared to the spatial dimension (consistency as discussed above). Figure 4 shows a code snippet from AutowareAuto-Pull-980, where a timer is added to ensure the stability of control output. The timer checks the elapsed time in a polling loop to trigger the control output function at expected intervals.

```
NERaptorInterface::NERaptorInterface(. . .){
  /* Use a ROS timer to ensure the stability */
  m_timer = node.create_wall_timer(m_pub_period,
                                   std::bind(&cmdCallback, this));
 }

/* In implementation of ROS timer */
while (rclcpp::ok()) {
// Use elasped time to check if timer is ready via a polling loop
  rcl_timer_get_time_until_next_call(m_timer, &time_until_next_call);
  if (time_until_next_call <= 0)    m_timer->call();
}
```

Figure 4: Stability check using a ROS timer to minimize control jitters (AutowareAuto-Pull-980).

Summary - These three key properties present a unique opportunity to address a large number of bugs with a small amount of temporal property checks.

3.1.2 Inadequate Timing Constraints (How to Check)

Even after solving the challenge of what to check, developers also have to tackle the challenge of how to check. There are 61 bugs caused by inadequate specification of timing constraints; among these, we found two common causes. The first category is that some of the hard-coded time constraints may not be appropriate for the deployment. This often happens due to insufficient testing or changing software/hardware [11] or operating environment [55] of the system. The second category is less straightforward. In real-time cyber-physical systems, there are other essential timing dimensions beyond latency (maps to freshness discussed earlier), such as alignment (maps to consistency discussed earlier) and jitter (maps to stability discussed earlier). For examples, issues can arise on arrival jitter [10], detection of data loss [24], processing data time ratios [13, 27], and requests of development of timing utilities [9, 16]. Figure 5 shows a simplified bug example from Google Cartographer [47] (Cartographer-Issue-242) that spans multiple patches before being finally fixed. The code snippet estimates the robot's velocity by dividing the difference in positions between two adjacent frames by the time interval. In this case, the freshness of data is a problem because if the incoming LiDAR frame is older than the latest one (i.e., out-of-order), it causes the time difference (delta_t) to be negative. The freshness check was added in patch [79] (highlighted in yellow on line 3 of the figure). However, another problem beyond data freshness persists even if delta_t is positive. The irregular timing may result in two LiDAR frames being too close in time, causing delta_t to be too short. In such cases, the position difference is divided by a very small `delta_t` value, which can significantly magnify any estimation errors, potentially causing the velocity to become infinitely large. This issue is finally fixed by inserting a check (on line 8) that the frames with intervals less than 1 ms are dropped.

```
 1 // Estimate the velocity estimate.
 2 if (time >  common::Time::min()
 3     && time > last_scan_match_time) {
 4
 5   // Prevent out-of-order data
 6   double delta_t = common::ToSeconds(time - last_scan_match_time);
 7
 8   if (delta_t < 1e-6) return;
 9   // Prevent too short intervals
10   velocity_estimate_ += (pose_estimate_.translation() -
11                          model_prediction.translation()) /
12                          delta_t;
13 }
```

Figure 5: Timestamp checking is incomplete in semantic.

Implication - Given the dynamic range of timing expectations in different platforms and physical environments, it is important to develop a mechanism that simplifies the configuration of these ranges for developers. Ideally, this mechanism should also enable the automatic discovery of the necessary ranges to maintain system safety.

3.2 Timing Enforcement Bugs

There are 62 bugs stemming from inadequate enforcement of timing constraints. Most of these (50/62) are due to conventional software bugs, such as memory corruption in the enforcement infrastructure with schedulers and timers. Another 13 of these bugs are caused by timing constraints not being delivered to the enforcement mechanisms. These are primarily caused by the fact that the specified timing constraints are limited to userspace applications and are not propagated to other scheduling layers. Figure 1 schematically illustrates the scheduling layers involved in designing and deploying autonomous systems. Due to the inadequate support for delivering scheduling contexts across schedulers, timing constraints (or scheduling decisions) specified at one scheduler fail to propagate to others. This type of problem can be observed in issues where priorities are inverted across layers [22], leading to critical tasks not being reliably triggered [26], executing at varying periods [25], or executing out of order [15]. As a result, mitigation methods to maintain relative priority at the user level or middleware alone are often quite challenging if not impossible.

```
void SchedulerChoreography::CreateProcessor() {
  proc->BindContext(ctx);
  /* Reserve a set of CPU cores for the tasks */
  SetSchedAffinity(proc->Thread(), pool_cpuset_, pool_affinity_, i);
  SetSchedPolicy(proc->Thread(), pool_processor_policy_,
                 pool_processor_prio_, proc->Tid());
}
```

Figure 6: Mitigating disconnection across scheduling layers.

Figure 6 is the mechanism adopted to handle Apollo-Issue-9433. It introduces a new scheduling strategy that reserves a set of CPU cores for middleware tasks, allowing them to be directly scheduled on these cores and avoiding disconnection between layers. However, implementing this scheduling strategy necessitates a thorough understanding of the tasks, including their dependencies and execution times.

Implication - Assurance of timing expectations is more effective when scheduling contexts are visible across all layers of abstraction.

3.3 Summary

Table 1 shows the timing bugs we studied, and the scope of the proposed mechanism DFA. Based on the study, we summarize the opportunities and insights that inform the design of DFA:

- Timing expectations are often added by programmers by checking the age of data, hinting at the potential to use information(data)-flow as a mechanism to capture the programmer's intention.
- There are three types of key temporal properties we systematized based on the cyber-physical control loop abstraction, freshness, consistency, and stability.
- Timing enforcement would often benefit from visibility across different layers of abstractions in the OS.

4 Data-flow Availability

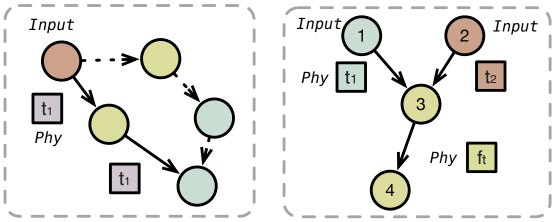
Motivated by the challenges in Section 3, this paper introduces ***Data-Flow Availability*** (DFA), which approaches the policy definition of temporal property from a data-flow perspective.

4.1 Timed Data-flow Graph

A *Timed Data-flow Graph* (TDFG) is a representation of a DFA-enabled program, extended from the program's data-flow graph.

Graph Definition. TDFG is a directed graph $\mathbf{G} = (\mathbf{V}, \mathbf{E}, \mathbf{T}, \mathbf{C})$ constructed from program's intermediate representation:

- *Vertex:* Each vertex v in the set $\mathbf{V}$ corresponds to a statement in the intermediate representation.
- *Edge:* Edges $\mathbf{E} \subseteq \mathbf{V} \times \mathbf{V}$ represent data dependencies between vertices. An edge is added if the corresponding statements have a data dependency.
- *Timing Tag:* A timestamp $t_{phy} \subseteq \mathbf{T}$ is generated with `def` of memory SSA (Static Single Assignment) in the graph and propagated along edges at runtime. It includes two types of timing, either the physical world sensor reading or the range of a derived value from the timed sensor values.



(a) Sequential propagation. (b) Merge from different inputs.

Figure 7: Two cases of timing propagation in data flows.

```
void EvaluatorManager::DumpCurrentFrameEnv() {
  FrameEnv curr_frame;
  auto obstacles = ContainerManager()->Get(PERCEPTION_OBSTACLES);
  curr_frame.set_timestamp(obstacles->timestamp());
}

(a) The timestamp propagates on a single data flow (Apollo-Pull-8503).

```
bool Fusion::GenerateMsg(Obstacles* obstacles) {
  common::Header * header;
  header->set_lidar_stamp(lidar_timestamp * 1e9);
  header->set_camera_stamp(camera_timestamp * 1e9);
  header->set_radar_stamp(radar_timestamp * 1e9);
 /* Processing */
```

(b) The timestamps of multiple data flows merge (Apollo-Pull-5459).

Figure 8: Code examples for timing propagation in data flows.

- *Timing Constraints:* The edges can be assigned timing constraints $C \in \mathbf{C}$. These constraints define the temporal properties that the edge is expected to meet within specified tolerance thresholds. The constraints are evaluated upon information flow. These temporal properties are defined by DFA's metrics, which are detailed in Section 4.2. Note that some of the temporal properties require analyzing the statistics of data flows into a vertex over time/iterations.

Timing Information Propagation. Timing tags can be propagated along edges E at runtime. There are two forms of timing tag propagation patterns (shown in Figure 7) that are common in a cyber-physical system:

- *Propagation of Timing Tag in Single Data Flow.* The timing information is propagated along a single data flow (Figure 7(a)), where edges inherit the timing tag from the predecessor edge, unless the data flow comes from a new sensor reading. Since the timing tag represents the time when the physical world observation is made, the data flow within cyber space does not change the tag. This is the most common case. In practice, developers programmatically add the timestamps to the variables according to data received from the predecessor tasks. Figure 8(a) shows an example from the Baidu Apollo self-driving car project (Apollo-Pull-8503). The prediction task inherits the timestamp of obstacles from the object detection task. The timestamp is then used to calculate the data age of the currently perceived environment upon which the prediction is based.

- *Merging Timing Tag from Multiple Data Flows.* This category (Figure 7(b)) involves merging multiple data flows at a vertex. This is typically required for tasks that fuse information from different sensors. In this case, the resulting memory SSA from the statement inherits the timestamps from its incoming edges, and maintains $t_{phy} = f_v(t^1_{phy}, ..., t^n_{phy})$, where f_v is the merging function for the vertex v. While the figure shows only two data flows, there could be more than two. Note that there is a one-size-fits-all solution in how timing tags can be merged, since it is effectively merging observations on the physical world from different time instances. One common approach is to keep the range of the time tags. The code snippet in Figure 8(b) depicts a fusion task in Apollo, added in Apollo-Pull-5459. Since this task fuses detection results from LiDAR, cameras, and radar, it also incorporates their timestamps to check the temporal alignment later.

4.2 Timing Constraints in TDFG

Based on the timing bug study, three essential temporal properties were formulated based on the cyber-physical control loop abstraction: freshness, consistency, and stability. In the following, we will show how they can be captured using TDFG in the form of *Timing Correctness*.

Freshness focuses on the difference between the time when a physical observation is made and the time when this observation is used by the control system. In cyber-physical systems, this difference often has to be bounded, as any latency increases the temporal gap between the cyber and the physical world, as previously discussed in Section 3. As a result, given an edge e with a maximum tolerable timing threshold θ_f, its freshness is calculated by:

$$C_f = \theta_f - (t_{-} - t_{\text{phy}})) \tag{1}$$

where t_{-} is the current time.

Consistency concerns the time differences between the timing tags from different data flows into a vertex, which intuitively indicates the differences in the physical world status at different times. Generally, the smaller it is, the closer the time stamps are, and the more consistent the physical world observations should be. Consider n edges that have the same egress vertex: $T_{\text{def}} = \langle t^1_{\text{def}}, \ldots, t^n_{\text{def}} \rangle$. Their temporal consistency can be checked by:

$$C_c = \theta_c - \max_{i,j \le n}(t^i_{\text{phy}} - t^j_{\text{phy}}) \tag{2}$$

where θ_c is the tolerable threshold (or range).

Stability captures differences in timing characteristics of data flows into/out of a vertex temporally. Many tasks in real-time systems are implemented as periodic workloads and thus some underlying algorithms/models are designed with the assumption of periodicity, which necessitates periodicity in data usage, such as input (e.g., sensor input) or output data (e.g., actuation command) [71]. For w edges belonging to a

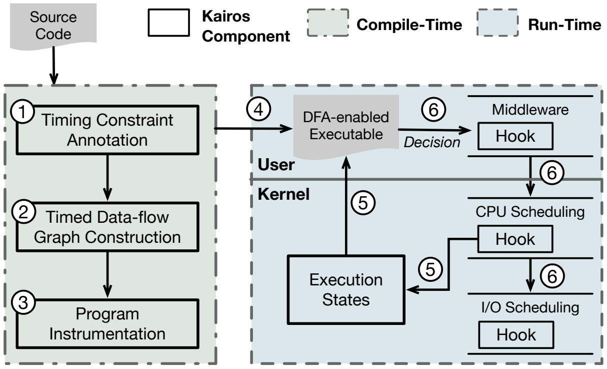

Figure 9: Workflow of Kairos.

set of data flows from sequential loops via the same program point, they have $T = \langle t^1_{\text{phy}}, \ldots, t^w_{\text{phy}} \rangle$. One typical way to check stability is by measuring jitters:

$$C_s = \theta_s - \max_{i,j \le w-1} |D_i - D_j|, D_i = \Delta_i - I, \Delta_i = t^{i+1}_{\text{phy}} - t^i_{\text{phy}}. \quad (3)$$

where Δ represents the interval between two iterations and I is the expected interval. In practice, the form of stability can vary based on the design of the target systems, with alternatives potentially being variations of freshness.

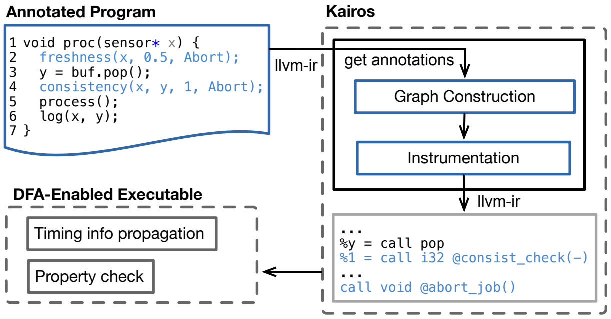
An edge e is evaluated upon the program's execution reaching its egress vertex, and it is considered compliant with timing correctness if all its added metrics meet $C > 0$, namely $(C_f > 0 \wedge C_c > 0 \wedge C_s > 0)$.

5 Design and Implementation of Kairos

Kairos is a proof-of-concept realization of Data-flow Availability. There are two main components, the temporal policy definition using TDFG and the mitigation of policy violation. Kairos is composed of a compiler extension and a run-time system. Figure 9 outlines its key components and workflow. At compile-time, Kairos leverages program analysis and user annotation/automatic annotation ① from profiling to construct the TDFG of the target application ②; Utilizing the TDFG, it instruments code to perform timing information propagation ③; At run-time, tasks update timing information and evaluate timing correctness ④; Upon timing constraint violation, the task triggers a handler to execute the pre-defined policy ⑤; The scheduling decisions from handling policy are then shared with schedulers across different layers ⑥.

5.1 DFA-enabled Application

As shown in Figure 10, there are two main steps in the construction of DFA-enabled application, the construction of TDFG, which defines the temporal properties the application has to follow and the instrumentation of the application to enable detection and mitigation of the property violation.



```
void proc(sensor* x) {
  freshness(x, 0.5, Abort);
  y = buf.pop();
  consistency(x, y, 1, Abort);
  process();
  log(x, y);
}
```

```
...
%y = call pop
%1 = call i32 @consist_check(-)
...
call void @abort_job()
```

Figure 10: Pipeline of DFA-enabled application construction.

TDFG Construction. TDFG captures the expected temporal properties of the developers. Upon extraction of value-flow graph [49, 86], the timing constraints in TDFG are expressed either manually via developer annotations or automatically via dynamic profiling.

Table 2: Kairos API

Function Name	Arguments				Description
	Targets	Tolerance	Window	Handling Policy	
freshness	var	threshold	-	abort	Checks the expected properties. If violated, triggers the handling policy function.
consistency	var, ...		-	prioritize	
stability	var		size	skip-next	

To facilitate manual annotation, three APIs are provided for annotating the source code to express timing constraints over the three key properties (freshness, consistency, and stability) that were previously discussed in Section 3. As shown in Table 2, the functions take four types of arguments: target variables, tolerance threshold, window size (for stability only), and handling policy. The threshold and window size parameters enable the check of timing correctness. The handling policy argument specifies the function to be invoked if timing correctness checks fail.

However, manual annotation often requires strong domain knowledge not only of the physical system but also of the computing stack, which may not always be available. To tackle this, Kairos also provides an option to extract the timing constraint using performance profiles from dynamic analysis. To do so, Kairos needs two key components: first, an oracle (criteria) to determine if the timing behavior of the software needs to be corrected or not; second, inputs to instrument the system such that all potential behaviors can be observed. For the oracle, Kairos borrows existing practice in CPS evaluation, where safety (often measured as control state deviation) is used as the metric. When physical safety (such as vehicles crashing into pedestrian or drones falling from the sky) is compromised by the violation of a specific temporal property, Kairos considers this temporal property to be essential and has to be monitored and checked at runtime. Inputs to the system, i.e., the physical scenarios, to test the system is an open challenge in CPS testing [72]. In Kairos, in addition to relying on the user to supply scenarios that might reveal temporal property violations, we use the performance interference tool [65] to probe the system with different potential timing impacts. To minimize the impact on the timing behavior of the software due to the profiling system, hardware performance monitors and debug functions are used. Among all flows that cause the same property violation, Kairos only adds the check on the first occurrence. It is important to note that dynamic profiling is much more effective in finding the acceptable range of the constraints rather than finding where to add the constraint (which has a much larger search space).

TDFG Embedding. Before constructing the TDFG, Kairos analyzes the source code to identify statements that receive sensor inputs, and automatically instrument them to extract timestamps t_{phy} from the sensing or input payloads. To begin the construction of TDFG, Kairos builds on top of the value-flow analysis in the SVF [86] tool with LLVM-IR [63], then uses a set of python scripts to add the timing constraints and annotation. Additionally, a set of LLVM compiler passes is also developed to instrument the necessary code for timing information propagation and checking. Kairos also leverages several heuristics to reduce the performance overhead. First, to avoid instrumenting every instruction for timing metadata propagation, Kairos automatically bypasses the timed data flows with the same time tag t_{phy} (sensor timestamps). Without loss of generality, a vertex is selected to be in the TDFG based on three criteria: *(i)* it is either a physical input or physical output vertex, *(ii)* it merges multiple data flows, or *(iii)* it is annotated with timing constraints as a vertex of interest.

5.2 Timing Constraint Violation Mitigation

Timing Constraint Violation Handler Policies. Mitigation of timing constraint violations often requires consideration of the physical components, and there is no one-size-fits-all solution. Drawing inspiration from our bug study, prior works in real-time computing [39, 46, 69, 91] and current industrial practices [29], Kairos offers three policies: *abort*, *prioritize*, and *skip-next*. More specifically, *abort* discards the task instances with timing constraint violations. *prioritize* switches the system into a different set of task models, often involving raising the priority of the task. Lastly, *skip-next* allows the delayed task to continue but skips its next instance to recover.

It is important to note that individually, these policies may give rise to further timing constraint violations in a cascading effect. For example, prioritizing a task that has missed its deadline might prevent other tasks from making progress, resulting in subsequent deadline misses. However, if correctly composed, these policies support existing adaptive real-time scheduling paradigms, e.g., elastic scheduling [46] and mixed-criticality scheduling [90].

Under *elastic scheduling*, task utilizations are decreased (typically by increasing the periods at which they are invoked) to avoid deadline misses. Though originally proposed in [46] as a mechanism to adapt to system overload, elastic scheduling has since evolved as a means by which systems can adapt to unexpectedly long task execution times [45] or interference from other tasks [85]. In response to a violation of timing constraints, Kairos can use the algorithm from [84] to quickly recompute task periods, then enforce this with multiple *prioritize* policies to change task priorities or `SCHED_DEADLINE` attributes accordingly.

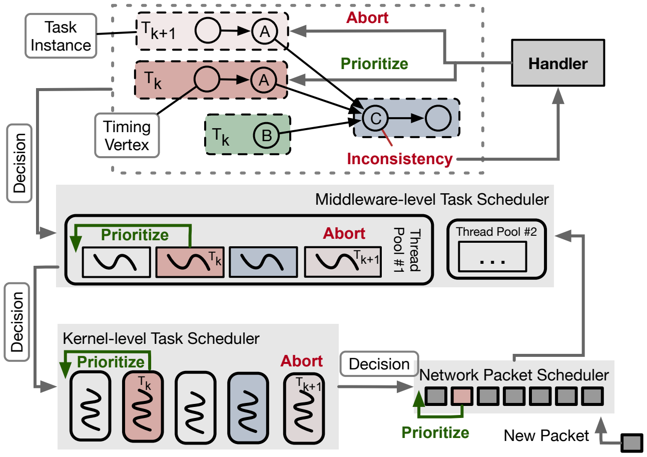


Figure 11: An illustrative case of Path across layers.

In *mixed criticality systems*, non-critical task instances may be dropped in response to timing anomalies in critical tasks. Earliest-deadline first (EDF) scheduling with virtual deadlines (EDF-VD) is an optimal scheduling algorithm for non-clairvoyant mixed-criticality systems (i.e., those for which timing anomalies can't be predicted a priori, but are only identified when they occur) [39]. Under EDF-VD, each critical task is prioritized according to its virtual deadline, which is assigned as a constant parameter. When a critical task overruns its expected execution time, instances of non-critical tasks are dropped to maintain guarantees to critical tasks, and critical tasks are re-prioritized according to their absolute deadlines [39]. Kairos's handler supports this mode switch via a combination of its *abort* and *prioritize* policies (applied to the non-critical and critical tasks, respectively). While developing more sophisticated policies presents intriguing research opportunities, it is left for future exploration.

Implementation. Handlers can be implemented in individual layers or across multiple layers. In our prototype, we implement it as a modification to the kernel schedule where the mitigation mechanism is invoked before the built-in scheduler for proof-of-concept. For task abort, our prototype instruments code to enable early return. However, it is important to note that resource deallocation and inconsistent state removal often require sophisticated management [82]. The skip-next is demonstrated in the middleware by dropping the next task invocation message at ROS.

Cross Layer Scheduling Association. While the handling policies for timing constraint violation are relatively well understood under the real-time task problem formulation at the task level. Existing software ecosystems come with schedulable entities at different layers of architectural abstractions from I/O layer (such as network packet) and operating system (real-time process) to middleware (ROS component) to application (application-specific schedulers). This presents non-trivial system challenges in realizing consistency in the handler policy due to missing semantics across the abstraction layers.

This problem can be observed in 13 bugs [18, 38] from our earlier bug study. For example, the handling of a consistency violation often needs to adjust threads on sensor processing rather than the fusion process, necessitating the correlation of a subgraph of TDFG to the corresponding schedulable entities such that the timing constraint violation handler knows which one to intervene on [41]. Another example that commonly occurs in time-sensitive networking is the need to prioritize specific items in the network queue due to reprioritization of tasks [95], which can be part of the handling process.

To mitigate this, we propose to bridge the semantic gap by associating schedulable entities to data flows in TDFG. This not only allows the handler to know the schedulable entity to operate on, but also allows the other abstraction layers to respond to a handling mechanism much more effectively. To ensure the association is complete, Kairos draws inspiration from the Path concept from Scout system [73], where Path is used to track the components a packet travels through (e.g., network devices or protocol layers) on network appliance systems. In Kairos, upon dispatching, Path is updated to reflect the chain of schedulable entities that leads to execution of the application along a particular path, as shown in Figure 11.

Implementation. Our prototype modifies the data structure of native scheduling entities to store the Path to which they belong. This information is updated in a shared buffer accessible to four layers, i.e. user space, kernel, middleware, and network stack. The method of incrementing Path varies: in the kernel and network stack, it occurs where new tasks or packets are created; while in ROS middleware, it happens as threads are dispatched to execute callback functions.

6 Evaluation

This section seeks to answer the following questions: *(i)* What is the capability of DFA in addressing real-world timing bugs? – Section 6.1; *(ii)* What is the cost and efficacy of Kairos? – Section 6.2; *(iii)* How do DFA and Kairos improve performance/safety in abnormal timing situations? – Section 6.3.

Experimental Setup. The evaluations were performed on synthetic workloads and the workloads of three real-world autonomous systems: (1) Autoware.Auto [36] – an open-source full-stack autonomous driving project, which presents a high-end real-time autonomous system. (2) Jackal UGV – an unguided ground vehicle that represents mid-end autonomous system. It uses Google cartographer [47] for vehicle localization and ROS navigation [6] for path planning and control. (3) Turtlebot3 – a low-end indoor robot that relies on ROS navigation [6] for localization, planning, and control. Given that the software stacks of each system require distinct computing power, we used three different computing units that align with (or are similar to) the official recommendations to better emulate abnormal timing situations. The experimental hardware settings are listed in Table 3. Autoware and Jackal UGV were evaluated using hardware-in-the-loop simulations, while Turtlebot3 was also evaluated using a real robot.

Table 3: Evaluation Platforms

Platforms	Software Stack	Computing	Cores	RAM	Kernel
Autoware	Autoware.Auto [36, 61]	AMD 9 3900X RTX 3070 Ti	12	128GB	Linux 5.11
Jackal	Cartographer [47] & Navigation [5]	Intel Nuc 8	4	16GB	Linux 5.11
Turtlebot3	Navigation [5]	RPi 4B	4	4GB	RPi 5.15
Microbenchmark	ORB-SLAM3 [4]	Intel i9-12900K	12	128GB	Linux 5.11

Table 4: Root Cause Analysis of Bug Fix Capability

Category		**Description**	**Number**
Fixable	Non refactoring	Inadequate timing information/constraints/propagation	104
	Refactoring	Remove built-in conflict logics	5
		Adapt with software semantic	7
Unfixable	Out-of-Scope	Hardware-related timing faults	6
		Algorithm-related timing bugs	8
		Infrastructure bugs (e.g., scheduler crash)	41
	Limited	Concurrency bugs	12
		Performance issue	6

6.1 DFA in Solving Real-world Bugs

A key question to answer in evaluating the efficacy of Kairos is its ability to address the timing problems. To do so, our evaluation leverages the collection from the bug study and analyzes if Kairos can detect the timing problems (through temporal policy defined in TDFG) and mitigate the timing problems (using the cross-layer temporal policy violation handler). Due to the need to use physical system or emulation to exercise the system, most of the results from this evalua-

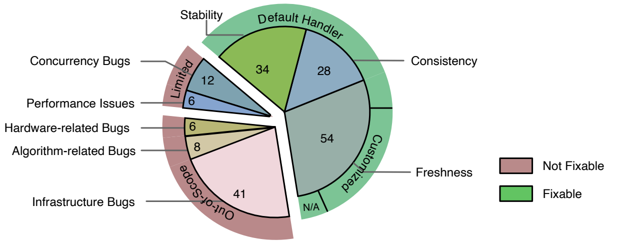

Figure 12: Statistics on bug fixability and root causes.

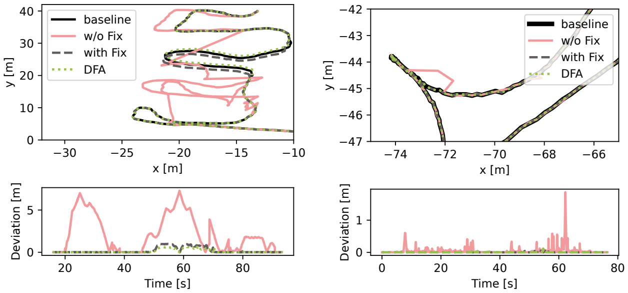
tion item are acquired through manual inspection by three cyber-physical system developers with 6, 10, and 17 years of experience respectively. A bug is considered fixable if all three developers agree that the mitigation can be expressed using primitives in Kairos. Furthermore, we've also conducted two case studies to demonstrate that Kairos can be used to detect and mitigate violations of the key temporal properties.

The results of the manual inspection are shown in Figure 12. From our earlier case study, there are 189 timing bugs. 116 of them can be detected by DFA, and 23 are not detectable, because they are caused by underlying infrastructure bugs, design flaws, or hardware issues (beyond the scope of Kairos). 76 bugs can be mitigated directly using default mitigation handling policies, while 35 bugs can only be mitigated using customized temporal violation handlers. 5 bugs cannot be mitigated even with customized handlers, because they require adaptation in the underlying design model or algorithms, necessitating a complete software redesign. Table 4 summarizes the reasons on all the bugs that Kairos cannot address. To further understand how Kairos can be used to address real-world bugs, we reproduce two bugs violating stability and consistency respectively, since freshness is often easier to handle.

Case-1: Abnormal timing of LiDAR Pointcloud in Cartographer. This case study demonstrates the effectiveness of Kairos in identifying and mitigating violations of stability timing constraint. Specifically, we evaluate Kairos on issue Cartographer-Issue-242 (code snippet shown in Figure 5) in Cartographer [56], a widely used localization package. According to the original issue report, the LiDAR pointcloud data, which is assumed to arrive at periodic intervals, sometimes arrives more closely than expected, violating the system's stability timing constraints. To reproduce the same impact of the issue, we modified the driver code to induce the same abnormal timing patterns, specifically manipulating the time between two pointclouds to be below 1 ms. Such timing patterns cause the vehicle to deviate from the baseline at most 10.3 m, as shown in Figure 13(a). To solve this issue, the patch in the codebase checks the timestamp of each point and removes abnormal ones with intervals of less than 1 ms. With this removal, the produced localization results are comparable to the baseline (deviation at 0.20 m). With Kairos, we specify stability timing constraint on *ScanMatch()* statement which consumes variable *msg* in task *HandleLaserScanMessage* that receives the point cloud with the annotation API *stability()*. The tolerance threshold argument in the API, which is set between 22 and 33 ms, is obtained through dynamic profiling of the ranges of intervals that do not incur adverse control outcomes. This process takes 18.3 minutes. We use *abort* as the default policy to mitigate the violation. The produced localization result aligns with the baseline at 0.19 m, which is comparable to the official patch as shown in Figure 13(a).

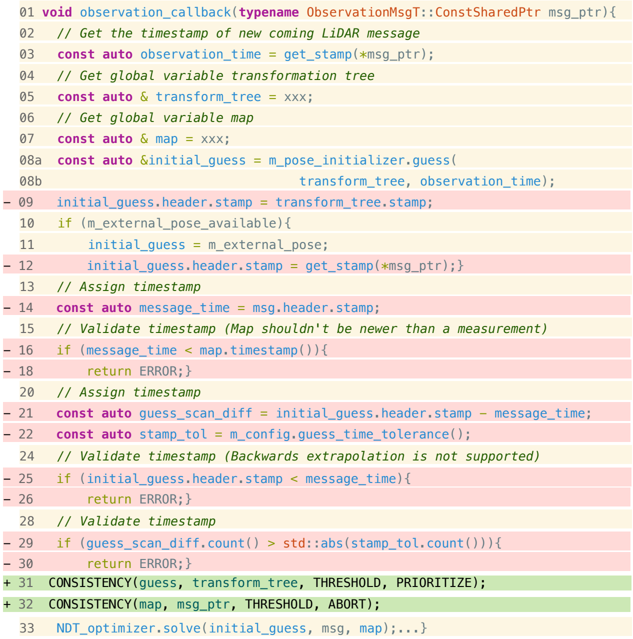


(a) Jackal case study.   (b) Autoware case study

Figure 13: Case studies on fixing timing bugs using DFA.

Case-2: Latency in Updating Location. This case study showcases the effectiveness of Kairos in detecting and mitigating violation of consistency timing constraints. Specifically, we evaluated Kairos on the issue Autoware-Issue-458 in Autoware (code snippet shown in 14). According to the original issue report, the timestamps of the generated LiDAR data and odometer data used by the optimization procedure (line 31), which aims to perform the localization, should be within a threshold but are sometimes misaligned, violating the system consistency timing constraint. Since the mechanism to trigger the bug was not discussed in the original issue submission, we inject an intermittent CPU overload at 60 % level using stress-ng [62] on the cores running localization-related tasks to introduce inconsistency between LiDAR and odometer data. Such inconsistency causes the vehicle to produce a trajectory that deviates from the ground truth by 1.88 m, as indicated in Figure 13(b). To solve this issue, the patch in the codebase tags the LiDAR and odometry data with timestamps. It then compares these timestamps. If the difference between them is more than 1 second, the results are discarded. With this removal, the produced localization results align with the baseline at 0.12 m. To solve this problem with Kairos, we use annotation API *consistency()* (line 31 in Figure 14) to specify the consistency timing constraint on *transform_tree* and *msg_ptr*. The tolerance threshold argument in the API, which is set between 1.2 s, is obtained through dynamic profiling of *the difference between timestamps of two variable generations* that do not incur adverse control outcomes. This process takes 8.5 minutes. We use *prioritize* as the default policy to mitigate the timing constraint violation. The produced localization result aligns with the baseline at 0.091 m, which is comparable to the official patch.

A Programming Example. We use case-2 (Autoware-Issue-458) as an example to showcase how Kairos reduces the effort in programming timing constraints. Figure 14 shows simplified code snippets from Autoware's localization component. In this component, incoming LiDAR pointclouds, HD maps, and the transformation tree (extrapolated pose based on past information) are used jointly, so their timestamps should



```
  void observation_callback(typename ObservationMsgT::ConstSharedPtr msg_ptr){
    // Get the timestamp of new coming LiDAR message
    const auto observation_time = get_stamp(*msg_ptr);
    // Get global variable transformation tree
    const auto & transform_tree = xxx;
    // Get global variable map
    const auto & map = xxx;
    const auto &initial_guess = m_pose_initializer.guess(
                                      transform_tree, observation_time);
-   initial_guess.header.stamp = transform_tree.stamp;
    if (m_external_pose_available){
        initial_guess = m_external_pose;
-       initial_guess.header.stamp = get_stamp(*msg_ptr);}
    // Assign timestamp
-   const auto message_time = msg.header.stamp;
    // Validate timestamp (Map shouldn't be newer than a measurement)
-   if (message_time < map.timestamp()){
-       return ERROR;}
    // Assign timestamp
-   const auto guess_scan_diff = initial_guess.header.stamp - message_time;
-   const auto stamp_tol = m_config.guess_time_tolerance();
    // Validate timestamp (Backwards extrapolation is not supported)
-   if (initial_guess.header.stamp < message_time){
-       return ERROR;}
    // Validate timestamp
-   if (guess_scan_diff.count() > std::abs(stamp_tol.count())){
-       return ERROR;}
+  CONSISTENCY(guess, transform_tree, THRESHOLD, PRIORITIZE);
+  CONSISTENCY(map, msg_ptr, THRESHOLD, ABORT);
    NDT_optimizer.solve(initial_guess, msg, map);...}
```

Figure 14: Simplified code for temporal consistency checks in Autoware. ‘-’ (red) represent built-in checks, while ‘+’ (green) are checks via Kairos’s API.

be checked as aligned. The standard checking mechanism (red lines marked by ’-’) requires developers to identify data provenance, label timestamps, and verify them before use. This often involves frequent jumps to other functions in different contexts, necessitating a deep understanding of data-flow relationships, which is both time-consuming and error-prone. In contrast, by using Kairos’s APIs, users can omit all timestamp assignments and checks and simply add two statements before using the LiDAR point cloud and map (marked by two green lines with ‘+’ in the figure).

Overall, Kairos eases programming with timing constraints in three ways. First, it removes the requirement of programmatically assigning timestamps to variables. Second, it avoids unnecessary or repeated timestamp checks. Third, it does not require developers to thoroughly understand the temporal relationships between different data flows in the source code.

6.2 Cost and Efficacy of Kairos

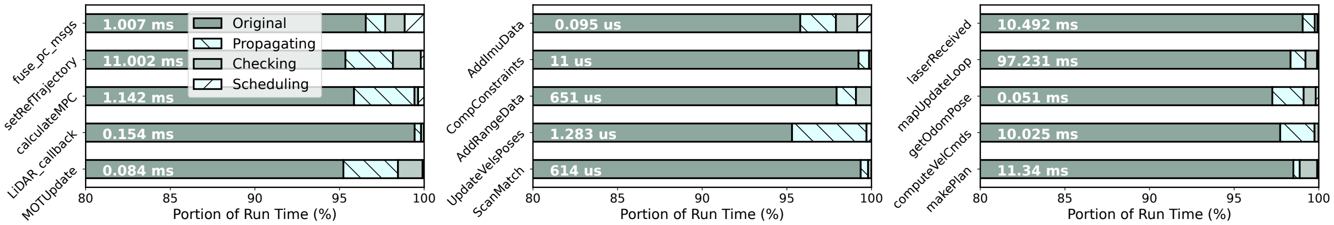
Runtime Overhead on Real-world Applications. The runtime overhead of Kairos stems from three aspects: timing information propagation, timing correctness checking, and the added logic in schedulers. We separately measured the overhead for each aspect on five representative tasks (or functions) per platform, averaging execution times over 100 runs. The results, shown in Figure 15, include original times and proportional increases.

The largest overheads observed in these tasks are *MOTUpdate* in Autoware (4.77%), *UpdateVelsPoses* in Jackal UGV (4.69%), and *getOdomPose* in Turtlebot3 (2.74%). Overall, the increased percentage of execution time is highly related to the number of edges in the task dependency graph (TDFG). Typically, tasks that involve more sensor inputs will introduce more edges. For example, the *MOTUpdate* task has a high overhead percentage because it is the multiple object tracking task in Autoware that fuses multiple pointcloud inputs. Furthermore, the tasks that maintain more historical timing states will also have a higher overhead. An example is the task *AddImuData* in Jackal UGV, which stores hundreds of inertial data frames in a queue, inducing a 4.21% overhead. Breaking it down, most of the overhead comes from propagating timing information along edges which can reach up to 4.39%. We found that Kairos’s add-on logic on schedulers introduces negligible overhead, where the largest overhead is 0.84% from task *AddImuData*. Besides the individual execution times, we also measure the end-to-end latency from sensor input reading to actuation output. The overhead on end-to-end latencies for Autoware, Jackal UGV, and TurtleBot3 are 3.24%, 2.44%, and 2.75%, respectively.

Scalability Analysis. The sensor reading rate, the number of edges in TDFG, and the number of timing tags in timing constraint checking affect the scalability of Kairos. Thus, we evaluate the scalability of Kairos by measuring the runtime overhead with respect to these three factors. We create synthesized workloads with varying scalability impact factors by modifying the original workload of ORB-SLAM3. Specifically, (1) to emulate varying sensor reading rates, we change the replay speed of the recorded sensor data from the original ORB-SLAM3 workload. (2) To adjust the number of edges, we duplicate tasks and annotate timing constraints on their shared data flows. (3) Since only *stability* performs timing constraint checks over multiple timestamps, we adjust its window size to assess the impacts of timing tag size.

Sensor Reading Rate. The sensor reading rate impacts runtime overhead. Figure 16(c) shows a linear increase in execution times for updating and checking timing tags as input frequency rises. The execution time for a single vertex increases from 37.537 μs at a frequency of 20 to 4087.95 μs at a frequency of 500Hz, primarily due to timing checks. A higher sensor reading rate also significantly increases lock wait times, increasing 100 times from 10 Hz to 500 Hz. Yet, CPU usage on a single core remains at just 0.23% even under high input frequency.

Number of Edges in Timing Propagation. We use the number of Paths created per second as a proxy for the size of TDFG. Figure 16(b) presents the runtime and memory overheads. The duplicated tasks are callback workers in the ROS middleware, thus increasing the number of tasks in the middleware but not significantly affecting the kernel scheduler. We observe that middleware scheduling time increases with the number of tasks. CPU usage on a single core peaks at 0.42% with



(a) Autoware

(b) Jackal UGV

(c) Turtlebot3

Figure 15: Run-time overhead breakdown. The execution time of the original task, the time spent logging timing information, online checking of timing correctness, and extra scheduling are shown.

(b) Number of Paths.

(c) Input frequency.

(d) Different CPU overloads.

Figure 16: Scalability analysis (16(a), 16(b), and 16(c)) and control impact of CPU overload 16(d).

5000 Paths, while memory overhead reaches 75 KB, which is relatively low given that the target platform typically has over ten GB of RAM.

Number of Timing Tags. Figure 16(a) shows the runtime and memory overhead induced by a single edge with different numbers of timing tags used during timing constraint checks. We can observe that the checking time increases proportionally with the number of timing tags. With a tag size of 100, the average overhead is 2.945 μs of runtime and 896 bytes of memory; increasing to 500, it reaches 9.4 μs and 4096 bytes, respectively. Given that the number of edges typically remains below a few hundred, the total overhead is low. The figure also shows that as the number of timing tags increases, lock wait time slightly rises but remains below 0.05% of CPU usage on one core.

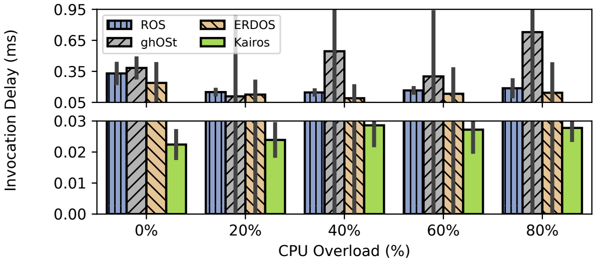

Figure 17: Invocation delays of handlers in different systems.

Invocation Latency in Delivering Execution Decision. In this experiment, we compared Kairos's efficacy to ROS [80], ghOSt [57] and ERDOS [55] in delivering scheduling decisions. ROS features the actionLib library [28], which supports preemptible tasks. ghOSt [57] is a userspace-informed kernel scheduling system that allows scheduling decisions to be made from userspace. EDROS is a robotic middleware that provides programming interfaces to deploy deadline miss handlers. We measure the delay from when the decision is made to the targeted task being executed. The experiments are conducted under different CPU overloads. We use *stress-ng* [62] tool to inject overloads, from 0% to 80%, then compare the increases and variations of latencies in Figure 17.

Under 80% overload, the response times for ROS, ghOSt, ERDOS, and Kairos are 0.186 ms, 0.72 ms, 0.14 ms, and 0.027 ms, respectively. Kairos has the fastest response time in fulfilling an execution decision, at least 2.16× faster than the others under high system overload. To be fair, these systems do not aim to achieve performance under high overload. Kairos has the cooperation in prioritizing the target task across scheduling layers. In contrast, ROS and ERDOS enforce scheduling decisions only at the middleware layers. Similarly, ghOSt enforces them solely through its own scheduler, which is a sub-scheduler with a lower priority than Linux's CFS scheduler. All four systems have stable invocation times while CPUs are idle, with variations of 0.095 ms, 0.094 ms, 0.18 ms, and 0.004 ms, respectively. However, we observe that the invocation latency and variations on ghOSt and ERDOS increase significantly (up to 0.81 ms under 80 % CPU overload) as the system overhead increases. This is because they

Table 5: DFA on Different Platforms

Platforms	Loc	# Inputs	# Tasks	# Vertices	Deviation (m)		# Collisions	
					Native	DFA	Native	DFA
Autoware	92 k	8	16	14	0.67	0.13	45	16
Jackal	68 k	4	6	6	0.27	0.09	12	4
Turtlebot3	34 k	3	4	3	0.87	0.21	35	13

are highly affected by Linux's underlying native scheduler (CFS). We conclude that Kairos takes faster and more stable countermeasures when mitigating a timing violation.

6.3 Effectiveness in Improving Safety

This section evaluates the capability of DFA model and Kairos in improving performance/safety in abnormal timing situations. We performed dynamic profiling on three platforms to identify which code regions required annotated timing constraints and to determine the expected temporal properties. Regarding handling policies, they also require understanding the task model and semantics of the target program. To mitigate the impact of this subjectivity, we employed an automatic strategy to apply three default policies for these timing constraints accordingly. Specifically, we model the target application's tasks as a directed graph. We adopted the *prioritize* policy for tasks on the critical path since aborting them will significantly increase end-to-end response time. For the tasks on the non-critical path, we apply the edges with *freshness* constraints and the *abort* policy for the remaining tasks. This is because violations of *consistency* and *stability* often lead to erroneous computation results, which should be prevented from propagating to downstream tasks. Table 5 shows the number of inputs and tasks on the three platforms as well as the number of edges annotated with timing constraints in TDFG. In generating the timing thresholds for those timing constraints, we observed an average variation of 8.82 ms.

We generated 100 trajectories in each scenario (Autoware in Parking Lot [34], Jackal UGV in Office [48] and Turtlebot3 in House [81] scenarios.)) for the vehicles to follow. During navigation, we injected CPU overload using the *stress-ng* tool [62] to emulate abnormal timings. We selected a 60% overload, as this condition typically triggers notable degradation in control performance. Figure 16(d) shows the number of collisions of Jackal UGV in 100 runs under overloads. We observed a significant increase in collisions at 60 %. Additionally, mission time increased with CPU overload because higher overload often triggered fail-safe, stopping the vehicle during the mission. At 80 % overload, vehicles typically halted, requiring manual intervention to continue.

Control Performance Improvements. The control performance is quantified by metrics (1) the distance vehicles deviate from the reference mission trajectories and (2) the number of collisions. The results are shown in Table 5. We observe that Kairos can considerably reduce control deviations across all three platforms. The lowest improvement of deviation is 2.97× on the Jackal UGV. As to collisions, Kairos reduces the collision by 64.4%, 83.3%, and 62.9% on Autoware, Jackal UGV, and Turtlebot3 respectively. Upon further investigation, the improvement is mainly due to proactively aborting false computational results to prevent the vehicle from outputting erroneous actuation commands. However, this approach will slow down the vehicle, which increases the mission time.

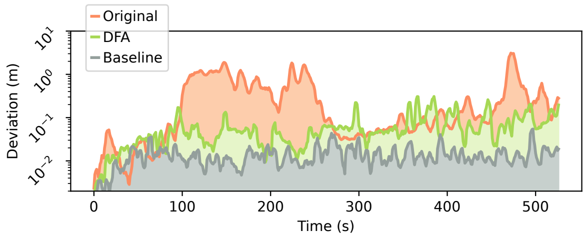

Figure 18: Comparison of control performance on Jackal UGV, with the deviation averaged over a window of 10.

Figure 18 plots the localization errors over time of one test run on Jackal UGV. We see that Kairos's abnormal timing detection and handling mechanism can significantly reduce the magnitude of intermittent computational errors, from ∼ 1m level to ∼ 10cm level. In this case, nearly one-third of the frames are dropped under high system overload, preventing the software from using data with abnormal timings and avoiding erroneous computational results. Aborting or skipping data also slows the robot's movement, reducing collision risks but increasing mission time by 56.8%. This policy may not suit hard real-time systems with strict deadline requirements. However, it effectively reduces adverse control outcomes in soft real-time systems.

7 Discussion and Limitation

Expressing Real-time Computing Constructs using DFA. DFA approaches timing assurance from a data-flow perspective, providing a more intuitive mechanism to express, detect, and mitigate timing constraint violations. However, to leverage this system coherently with existing constructions of real-time systems, DFA has to be able to express traditional real-time primitives. This will allow developers to build on top of the extensive advancements in real-time theory from the past several decades using the DFA-expressed real-time primitives. There are two categories of real-time computing primitives. The first category is execution time constraints, which specify the bounds of the execution period between two statements in the program. With Kairos, developers can use the statements *freshness(var, delay, abort)* and *freshness(var, delay, policy)* as firm and soft deadline specifications, where *var* is the task's output and *delay* is the deadline. The second category is synchronization primitives, which specify the order of shared data accesses among multiple real-time threads. This can be expressed by strictly ordering the timing of two data flows using statements such as *consistency(write_var, read_var, 0, policy)*, where *read_var* and *write_var* are SSA variables in read and written by different concurrent threads. This annotation will ensure that the write operation occurs before the read operation.

Manual Efforts. While Kairos provides tools for profiling through dynamic analysis, the search space for where and what temporal constraints to include is often prohibitively large. As a result, the automated tool may take a long time to identify the appropriate temporal policy. Developer guidance with some manual annotations can quickly narrow down this search space. Furthermore, once a policy is found, deploying it in a safety-critical system may require re-validation or even re-certification of the target system.

Multiple System Components in Violation Handling. Kairos requires seamless collaboration between the software instrumentation and multiple components across different scheduling layers for effective violation mitigation. This interdependency poses two limitations. First one is on reliability, as failures in one part can affect the entire system. Second one is maintainability, as migrating to different platforms may require substantial engineering efforts. However, the modularized design of detection and mitigation of temporal violations allows Kairos to integrate with other existing detection or mitigation techniques. Additionally, the infrastructure that bridges the semantic gap between different abstraction layers also reduces the engineering effort needed to build cross-layer timing mitigation.

Generality of DFA. While DFA is designed for cyber-physical systems, the concept of imposing temporal expectation on data flow generally applies to broader classes of computing, including conventional cyber-only environments such as data centers. For example, DFA's timing constraints on data usage can be adapted to systems with non-determinism to ensure logical correctness, such as the order of input events in distributed systems [74]. It is also possible to leverage DFA to track computation progress through the lens of data flow in distributed workloads.

8 Related Work

Timing Semantics in Programming Model. In data streaming systems, there have been efforts that incorporate timing information into the programming model to represent logical points, such as logic timestamps or watermarks [30,74,88,92]. This facilitates the coordination of computation among distributed nodes. Such extension of timing information on data-flow graphs inspired our design. However, these systems are designed for massive parallel data processing, rather than the cyber-physical timing alignment.

In real-time computing, several programming models have been proposed to react to timing violations [42,44,55,76,87]. In particular, Timed C [76] is a dialect of C that allows the specification of soft and firm real-time constraints. However, compared to these works, DFA introduces a design approach that focuses on the temporal policy on data flows, which builds on top of the cyber-physical control loop abstraction, allowing the detection and mitigation of cyber-physical state (data) misalignment.

Cross-layer Scheduling. There is a large body of work that focuses on cross-layer scheduling. However, existing works often target specific hardware [40,58,78,95], such as NICs. Furthermore, many target server platforms have abundant computation power, thus these solutions may not translate well to resource-constrained embedded systems. Notably, similar to Kairos, Syrup [60] offers programmable abstractions and interfaces for custom scheduling policies. However, it focuses on the rapid deployment of customized schedulers, rather than on enabling cross-layer scheduling actions.

Cross-layer scheduling has also been studied in the real-time community in the context of compositional scheduling [51, 83, 93]. However, deployment of these techniques often requires the target system to be rigorously modeled and deployed as real-time tasks, which may not always fit some of the existing software architectures for CPS.

9 Conclusion

In this paper, we presented data-flow availability, a concept that aims to define temporal policy for data-flow in real-time safety-critical cyber-physical systems. Through a bug study of 189 issues over 7 representative CPS software, three key temporal properties were extracted concerning the alignment of cyber states and physical states in time. To allow for the concrete expression of temporal expectation, we augment data-flow with timing constraints, captured by TDFG. To realize the concept in system, we design and develop Kairos that detects temporal violations by embedding the policy as checks in the application and mitigates them via a cross-layer scheduling infrastructure. Lastly, the system is evaluated on three CPS platforms for feasibility.

Acknowledgment

We express our gratitude to the anonymous reviewers and shepherd for their insightful feedback. We also thank Sanjoy Baruah and Ron Cytron for their valuable discussions. This work was partially supported by the NSF (CNS-2238635) and Intel.

Abstract

The virtues of security, reliability, and extensibility have made state-of-the-art microkernels prevalent in embedded and safety-critical scenarios. However, they face performance and compatibility issues when targeting more general scenarios, such as smartphones and smart vehicles.

This paper presents the design and implementation of HongMeng kernel (*HM*), a commercialized general-purpose microkernel that preserves most of the virtues of microkernels while addressing the above challenges. For the sake of commercial practicality, we design *HM* to be compatible with the Linux API and ABI to reuse its rich applications and driver ecosystems. To make it performant despite the constraints of compatibility and being general-purpose, we re-examine the traditional microkernel wisdom, including IPC, capability-based access control, and userspace paging, and retrofit them accordingly. Specifically, we argue that per-invocation IPC is not the only concern for performance, but IPC frequency, state double bookkeeping among OS services, and capabilities that hide kernel objects contribute to significant performance degradation. We mitigate them accordingly with a set of techniques, including differentiated isolation classes, flexible composition, policy-free kernel paging, and address-token-based access control.

HM consists of a minimal core kernel and a set of least-privileged OS services, and it can run complex frameworks like AOSP and OpenHarmony. *HM* has been deployed in production on tens of millions of devices in emerging scenarios, including smart routers, smart vehicles and smartphones, typically with improved performance and security over their Linux counterparts.

1 Introduction

Microkernels minimize functionality in the kernel and move components, such as file systems and device drivers, into well-isolated and least-privileged OS services, achieving better reliability, security, and extensibility than monolithic kernels such as Linux. Thanks to these virtues, state-of-the-art (SOTA) microkernels have been widely deployed in embedded and safety-critical scenarios [30, 52, 54].

On the other hand, while monolithic kernels like Linux dominate in general-purpose scenarios such as servers and the cloud, there are increasingly emerging scenarios such as smart vehicles and smartphones that require better security, reliability, and extensibility in addition to good performance, where Linux is less suitable. While being general, Linux evolves more towards servers and the cloud, making other scenarios less beneficial. For example, it took over 10 years for the preemptive-RT patch [1] to be partially merged, and its evolution is still out of the mainstream, let alone other domain-specific strategies [20, 21]. Moreover, it has been doomed to be difficult (if possible) for Linux to satisfy high-level industry certifications required for such scenarios [98, 113].

However, although microkernels have been extensively studied for decades [16, 28, 30, 46, 49, 52, 52–54, 64, 67, 73, 75, 76, 86], SOTA microkernels mainly target some specific domains, e.g., embedded and safety-critical ones. They usually use static resource partitioning and allocation, and lack general OS functionalities to run commercial off-the-shelf applications. Below, we summarize the major challenges in retrofitting a microkernel as a general OS kernel for such emerging scenarios.

Compatibility: POSIX subset-compliant is not enough. Rebuilding the entire software ecosystem is impractical. Therefore, SOTA microkernels, such as seL4 [67] and Zircon [46], achieve minimal POSIX subset compliance by providing custom libraries, e.g., musl-libc [47], that generate inter-process calls (IPC) to OS services. However, they face deployment issues [6, 116], e.g., not being binary compatible, and implementation challenges, e.g., `fork` and `poll`, in emerging scenarios. Moreover, they can hardly reuse device drivers with affordable engineering effort and uncompromised performance, which are crucial for production deployment.

Performance: IPC is not the only concern. Performance is the top priority in emerging scenarios, directly determining user experiences. While SOTA microkernels like seL4 [67] and recent architectural support [28, 49, 86] have achieved record-high IPC performance, we observe that they still cause non-trivial performance overhead because IPC frequency is significantly increased when microkernels go general (70x higher in smartphones than routers). Further, we observe equally severe performance issues caused by state double bookkeeping due to the multi-server design, which introduces additional performance overhead (2x slower than Linux) and memory footprint (35%). Moreover, capability-based access control, which hides frequently updated kernel objects behind capabilities, can cause significant overhead due to frequent invocations. For example, it causes page fault handling to be 3.4x slower than Linux.

We started the HongMeng kernel (*HM*) project over 7 years ago to re-examine and retrofit the microkernel into a general OS kernel for emerging scenarios. To be practical for production deployment, *HM* achieves full Linux API/ABI compatibility and is capable of reusing the Linux applications and driver ecosystems such that it can run complex frameworks like AOSP [42] and OpenHarmony [35] with rich peripherals. Despite the compatibility goal that may constrain its performance, *HM* still puts performance as its primary emphasis. Therefore, *HM* respects the design principles of microkernels but not to the extreme with careful compromises. Specifically, *HM* makes the following key design decisions.

Minimal microkernel with least-privileged and well-isolated OS services. HM retains the minimality principle by keeping only the necessary functionality in the core kernel, including thread scheduler, serial/timer drivers, and access control, and leaving all other components as isolated OS services (multi-server) outside the core kernel. In addition, *HM* adopts fine-grained access control to preserve the principle of least privilege for better security. As a result, *HM* inherits the security and reliability benefits of microkernels.

Maximizing compatibility by achieving Linux API/ABI-compliant and performant driver reuse. HM integrates existing software ecosystems by achieving full Linux API/ABI compatibility through ABI-compliant shim that identifies and redirects Linux syscalls to IPCs. Moreover, *HM* reuses unmodified Linux drivers via a driver container that provides Linux runtime atop *HM* with minor engineering effort, and eliminates critical path performance degradation by separating the control plane and the data plane with *twin drivers*.

Performance first by structural supports. HM prioritizes performance without violating the architectural principles of microkernels. Specifically, *HM* achieves flexible composition for hierarchically relaxing the isolation between trusted services to minimize IPC overhead, and coalesces tightly coupled services to minimize IPC frequency and eliminate state double bookkeeping in performance-demanding scenarios, while maintaining the ability to separate them in security-critical scenarios. *HM* also supplements capabilities with performant address token-based access control, facilitating efficient cooperation like policy-free kernel paging.

We have deployed *HM* on tens of millions of devices, including smart routers, smart vehicles, and smartphones, which provides not only better security and reliability but also better performance than their Linux counterparts. The critical components of *HM* are semi-formally verified [55] by formally specifying the design and using automated verification and verification-guided testing to validate the crucial security properties, such as free of integer and buffer overflow. *HM* has been certified with ASIL-D [61] (for safety) and CC EAL 6+ [62] (for security). In routers, *HM* allows 30% more client connections by reducing 30% system memory footprint. In vehicles, *HM* achieves a 60% faster boot time and a 60% lower cross-domain latency. In smartphones, *HM* achieves 17% shorter app startup time and 10% less frame drops.

2 The Case for a General Microkernel

2.1 Microkernel Review

A major hallmark of microkernels is the minimality principle [73, 76], which minimizes functionality in the core kernel and moves other functions to userspace services. SOTA microkernels also adopt capability-based fine-grained access control [46, 52, 67, 74] to preserve the least privilege principle. As a result, microkernels are inherently more secure, reliable, and extensible than monolithic kernels [12, 79].

However, although microkernels have been extensively studied for decades [16, 30, 52–54, 64, 67, 73, 75, 76, 122], SOTA microkernels primarily target specific domains, such as embedded and safety-critical systems. Examples include L4-embedded in Qualcomm cellular modem chips [30], QNX[1] in cars and embedded systems [54], and Zircon (kernel of Fuchsia) in smart speakers [46]. There has been little study on how microkernels could be extended as general OS kernels for emerging scenarios like smart vehicles and smartphones.

The industry adopted hybrid kernels such as Windows NT [88] and Apple XNU [4], which combine a core microkernel, e.g., Mach in XNU, with all other services (as a whole) in the kernel space, e.g., Executive in NT and BSD in XNU. Although hybrid kernels also minimize functionality in the core kernel, they do not inherit many advantages of microkernels. For example, OS services in hybrid kernels are not least privileged and not well isolated. Thus, any compromised or buggy OS services can corrupt the system [88], potentially causing severe consequences, such as corrupting user data.

2.2 Demand for a General Microkernel

Emerging scenarios like smart vehicles and smartphones demand rich peripherals and applications. For example, the industry standard of vehicles has evolved to require richer OS

[1] While QNX once supported tablets/phones [14] and ran AOSP apps via virtual machine, QNX discontinued this due to limited compatibility and performance [15, 110] and has fully transitioned to embedded markets [13].

functionalities [7]. Meanwhile, emerging scenarios also emphasize security and safety. For instance, vehicles require high reliability for passenger safety, and smartphones require enhanced security to protect sensitive data. We list the major differences from domain-specific scenarios below.

Software ecosystem. In domain-specific scenarios, applications are mostly *customized and source-available*. Thus, being POSIX-compliant is believed to be sufficient for application transplanting (not even true based on our deployment experiences). However, in emerging scenarios like smartphones, apps and libraries are typically distributed in *binary form*, and frameworks require *more than POSIX compliance* [6], which mandates Linux ABI compatibility.

Resource management. In domain-specific scenarios, there are only a few pre-determined applications, and the hardware resources are limited. Therefore, applications mostly *manage resources themselves*, and the kernel is primarily responsible for reserving resources. In emerging scenarios, however, competing applications require *coordinated resource management*. The kernel requires more fledged functionalities such as efficient resource management and fair allocation.

Performance. In domain-specific scenarios, microkernels prioritize security and strict resource (e.g., timing) isolation for mostly static applications, where performance is *not a primary concern*. In emerging scenarios, however, performance is also *a top priority*, which directly determines the user experience and, thereby, the widespread deployment of the kernel.

The call for integrating both rich software ecosystems and functionalities, as well as security and reliability, makes it difficult for existing OS to satisfy them simultaneously. One approach would be customizing a stock OS such as Linux for such scenarios, which is unfortunately very expensive to evolve with upstream (section 2.3). Previous work also proposes various architectures, including unikernel [65, 81, 102], multikernel [9], exokernel [31], and splitkernel [109]. However, they primarily target server scenarios with clear resource separation while lacking support for efficient and coordinated resource management required in emerging scenarios. Moreover, the synchronization overhead and complexity introduced by split states make it challenging to achieve compatibility.

Therefore, we believe it is worthwhile to explore another avenue of evolving the microkernel into a general OS kernel.

2.3 Issues with Linux

Linux has dominated the server and cloud markets and is increasingly penetrating other domains such as PC and embedded. However, it comes at the cost of compromised security, reliability, and performance, especially in emerging scenarios.

Security and Reliability. Linux modules such as file system (FS) and device drivers cover about 80% of its 30 million line code base. They contribute to the majority of defects and vulnerabilities (90% of the total 1000 CVE [23] in the last 4 years) and significantly reduce reliability and security [19]. Additionally, about 80% of these CVEs are data leaks that can be avoided with proper isolation. Therefore, a long line of research [18,25,38,48,56,83,90–92,100,105,106,112,120,123] aims at isolating the kernel from the modules in a compartmentalized manner. However, the inherent tight coupling requires significant engineering effort and even rewriting [56, 90, 91]. Moreover, the instability of kernel module APIs and security patches force frequent upgrades, making them less practical for real-world deployments.

Generality vs. Specialization. While Linux targets general scenarios, recent patches and features witness that innovations are primarily driven by servers and the cloud, which even hamper the performance of other scenarios [89, 103]. Moreover, the growing diversity of devices with rich peripherals and varied scenarios call for specialized strategies to exploit the performance and energy efficiency headroom, such as allocating resources according to the quality of service [20, 21] or minimizing space usage [119]. However, such strategies require significant engineering effort to customize the kernel due to the inherent tight coupling of kernel modules. While there is much effort [58, 66, 78, 84, 93] to improve customizability, it is hard to integrate them into the mainstream kernel.

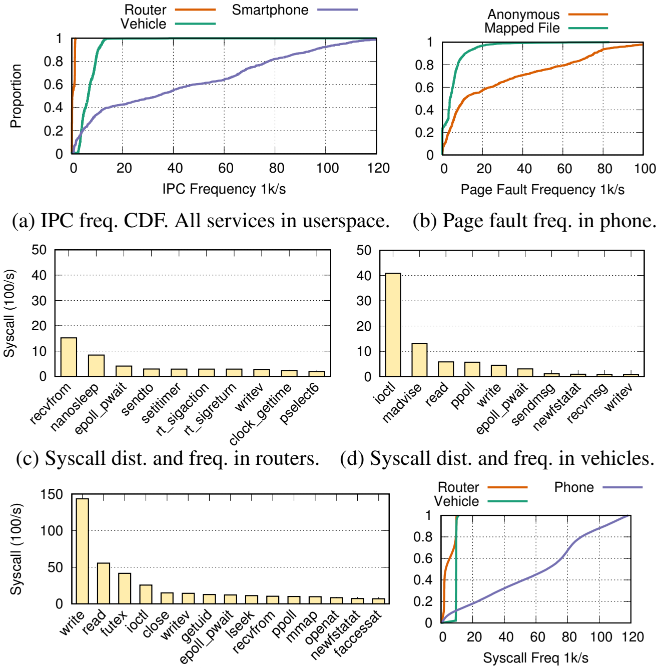
Customization vs. Evolution. Another issue is evolving the custom code. Synchronizing with upstream requires significant effort to reapply the changes, while not synchronizing may expose the system to security vulnerabilities. Years of production experience suggest that it is expensive due to the frequent changes in kernel internal APIs, and performance regressions require substantial effort to locate and even redesign the entire patches. This severely limits customizability in real-world deployments. Hence, a massive amount of products on the market are still running Linux 2.6 [50, 51, 117], which reached End-of-Life (EOL) 7 years ago [114] and has many known security vulnerabilities [24, 117].

3 Revisiting Microkernel for Going General

3.1 Microkernel at Scale

Deploying a microkernel in emerging scenarios poses challenges in both performance and compatibility. Figure 1 presents the observed characteristics of emerging scenarios from deploying *HM* in productions. For routers, we collected data directly from the production environment. For vehicles and phones, we replayed a typical usage (lasting 24 hours) derived from recorded massive amount of real-world executions at scale (anonymous and with user consent).

Observation 1: IPC frequency increases rapidly in emerging scenarios. Figure 1a shows the IPC frequency CDF in *HM* when configuring all OS services to be isolated in userspace. Smartphones (avg. 41k/s) and vehicles (7k/s) have a much higher IPC frequency than routers (0.6k/s, more similar to domain-specific scenarios). Figure 1b, 1e, and 1f illustrate it by showing the minor (i.e., not from disk/device)



(a) IPC freq. CDF. All services in userspace. (b) Page fault freq. in phone.

(c) Syscall dist. and freq. in routers. (d) Syscall dist. and freq. in vehicles.

(e) Syscall dist. and freq. in smartphones. (f) Syscall freq. CDF.

Figure 1: Characteristics of emerging scenarios obtained from the deployment of *HM* in tens of millions of devices. All OS services in *HM* are configured to be well-isolated in userspace.

page faults' frequency and the distribution and frequency of syscalls in phones. As shown in the figures, the high IPC frequency is not only caused by the higher syscall frequency (61k/s, 13x higher than routers), but also by invoking massive amounts of file operations (IPC to the FS), and triggering numerous page faults on memory-mapped files (5k/s), which requires an additional IPC roundtrip between the memory manager and the FS. Hence, we should not only optimize IPC performance but also minimize the IPC frequency.

Observation 2: Distributed multi-server causes state double bookkeeping. The minimality principle determines that there is no centralized repository for shared objects, such as the file descriptor (fd) and page caches, and distributes them in multiple places. However, as shown in Figure 1c-1e, applications in emerging scenarios frequently invoke functions like `poll` that rely on the centralized management of such states. Figure 2 further presents the CPU flame graph of application startup, which relies heavily on the performance of file mapping and is crucial to the user experience [45]. As marked in the figure, 16% of the time is spent on handling page cache misses, which introduces an additional IPC roundtrip and is 2x slower than Linux. Moreover, the double bookkeeping of page caches consumes an additional 50MB of memory on top of the 120MB base (FS+mem) in smartphones.

Observation 3: Capabilities inhibit efficient cooperation. Capabilities, which hide the kernel objects behind them, introduce significant performance overhead due to the frequent updating of some kernel objects (e.g., the page table) managed outside the kernel and inhibit efficient cooperation between them. For example, this may cause the handling of anonymous page faults 3.4x slower than Linux, which frequently occurs in smartphones (avg. 27k/s, 80% of minor page faults in Figure 1b) and adds a non-trivial overhead to the app startup time (4% in Figure 2).

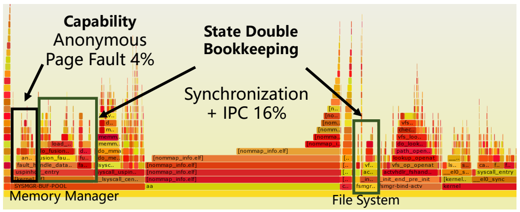


Figure 2: CPU flame graph of smartphone app startup in *HM*. Services coalescing and kernel paging are disabled.

Observation 4: Eco-compatibility requires more than POSIX compliance. Many SOTA microkernels achieve a minimal subset of POSIX compliance by providing custom runtime libraries [47] that link directly to applications and generate IPC to OS services. However, it faces deployment issues of being not binary compatible and requiring a customized building environment. Moreover, since Linux uses file as a unified interface, which no longer exists in the microkernel, it is also challenging to implement efficient fd multiplexing like `poll` and vectored syscalls like `ioctl`, which are frequently used in emerging scenarios as shown in Figure 1c-1e.

Observation 5: Deployment in emerging scenarios requires efficient driver reuse. When deploying *HM* on smartphones, we observe a massive increase in the number of drivers required to function correctly. For routers, fewer than 20 drivers are required (primarily maintained in-house), which increases to more than 700 for vehicles and phones. Our estimates indicate that it would take more than 5,000 person-years to rewrite those drivers, and it takes time to get mature and keep evolving. Thus, reusing device drivers is a more reasonable option. However, previous work, including transplanting the runtime environment of drivers [3, 17, 32, 41, 118] and using virtual machines [72], faces compatibility, engineering effort, and performance challenges (discussed in section 5.2).

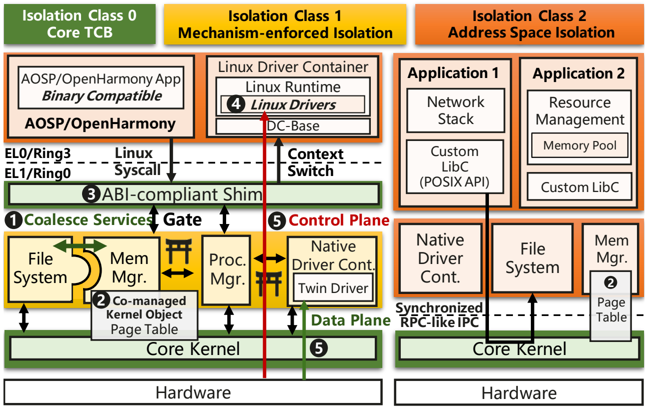
3.2 Overview of HongMeng

HM respects the core design principles of microkernels but not to the extreme, with careful compromises to address the performance and compatibility challenges in emerging scenarios. We summarize *HM*'s design decisions in Table 1 and list design principles below. Figure 3 shows *HM*'s overview.

Principle 1: Retain minimality. The security, reliability, and extensibility of microkernels derive from three fundamental architectural design principles, including separating policy and mechanism, decoupling and isolating OS services, and enforcing fine-grained access control. Hybrid kernels also enforce minimality through code decoupling but without proper isolation. Thus, it fails to inherit the major benefits of mi-

Table 1: Design decisions of HongMeng.

	SOTA Microkernels	Hybrid Kernels	HongMeng's Design
Minimality	Minimal Kernel	Code Decoupling	**Retained:** Minimal microkernel with isolated, least-privileged OS services.
IPC	IPC w/ Fastpath	Function Call	**Enhanced:** Synchronous RPC addresses resource alloc./exhaustion/acct. issues.
Isolation	Userspace Services	Coalesce w/ Kernel	**Flexibilized:** Differentiated isolation classes for tailored isolation and performance.
Composition	Static Multi-server	Static Single Server	**Flexibilized:** Flexible composition to accommodate diverse scenarios.
Access Control	Capability-based	Object Manager	**Extended:** Address tokens enable efficient kernel objects co-management.
Memory	Paging in Userspace	Paging in Kernel	**Enhanced:** Centralized management in a service with policy-free paging in kernel.
App Interfaces	POSIX-compliant	POSIX+BSD/Win	**Extended:** Linux API/ABI compatible via an ABI-compliant shim.
Device Driver	Transplanting/VM	Native Driver	**Enhanced:** Reusing Linux drivers efficiently via driver container with twin drivers.



(a) Smartphone (b) Smart Router

Figure 3: HongMeng overview. (a) and (b) show its composition in smartphones and routers. Different colors imply different isolation classes. ❶ coalesces coupled services. Address tokens enable kernel objects co-management ❷. ABI-compliant shim ❸ enables binary compatibility. Driver container ❹ reuses Linux drivers efficiently via data/control plane separation ❺.

crokernels. Therefore, while emphasizing compatibility and performance, *HM* respects the architectural design principles of microkernels.

HM keeps only minimal and necessary functionality in the core kernel, including thread scheduler, serial and timer drivers, and access control. All other functionality is implemented in isolated OS services, such as process/memory manager, drivers, and FS. Moreover, *HM* adopts fine-grained access control to preserve the least privilege principle. Services can only access strictly restricted resources (kernel objects) necessary for functionality. As such, *HM* inherits the security, reliability, and extensibility of microkernels.

> **Retained:** *Minimal microkernel with well-isolated and least-privileged OS services.*

Principle 2: Prioritize performance. The promising benefits of microkernels are compromised by architecture-inherent performance issues in emerging scenarios. Therefore, instead of enforcing uniform but overly strong isolation, *HM* provides structural support for assembling the system to satisfy both the performance and the security requirements. In particular, besides adopting an RPC-like fastpath that addresses the resource allocation/exhaustion/accounting issues (section 4.1), *HM* proposes differentiated isolation classes to reduce IPC overhead by relaxing the isolation between trusted OS services (section 4.2). *HM* also coalesces tightly coupled OS services (❶ in Figure 3) to minimize the IPC frequency in performance-demanding scenarios (section 4.3). Moreover, *HM* enables efficient kernel objects co-management (❷) by supplementing capabilities with address tokens (section 4.4), which facilitates policy-free in-kernel paging of anonymous memory (section 4.5).

> **Flexibilized:** *Prioritize performance by providing structural supports for flexible assembly to adapt to diverse scenarios.*

Principle 3: Maximizing eco-compatibility. *HM* integrates with existing software ecosystems by achieving Linux ABI compliance through a shim (❸) that redirects all Linux syscalls to appropriate OS services and serves as a central repository to store and translate Linux abstractions (e.g., fd) to efficiently support functions like `poll` (section 5.1). Moreover, *HM* reuses unmodified Linux device drivers via driver container (❹), which provides the necessary runtime derived directly from the mainline Linux with minor engineering effort (section 5.2). *HM* further improves drivers' performance by exploiting control and data plane separation (❺).

> **Enhanced:** *Maximize compatibility by achieving Linux API/ABI-compliant and performant driver reuse.*

***HM*'s Threat Model.** *HM* retains the architectural design principles of microkernels, thus maintaining a similar threat model to SOTA microkernels, which prevents malicious applications and OS services from accessing other's memory and ensures the confidentiality, integrity, and availability (CIA) properties of data, with the following differences.

First, since applications in emerging scenarios require centralized memory management for compatibility reasons (section 4.5), the memory manager (the only exception), including its coalesced services (only FS in phones on deployment), can inevitably access applications' address spaces. Besides, in safety-critical scenarios where memory is self-managed, *HM* does not create such a centralized memory manager.

Moreover, for the sake of performance, there are compromises on additional attack surfaces (section 4.2), different partitioning of failure domains (section 4.3), and additional data leakage possibilities on carefully selected objects (will not corrupt the kernel, section 4.4). The detailed security design will be discussed in the corresponding section.

4 Performance Design of HongMeng

4.1 Synchronous RPC-like IPC Fastpath

Microkernels use IPC to invoke OS services. A long line of research has proposed numerous optimizations to minimize IPC overhead. However, when applying them to emerging scenarios, we encountered several severe issues, either previously neglected or caused by changed assumptions. *HM* carefully addresses these issues, as summarized in Table 2.

Table 2: Comparison of IPC in *HM*.

	IPC Fastpath	Migration	HongMeng IPC
Bypass Scheduling	Yes	Yes	Yes
Reduced Switches	N/A	Registers	Reg./Address Space/Priv.
Resource Allocation	Pre-alloc	Pre-alloc	Pre-bind & Adaptive
Resource Exhaustion	Blocked	Blocked	Reserved for Reclaiming
Resource Accounting	Temporal	Temporal	Temp./Energy/Memory

Synchronous RPC or Asynchronous IPC. IPC typically assumes *symmetric endpoints* with the same execution model. Therefore, previous work suggests that asynchronous IPC can avoid serialization on multicore [30], allowing both endpoints to continue execution without blocking. However, in emerging scenarios, we observe that most IPCs are procedure calls, where the caller and callee can be clearly identified. Furthermore, OS services are mostly invoked passively rather than working continuously, and most subsequent operations of the application depend on the results of the procedure call. Therefore, synchronous Remote Procedure Call (RPC) is a more appropriate abstraction for service invocations.

HM adopts an RPC-like thread migration [33, 94] as the IPC fastpath for service invocations. When sending an IPC, the core kernel performs a direct switch (bypassing scheduling, similar to prior work [10, 30, 49, 67, 70]) and switches only the stack/instruction pointer (avoids switching other registers) as well as the protection domain. Specifically, *HM* requires OS services to register a handler function as the entry point and to prepare an execution stack pool. When an application invokes a service, the core kernel records the caller's stack/instruction pointer in an invocation stack and switches to the handler function with the prepared execution stack. On return, *HM* pops an entry from the invocation stack and switches to the caller. The IPC arguments are primarily passed through registers, with additional arguments passed through shared memory.

Performance gap. Although *HM* bypasses scheduling and avoids switching registers, it still faces non-trivial performance degradation due to privilege level/address space switching and cache/TLB pollution [9, 30, 49, 86] (accounts for 50% of total IPC cost). We further bridge this performance gap using differentiated isolation classes in section 4.2.

Resource Allocation. The *memory footprint of IPC has been largely neglected* by previous work. However, due to the extremely high IPC frequency and massive number of connections (>1k threads simultaneously) in emerging scenarios like smartphones, we find it essential to consider IPC's memory footprint in production, as it can cause severe problems such as out-of-memory (OOM) and even system hangs. Although each IPC connection in *HM* requires only an individual execution stack (rather than a full-fledged thread with all related data structures), its memory footprint is still non-trivial, given the massive amount of IPCs.

Previous work pre-allocates a thread/stack pool of a fixed size and binds it to connections. However, its size is hard to decide due to the diversity and dynamism of workloads, including the number of running threads and requirements for different OS services. A large pool would quickly drain the memory, while dynamic allocation on connection introduces runtime overhead on the critical path of IPC. We initially tried to prepare and bind stacks in each OS service for each thread on creation. However, we quickly realized that the problem still exists because some services are barely used by some threads (wasted), and there exist many IPC chains (to another OS service) that need another stack.

Therefore, *HM* strikes a sweet spot by *pre-binding stacks* in frequently-used OS services (e.g., process/memory manager and FS) for each thread while still maintaining a stack pool whose size is *adjusted adaptively* at runtime. When the remaining stacks fall below a threshold, the OS service will allocate more to reduce synchronous allocation. *HM* further reduces its memory footprint by reusing the same stack when calling the same service (e.g., ABA-like call) in an IPC chain.

Resource Exhaustion. IPC *can fail due to resource exhaustion*. Specifically, when the stack pool runs out while OOM occurs, OS services cannot allocate a new stack to process the IPC request. However, apps cannot handle such an error (not existing in a monolithic kernel). Therefore, such requests are queued (blocked) in SOTA microkernels, which may cause severe issues like circular wait and even system hangs.

An intuitive approach is to send another IPC to the memory manager to reclaim some memory synchronously. However, we find that under such a scenario (already OOM), the IPC to the memory manager is likely to fail again. Such a failure is likely to occur in emerging scenarios where workloads are non-deterministic and heavy loads occur frequently (e.g., opening multiple apps simultaneously).

HM mitigates this by reserving an individual stack pool. Once OOM occurs, the kernel will synchronously IPC to the memory manager using the pool for memory reclaim (repeatedly) until the user's IPC succeeds. Thus, applications' IPCs are guaranteed to be handled correctly.

Resource Accounting. IPC *assumes a different execution entity* when handling requests, thus attributing the consumed resource to OS services. However, since competing applications in emerging scenarios require a clear accounting of resources, the consumed resource should be precisely accounted to the caller app. Previous work achieves temporal isolation by inheriting the caller's scheduling context [70, 80]. However, emerging scenarios also require an accounting of both energy and memory consumption. Therefore, *HM* records the

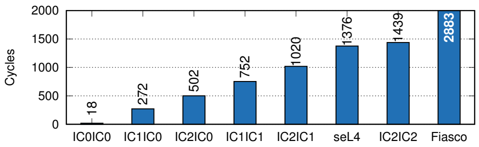


Figure 4: Round-trip IPC latency between ICx & ICy (`ICxICy`) in Raspberry Pi 4b. `IC0` includes the core kernel. `IC2` includes user apps. Zircon cannot run on Pi4b and is several times slower [49].

identity of the user app (root caller in the IPC chain), and attributes the consumed resources to it when handling IPC.

Decision: *Supplement async./sync. IPC with an RPC-like fastpath for invoking OS services while carefully addressing the resource allocation/exhaustion/accounting issues.*

4.2 Differentiated Isolation Classes

Isolation of OS Services. Placing all OS services in userspace may improve security, but it fails to meet performance requirements in emerging scenarios. We observe that *not all services require the same class of isolation*. In particular, mature, verified, and performance-critical OS services can be subjected to weaker isolation for optimal performance in practical deployments. Moreover, rapidly evolving services may frequently introduce bugs and vulnerabilities, thus requiring more robust isolation to prevent kernel corruption. OS services with large codebases and cumbersome features, such as drivers, require isolation to reduce the trusted computing base (TCB).

Therefore, *HM* adopts differentiated isolation classes (IC) to provide tailored isolation and performance for different OS services. Specifically, isolation classes *classify services and define the isolation between them*. Figure 4 shows the round-trip IPC latency between services at different isolation classes, compared to seL4 [67] and Fiasco.OC [69].

Isolation Class 0: Core TCB. IC0 applies to carefully verified, extremely performance-critical, trusted OS services, such as the ABI-compliant shim (the only IC0 service in deployment). No isolation is enforced between these services and the kernel. Therefore, IPCs are all indirect function calls.

IC0 Threat Model: IC0 is part of the core TCB, and any compromised IC0 services can arbitrarily read and modify others' memory. Therefore, placing services at IC0 should be carefully validated to avoid core kernel corruption.

Isolation Class 1: Mechanism-enforced Isolation. IC1 applies to performance-critical and validated OS services. Inspired by previous intra-kernel isolation approaches [11, 49, 59, 71, 112, 120], *HM* places these services in the kernel space and uses mechanisms to enforce isolation between services. Specifically, *HM* carefully divides the kernel address space into distinct domains and assigns each service a unique domain (IC0/core kernel also resides in a unique domain). *HM* uses ARM watchpoint [63] and Intel PKS [60] to prevent cross-domain memory access. Moreover, since IC1 services run in kernel space, they can execute privileged instructions. To prevent this, *HM* adopts binary-scanning and lightweight control-flow integrity (CFI, leveraging ARM pointer authentication (PA) [77]) to ensure services cannot execute illegal control flows that contain privileged instructions, and uses a secure monitor [49, 108] to guard the page table against code injection, which also traps any privileged instruction through *VM Exits* as a complement to CFI.

IPC between IC1 services (or to IC0) will enter a gate in the core kernel that performs a minimal context switch (switch instruction and stack pointers, w/o address space switching and scheduling) and configures the hardware to switch domains (take only a few cycles). Such a gate cannot be bypassed since domain switches require privileged instructions. Therefore, the IPC overhead is significantly reduced. As shown in Figure 4, it reduces the IPC latency between IC1 services by 50% compared to userspace services (IC2IC2).

IC1 Threat Model: IC1's threat model differs from other multi-server microkernels by assuming the correctness, soundness, and security of the applied isolation mechanism, which does expose some additional attack surfaces. For example, there are new attacks on ARM PA emerged recently [22]. Besides that, IC1 shares the same threat model, which prohibits any compromised service from reading/writing the core kernel's memory (and other OS services') and executing privileged instructions.

Isolation Class 2: Address Space Isolation. IC2 applies to non-performance-critical services or those containing third-party code (e.g., Linux drivers), enforced by address space and privilege isolation. IPC between IC2 services in *HM* (IC2IC2) is slightly slower than in seL4, mainly due to fine-grained locking, which is essential for scaling to multi-core processes under real-world loads.

IC2 Threat Model: IC2 shares exactly the same threat model as other multi-server microkernels.

Although IC1 significantly reduces the IPC overhead, it also introduces additional attack surfaces and has resource limitations (e.g., 16 domains in Intel PKS, 4 domains in ARM Watchpoint). Therefore, only performance-critical and validated OS services are placed at IC1. In addition, *HM* can quickly move all services back to IC2 if new attacks emerge. We further discuss deployment experiences on configuring isolation classes in section 4.3. Moreover, IC0/1 does not imply coupling to the kernel. The isolation classes allow for configurable isolation decisions during deployment rather than an isolation assumption during development. Different scenarios use different configurations, as shown in Figure 3.

Decision: *Not all OS services require the same class of isolation. Adopt differentiated isolation classes to relax isolation between trusted services for improved performance.*

4.3 Flexible Composition

Partitioning of OS Services. Although intuitively, OS services should be well-decoupled, e.g., FS and memory manager, we observe that *OS services are asymmetric* since some functionalities require close cooperation between specific services. For example, the FS is not the only entrance to accessing a file. POSIX supports file mapping that reads files through the memory manager, and it frequently appears on the critical path and significantly affects the user experience.

The isolation classes enforce the same isolation between same-class OS services. Therefore, without further structural support, *HM* still faces performance degradation compared to the monolithic kernel. First, the frequently invoked IPCs between tightly coupled services still cause noticeable overhead (20% in page fault handling for memory-mapped files) even in IC1 (kernel space). Moreover, double bookkeeping of shared states, such as page caches, introduces significant memory footprint and synchronization overhead. Finally, there is no global view of page caches to guide resource recycling (e.g., Least Recently Used, LRU).

To bridge the performance gap, *HM* adopts a configurable approach that allows coalescing tightly coupled OS services in performance-demanding scenarios, trading off isolation for better performance, while retaining the ability to separate them in safety-critical scenarios. When coalesced, no isolation is enforced, and IPCs between two services become function calls, while others remain as they are (well-isolated).

Coalescing also enables efficient co-management of page caches. Instead of maintaining them in both the FS and the memory manager, they can be co-managed when coalesced. It eliminates double bookkeeping and synchronization overhead and provides a global view for efficient recycling. To retain the ability to separate them, we provide a mechanism to automatically convert accesses of shared page caches into IPCs when separated. However, it will introduce non-trivial overhead. Therefore, in deployment, we implement both versions (sep./shr.) manually and enable them accordingly.

Performance. As shown in Table 3, when coalescing the FS with the memory manager, replacing the IPC reduces the latency of handling page faults caused by page cache misses by 20% (*Sep. Cache*). It can be further reduced by 30% (*Shr. Cache*) and achieves similar performance with Linux (5.10, detailed in section 6.2) by co-managing the shared page caches. Coalescing also speeds up the write throughput of *tmpfs* by 40%. Moreover, the memory footprint of coalesced services is reduced by 37% (FS+memory) in smartphones.

Security. The coalesced services are in a single failure domain, whose threat model (as a whole) remains the same as the isolation class in which it resides. Therefore, any failed or compromised service can only corrupt its coalesced services, which is also the primary compromise for performance. Hence, service coalescing should be carefully evaluated. In practice, due to the extremely high frequency of file operations in smartphones (Figure 1e), their performance targets can only be achieved by coalescing the FS with the memory manager. However, the security is still improved (isolated from other services) compared with monolithic kernels.

Deployment Experiences. Together with the differentiated isolation classes, *HM* enables flexible composition, allowing the key components to be assembled flexibly (user-space or kernel-space, separated or coalesced), enabling exploration of tradeoffs between isolation and performance according to scenarios' requirements, and the ability to scale from routers to smartphones with the same code base. The evolution of *HM* witnesses such explorations. Initially, all services were isolated at IC2. To meet the performance goal, we carefully assemble the system to retain most security properties by preserving the following rules.

Table 3: Performance improved by coalescing the FS service and the memory manager in the big core of Kirin9000 [57].

	Separated	**Coalesced**	**Linux**
Page Fault (Cycles)	7092	5290 (Sep. Cache) 3785 (Shr. Cache)	3432
Tmpfs Write (MB/s)	1492	2067	2133
Memory Footprint (MB)	190	120	N/A

Table 4: Address tokens support most operations of capabilities and allow direct access, except restricting fine-grained operation and chain revocation.

	Capabilities	**Address Tokens**
Token	CSlot id	Mapped Address
Access	Delegate to Kernel	Direct(RW)/`writev`(RO)
Ownership	Caps in CNode	Mapped Pages
Grant	Move to CNode	Map Page to VSpace
Revoke	Remove from CNode	Unmap Page
Chain Revoke	Support	No support
Security	Monitor all operations	Restrictions on mapped Obj.

First, due to the additional attack surfaces, IC1 services cannot contain any third-party code. Thus, although some drivers are also performance-critical, we kept them at IC2 and sped up via control/data plane separation (section 5.2). Second, service coalescing, especially with the memory manager, undeniably weakens isolation and security (though still improved compared with monolithic kernels). Therefore, we leave it configurable and only enable it on phones. Moreover, IC0 not only increases the core TCB but also has strict memory limitations and non-blocking requirements. Thus, in practice, *HM* only places the ABI shim (which can be opted out) in IC0. Section 6.1 details the configurations.

Decision: *OS services are asymmetric. Coalesce tightly coupled OS services and flexibly assemble the system to meet diverse requirements in various scenarios.*

4.4 Address Token-based Access Control

SOTA microkernels make all kernel objects explicit and subject to capability-based access control [30] to preserve the principle of least privileged, which is primarily implemented in a partitioned fashion that keeps a token (typically a slot ID) in userspace representing the permission to access a kernel object. However, we encountered severe performance issues when deploying it in emerging scenarios.

Clear relationship but slow access. Although capabilities are effective in describing the *external relationships* of kernel objects, i.e., the authorization chain, *accessing their internal* *contents* requires sending the token with the operations to the core kernel, which introduces non-trivial performance overhead due to privilege switches and accesses to multiple metadata tables. Kernel objects are hidden behind the capabilities and are only accessible by the core kernel. However, due to the minimality principle, the content of some kernel objects (e.g., page tables) should be frequently updated by OS services outside the core kernel, for which partitioned capabilities are no longer efficient.

Some microkernels speed up access by mapping specific objects to userspace. However, they can only be applied to few limited objects (e.g., memory objects [30, 67], part of the thread control block [3, 9, 76], and kernel interface page [76]) for security and lack the ability to synchronize data correctly, which inhibits the cooperation between the kernel and OS services. To address these issues, *HM* proposes a generalized address token-based approach that can be applied to a broader range of objects, enabling efficient co-management.

Specifically, as shown in Figure 5, each kernel object is placed on a unique physical page in *HM*. Granting a kernel object to an OS service requires mapping such a page to its address space (❶). Thus, the mapped address serves as the token to access the kernel object directly from the hardware without involving the kernel (unwillingly). Kernel objects can be granted (mapped) as read-only (RO) or read-write (RW). OS services can read RO kernel objects without kernel involvement. To update them, a new syscall, `writev`, should be used, passing the target address with the updated value, and the core kernel will verify permissions by referring to the kernel object's metadata (❷). For RW kernel objects, once granted, can be updated by OS services without kernel involvement (❸). Moreover, for objects smaller than a page with the same property (permission) and a similar life cycle, *HM* batches these objects into a single page upon allocation, allowing them to be granted and revoked collectively.

Functionality. Address tokens support most operations of capabilities, as shown in Table 4 (compared to seL4 [107], Zircon has similar functionality [37]), with two exceptions. First, address tokens cannot restrict fine-grained operations once granted, which weakens security and exposes additional attack surfaces. Besides, capabilities store the detailed relationship, allowing chain revocation, which address tokens do not support due to implicit ownership. Nevertheless, address tokens are only used by selected co-managed kernel objects. The attack surfaces are carefully mitigated (discuss below). Moreover, due to the centralized resource management, kernel objects have specific owners (will not be granted to others). Thus, chain revocation is rarely used.

Security. Once an address token is granted to an OS service, the kernel cannot monitor the subsequent operations. *HM* mitigates this by restricting the objects mapped to userspace (enforced by static analysis). Only kernel objects that exclusively contain the values of certain variables in kernel-preserved structures (pointers are not allowed to prevent the time-to-check to time-to-use attack) are mapped RW (e.g., PCache in section 4.5), ensuring they will not corrupt the kernel with incorrect or inconsistent data. The rest of the kernel's internal states (e.g., pointers and reference counters) can only be mapped RO or not granted at all to prevent it from being corrupted. *HM* further applies a sanity check when reading from RW objects. It does introduce some attack surfaces by leaking kernel-internal information, which can be mitigated by hardware encryption like ARM PA.

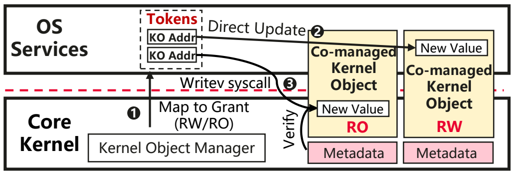

Figure 5: Address token-based access control in *HM*. ❶ Map kernel object's page to grant. ❷ Direct access to RW objects. ❸ Use `writev` to update RO objects, verified by the kernel.

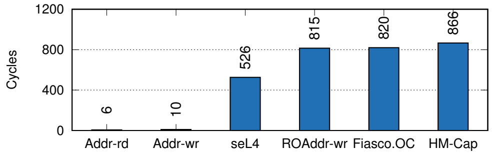

Figure 6: Latency of accessing kernel objects on Raspberry Pi 4b. *Addr-rd/wr* represent address tokens in *HM*. *ROAddr-wr* represents writing to read-only objects in *HM*.

Synchronization. There are two approaches to sharing data between OS services and the kernel leveraging address tokens. First, OS services and the kernel can exchange messages asynchronously (message-passing). For example, PCache in section 4.5 sends pre-allocated pages to the kernel for future kernel paging. *HM* uses a lock-free ring buffer to synchronize the data correctly. Besides, OS services can apply in-place updates to the objects (e.g., VSpace in section 4.5, which stores the memory layout) that the kernel may read concurrently. *HM* adopts fine-grained locking to ensure correctness. However, it may block the kernel when the service is preempted while executing critical sections. Therefore, the kernel can only use the `trylock` operation on RW-mapped objects. If it fails, *HM* will redirect to the OS services (slow path) to finish the procedure (e.g., paging in section 4.5).

Performance. Figure 6 compares the latency of accessing kernel objects after applying address tokens. The reading and writing (to RW) latencies are significantly reduced compared with capability-based approaches. However, the latency of writing RO objects is slower than seL4 on RPi4b, mainly due to the use of `AT` instruction on ARM to translate the address and check the permissions, which is slow on RPi4b (yet optimized in the advanced smartphone chips).

Usage Scenario. For security concerns (see above), address tokens are OS-internal abstractions that supplement the capabilities for efficient co-management with OS services. Specifically, besides enabling direct updates to kernel objects managed by services, it allows them to read internal states (e.g., poll list in section 5.1) without kernel involvement, sim-

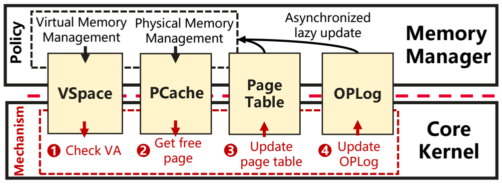

Figure 7: Policy-free kernel paging in *HM*. On page fault, the kernel checks the address ❶ and, if anonymous, ❷/❸ maps a pre-allocated page, and ❹ records an OPLog.

ilar to virtual dynamic shared objects (vDSO) in Linux [82]. It also allows handling performance-critical events (e.g., page faults in section 4.5) entirely in the kernel without violating the minimality principle by making policy-driven decisions in advance (by services) and communicating with the core kernel through co-managed objects.

Decision: *Capabilities that hide kernel objects behind interpose kernel (unwillingly) on the data plane. Supplement with address tokens for efficient co-management.*

4.5 Policy-free Kernel Paging

Centralized Management vs. Distributed Pager. Some SOTA microkernels (e.g., seL4) delegate memory management to applications with individual custom pagers. However, since competing applications in emerging scenarios require coordinated and centralized management, we found it difficult to implement certain features efficiently that require a global view of memory with decentralized pagers, such as the control group (cgroup) and memory recycling. Therefore, *HM* manages the memory through a centralized memory manager. For minimality, the memory manager is outside the core kernel, which manages the physical and virtual memory and handles page faults for all applications and OS services.

Slow userspace paging. We observe a significant performance degradation in performance-critical scenarios (e.g., app startup in Figure 2) due to the slow paging procedure of anonymous memory (e.g., stack/heap), which occurs frequently in smartphones, as shown in Figure 1b. The degradation is primarily due to the extra round-trip from the kernel to the pager. Specifically, after throwing a page fault exception, the kernel issues an IPC to the pager, which checks the address and assigns a new page, then returns to the kernel to update the page table before finally returning to the application. Such a round-trip is inevitable because page fault handling involves a policy of deciding whether and which physical page to map, which should be kept out of the kernel [27], while the exceptions are handled inside the kernel, and the page table is hidden behind a capability in the kernel.

To improve the performance of handling page faults of anonymous memory, *HM* makes policy-driven decisions in advance, and leaves a policy-free page fault handling mechanism in the core kernel. Thus, it eliminates the extra IPC round-trip on the critical path. Specifically, the memory manager provides the address range of anonymous memory along with several pre-allocated physical pages. As shown in Figure 7, if the page fault is triggered within the range (❶), the core kernel can map it directly to a pre-allocated physical page (❷ and ❸), and record an operation log (OPLog, ❹), which the memory manager will use to asynchronously update its internal states (e.g., the counter of the mapped anonymous pages). Otherwise, if the address is outside the specified range (not performance-critical) or the pre-allocated pages are exhausted, the core kernel will make an IPC to the memory manager. The involved kernel objects are co-managed by the memory manager via address tokens, including the page table, the operation log, the VSpace, which records the layout of virtual memory space for identifying anonymous memory, and the PCache, which stores the pre-allocated pages.

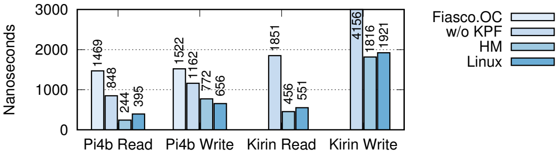

Figure 8: Page fault latency of private anonymous memory. Read is optimized with zero page. seL4 is not included since it does not support demand paging by default.

Compromises. By making policy-driven decisions in advance, the policies (whether/which to map) are still kept outside the core kernel. The only compromised ability is to change the policy after being pre-allocated to the PCache, which reduces flexibility. PCache also introduces some additional memory footprints. However, since PCache can be periodically replenished (off the critical path), its size remains relatively small, making these tradeoffs acceptable.

Performance. Figure 8 shows the reduced latency of kernel paging (KPF) in *HM*. *HM* reduces read/write latency by 72%/33% on Pi4b and 75%/55% on Kirin9000 (little core), making it even slightly shorter than Linux (6.1 on Pi4b and 5.10 on Kirin9000). seL4 is not included since it requires a custom pager and does not support demand paging by default. The round-trip (to the pager) of fault handling takes about 140ns on Pi4b (measured using sel4bench), which makes it significantly slower than Linux.

Decision: *Enable policy-free kernel paging by preempting policy-driven decisions.*

5 Compatibility Design of HongMeng

5.1 Linux ABI Compatibility

Deploying in emerging scenarios requires Linux ABI compatibility, which poses challenges in multi-server microkernels. K42 [68] achieves Linux ABI compatibility through trap reflection, which redirects syscalls back to the k42 library loaded into the application's address space. However, it introduces significant performance overhead due to the additional roundtrip to the kernel [2] and also faces implementation challenges [29, 111] due to keeping states in userspace. FreeBSD [36] and Windows (WSL1 [87]) also achieve partial Linux ABI compatibility through syscall emulation. However, since all their OS services reside in kernel space, the emulation layer can map abstractions like fd directly to their internal states and efficiently support functions like `fork` and `poll`, which is challenging in multi-server microkernels.

Syscall Redirection. *HM* achieves Linux ABI compatibility by placing an ABI-compliant shim in IC0 (kernel space), which redirects Linux syscalls into IPCs towards appropriate OS services (identified by syscall number, with native syscalls bypassing the shim), as illustrated in Figure 3a. In addition, the shim is optional. In scenarios where applications are predominantly custom, *HM* replaces the shim with POSIX-compliant libraries, as shown in Figure 3b.

Centralized States. Apart from binary compatibility, microkernels no longer have a central repository for global states, such as the file descriptor (fd) table, making functions like fd multiplexing (i.e., polling) and syscalls like `fork`[2] challenging to implement. Specifically, the fd table is usually kept in the application's address space (only contains credentials verified by OS services). Thus, fd multiplexing requires mapping all waiting fd to a notification primitive and sending it to all related services. Moreover, syscalls like `fork` have to correctly assemble such distributed states in the userspace. It introduces significant complexity and performance overhead, primarily due to passing states from parent to child and the additional page faults caused by updating these copy-on-write states [8, 29]. Therefore, SOTA microkernels, including seL4, Fiasco, and Zircon, do not support `fork`, while `fork` in K42 is known to have severe performance issues [29, 111].

Therefore, the ABI-compliant shim in *HM* also serves as a central repository for global states like the fd table, enabling efficient implementation of both fd multiplexing like `poll` and syscalls like `fork`. Specifically, the shim maintains the fd table, which maps fd to credentials (used by OS services to identify the user). Therefore, implementing `poll` only requires maintaining a poll list within the shim, co-managed with OS services via address tokens. It also avoids copying the fd table in userspace when executing `fork`.

Vectored Syscalls. Although most of the syscall translations are achieved solely in the ABI-compliant shim, there are vectored syscalls [116] (e.g., `ioctl/fcntl`) that extend system APIs and allow custom extensions (for drivers/modules) via the file abstraction. *HM* redirects and handles them in the FS service (e.g., invoking driver containers in section 5.2).

Deployment Experiences. *HM* passes all the tests in the AOSP compatibility and vendor test suite (CTS/VTS [43, 44]), which examines both the kernel functionalities and driver behavior. Although most binaries can run out of the box, we observe that some apps rely on unstable/undocumented Linux behavior and fail to run on *HM*. For example, an application that depends on a specific `epoll` return order [95] fails to run on *HM* (it also fails with different Linux versions).

Decision: *Achieve Linux binary compatibility through ABI-compliant shim.*

5.2 Driver Container

Linux undeniably has the richest device driver ecosystem. Further, some drivers are not source-available, which makes porting challenging. Therefore, reusing Linux drivers is essential for widespread deployment.

Challenging practical and performant driver reuse. Previous work, including both transplantation [3, 17, 32, 41, 118] and VM-based methods [72], face challenges in *achieving high compatibility, reasonable engineering effort, and uncompromised performance simultaneously*. In particular, transplanting the runtime environment requires re-implementing all kernel APIs (KAPIs) used by drivers. Since some drivers use a large number of KAPIs, some of which are even constantly evolving, this approach faces challenges of compatibility and affordable engineering effort. In addition, reused drivers (with large untrusted code base) should be enforced with strict address space isolation for better security and to avoid license contamination [34], which also degrades performance. Reusing drivers through a virtual machine can achieve better compatibility with less human effort. However, it introduces issues including memory double management that causes extra memory footprint (crucial in memory-constrained scenarios like smartphones) and thread double scheduling that degrades performance due to the frequent use of asynchronous notifications in drivers.

HM reuses Linux drivers (Figure 9) through a driver container, which strikes to find a sweet spot between compatibility, engineering effort, and critical-path performance.

Compatibility. Inspired by LKL [101], UML [26], and SawMill [39], the Linux Driver Container (LDC) provides all necessary Linux KAPIs by reusing the Linux code base as a userspace runtime, allowing existing Linux drivers to run without modification. The main difference with LKL/UML/SawMill is that LDC reuses the driver rather than components like the file system and network stack. Thus, drivers should be able to access the hardware devices directly rather than redirecting to host drivers. Further, the runtime relies on *HM* for resource management. Therefore, all related functionalities, like the thread scheduler, are removed.

HM creates another device manager that manages both the Linux and the native driver containers (where the native drivers reside). Besides initializing driver containers, it registers entries (❶ in Figure 9) in the virtual file system (VFS) so that driver invocations through VFS (e.g., `ioctl` ❷) can be correctly redirected to the appropriate driver container (❸).

Using the LDC, *HM* has successfully reused over 700 device drivers from Linux, including all the needed ones for

[2] While there have been arguments that `fork` should be deprecated [8], popular frameworks like AOSP/OpenHarmony still use `fork`.

smartphones and vehicles to function correctly, such as camera, display, audio, NPU/GPU, and storage. Though most drivers can directly run out of the box, several exceptions exist. Since the LDC runs in userspace (IC2), drivers that use privileged instructions (e.g., `smc`) will trigger faults. They require binary rewrites or manual porting (for those frequently using privileged instructions, e.g., GIC) in the core kernel.

Engineering Effort. The Linux runtime in the LDC is derived directly from mainline Linux, with minor modifications to redirect several functionalities to the driver container base (DC-base in Figure 9) for proper execution. Therefore, the required engineering effort is minor. Specifically, we provide a virtual architecture and redirect the kthread/memory interfaces to *HM*. To make the drivers work correctly, DC-base creates a virtual timer and a virtual IRQ chip to provide the interrupt request and reserves a linear mapped space for functions like `virt_to_phys`. Compared to the VM-based method, which introduces double memory management and double thread scheduling, the driver container avoids these issues by redirecting and managing them in *HM*.

In practice, supporting long-term support (LTS) kernel distributions is sufficient for reusing most drivers (currently, *HM* supports 4.4, 4.19, and 5.10). In addition, since the Linux interfaces associated with the DC-base are relatively stable, only minor modifications are required to upgrade the Linux runtime. Upgrading from 4.19 to 5.10 requires less than 100 changes to the DC-base, most of which are minor modifications to the procedure names, arguments, and structures.

Critical Path Performance. The LDC is placed in IC2 (userspace) to preserve security (drivers have large untrusted code bases) and avoid license contamination. However, it introduces non-trivial overhead in driver-critical scenarios, such as app startup and camera. Therefore, *HM* applies control plane and data plane separation by creating a twin driver in the native driver container that handles I/O IRQs on the performance critical path (❹ in Figure 9). The twin driver rewrites the data handling procedure and can thus be enforced with weaker isolation (placed at IC1 in kernel space), resulting in significantly better performance. The control planes, which contain cumbersome procedures like init/suspend/resume, remain in the LDC (❺).

The twinned drivers synchronize the states (usually a variable) via IPC. Since the control plane is handled entirely in the LDC, the twin driver does not modify the states (I/O errors are redirected to the LDC). On initialization, the LDC passes device information to the native one to create the twin driver. When handling non-I/O IRQs and errors, the LDC synchronizes the updated states back to the twin driver. Unlike the transparent integration solely in LDC, which results in poor performance, the twin driver requires additional engineering effort to split and redirect interrupts and synchronize states. Therefore, the twin driver is used only for performance-critical drivers like the Universal Flash Storage (UFS) driver (others are integrated transparently w/o modification).

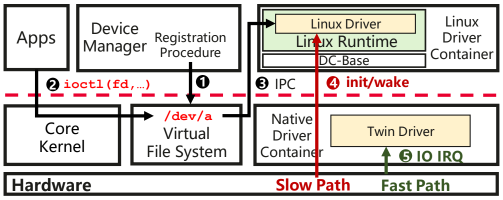

Figure 9: Drivers in *HM*. The device manager creates file nodes in the VFS ❶. VFS redirects invocations ❷ to drivers ❸. *HM* improves performance by separating the control ❹/data ❺ plane.

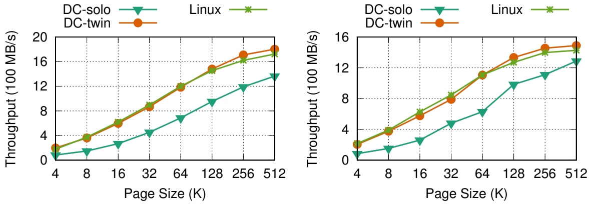

(a) BIO read.

(b) BIO write.

Figure 10: Block I/O throughput on Kirin9000. DC-twin applies data and control plane separation, while DC-solo does not.

Figure 10 shows the improved throughput in the UFS Block I/O benchmark. In the experiment, I/O requests are issued directly from the driver. DC-twin (applied data/control plane separation) achieves a similar throughput to Linux 5.10 and outperforms DC-solo (w/o separation) by 140% at 4K size.

Security. The LDC is almost a normal userspace (IC2) OS service in *HM*, with an additional ability to create a linear mapped space whose range is strictly restricted to its allocated memory (by only setting the present bit on the allocated pages). Thus, it shares the same threat model as IC2 OS services and userspace drivers in other microkernels. In addition, *HM* uses SMMU [5] to prevent DMA attacks, with its driver residing in an isolated native driver container.

Decision: *Reuse Linux device drivers efficiently through driver containers with control/data plane separation.*

6 HongMeng in the Wild

6.1 Implementation and Deployment

The core kernel of *HM* is implemented primarily in a confined subset of C, consisting of 90k lines of code (LoC), which includes the basic functionalities. All other OS services are decoupled and can be deployed individually, totaling over 1 million LoC. The *HM*'s build system can assemble the OS services based on detailed configurations specified for various scenarios, such as placing OS services in different isolation classes or coalescing some OS services.

HM has been deployed in tens of millions of devices in various emerging scenarios, which share the same code base but with different configurations. In safety-critical scenarios, such as smart vehicles (dashboard and entertainment system) and the trusted execution environment (TEE) of smartphones, security and strict isolation are prioritized over performance. In addition, applications are mostly customized

[1] Argument "`-P 1`" is omitted.

[2] *Norm.* shows the normalized performance. For throughput, use *HM*/Linux, for latency, use Linux/*HM*. The more the better.

and source-available. Therefore, *HM* places all OS services in IC2 (userspace) and exposes the POSIX API to applications through libraries. Moreover, *HM* achieves fault tolerance by introducing a driver micro-reboot in the TEE. Drivers in the TEE can be considered stateless since only re-initialization is required to recover a corrupted driver. With micro-reboot, the TEE can recover from driver corruption within hundreds of milliseconds, whereas a complete system reboot is required with a monolithic kernel. Fault tolerance for a broader range of scenarios (e.g., stateful OS services in rich-OS) requires additional efforts to store states and preserve their consistency, which we leave for future work.

In performance-demanding scenarios like smartphones, *HM* places the performance-critical OS services in IC1 (kernel space), including the process manager, memory manager, FS, and native driver container, and coalesces FS with the memory manager. The Linux driver container and other non-performance-critical OS services, such as CPU frequency governor and power manager, remain in IC2 (userspace).

6.2 Performance

We present the end-to-end performance comparison between *HM* and Linux in emerging scenarios, including smartphones (using Kirin9000 SoC [57]), smart vehicles, and smart routers, which existing microkernels fail to support. The compared Linux 5.10 counterparts are already highly optimized (used in prior products) rather than vanilla versions.

LMbench. We evaluate the basic OS functionalities using LMbench [85] on Kirin9000. Table 5 shows the results related to OS architecture. Compared to Linux (5.10), the context switching `lat_ctx` (32%) and networking (avg. 21%) are faster on *HM*, mainly due to the simplified handling procedure compared to Linux [89,96]. Memory operations perform similarly to Linux. Although `fork` still performs worse than Linux in the microbenchmark, we observe that the major overhead of `fork` in the real-world load comes from copying virtual memory areas (VMAs). It can be accelerated through parallelism, which reduces its overhead from 150ms to 60ms (in typical apps, close to 30ms in Linux). `Clone` (creating thread) is also 1x slower than Linux, mainly due to the additional IPCs between multiple OS services (especially the driver container in IC2) and the core kernel.

Geekbench. Figure 11c presents the normalized single-core results of the CPU-intensive Geekbench 5.3.2 [99]. By assembling the system to prioritize performance, *HM* achieves similar performance with Linux, with minor differences due to the different CPU frequency altering strategies.

Application Cold Startup Time. App startup time is critical to the user experience, stressing multiple OS services (e.g., reading from flash memory and creating threads) with extensive IPCs. Figure 11a shows the startup time of the top 30 AOSP apps on *HM*. The framework/app versions are the same on Linux and *HM*. As analyzed in section 3.1, the major overhead of microkernel in such scenarios comes from state double bookkeeping and slow paging, which *HM* eliminates. Therefore, the startup time is even 17% shorter (geometric mean) than Linux, mainly due to the lighter loads (see below) and the custom scheduling strategies.

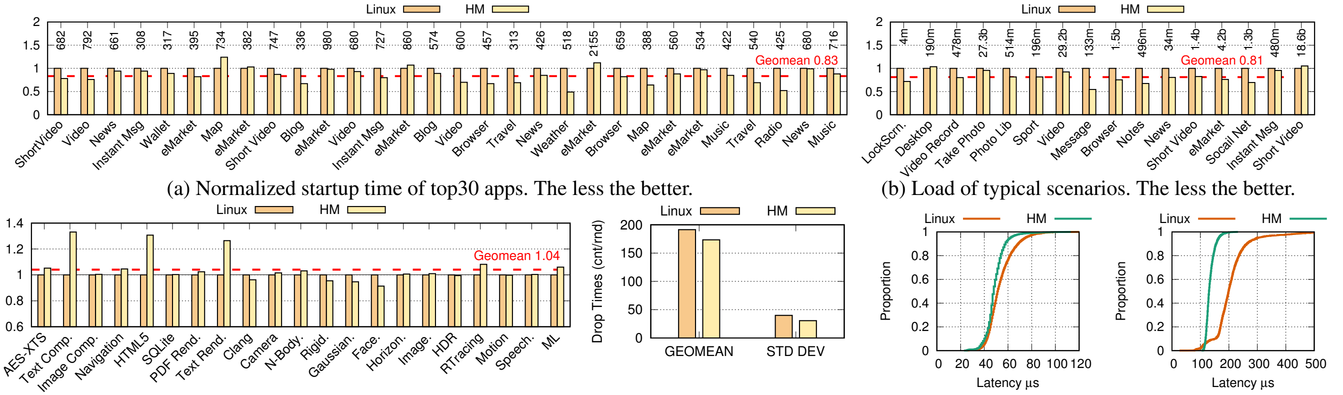
Application Loads. Figure 11b presents the loads in a period in different scenarios. The loads (number of executed instructions) are collected using `perf`, which includes the executed instructions in OS services (or in Linux kernel). The load on *HM* is 19% lighter (geometric mean) than on Linux. The proposed techniques in *HM* significantly reduce the overhead of minimality and fine-grained access control. Lighter loads also enable *HM* to achieve better performance and energy efficiency than Linux.

We further present improvements using custom strategies in *HM*, which are challenging to apply in Linux (section 2.3).

Frame Drops. Figure 11d shows the frame drop times (crucial for user experience) in 20 rounds of running the typical usage model in section 3.1. Due to the lighter load and a *custom QoS-guided scheduling* in *HM*, frame drops are 10% less and 20% stabler than Linux.

Interrupt Latencies. Figure 11e and 11f show the latency CDF of the related interrupts when playing video and audio, which are essential for user experience. *HM* reduces their latencies by 10% (video) and 65% (audio) by using a *custom experience-first strategy* that executes all the handling procedures at once, which is handled in another additional interrupt (due to lazy disable of ARM GIC [40]) in Linux.

Experiences in smart routers and smart vehicles. In smart routers, *HM* reduces OS memory footprint by 30%, allowing 30% more client connections. In smart vehicles, *HM* reduces system cold boot time from 1.5s (Linux) to 0.6s (critical for user experience, e.g., enabling 360-degree surround view) and reduces cross-domain (dashboard and entertain-



(a) Normalized startup time of top30 apps. The less the better.

(b) Load of typical scenarios. The less the better.

(c) Geekbench (single core). The more the better.

(d) Frame drops. The less the better.

(e) Video int. latency CDF.

(f) Audio int. latency CDF.

Figure 11: Performance of *HM* compared with optimized Linux 5.10 on Kirin9000. (a), (b) and (c) normalized the result for comparison. Labels in (a) show the startup time in milliseconds on *HM*. Labels in (b) show the executed instructions on *HM*.

ment) communication latency from 250μs to 100μs.

7 Lessons and Experiences

Compatible first, then nativize gradually. Compatibility is a crucial first step for commercial deployment. First, a product typically prefers a unified code base for various platforms for cost-efficiency. Second, some third-party apps/drivers are distributed in binaries. Moreover, even aiming to rebuild a new software ecosystem, many essential libraries still require Linux compatibility. Therefore, only by being compatible at first can a new OS be widely deployed and have a chance to evolve towards native interfaces for improved performance.

Specification alone is insufficient. Examine compatibility via large-scale testing. Achieving full compatibility is difficult (if possible), primarily due to Hyrum's Law [121], which reveals that all observable system behaviors will be depended on. Therefore, rather than satisfying certain specifications, we examine compatibility through large-scale testing, which is necessary to uncover hidden compatibility issues.

Deploy first, then optimize continuously. A microkernel is hard to satisfy all performance goals initially and requires full-system optimizations (e.g., framework, even hardware). Without deployment, promoting cooperation among multiple teams for such optimizations is difficult. Moreover, production deployments require time to test reliability. Therefore, deployments should commence early, starting on a small scale.

Use automated verification as much as possible. We found that complete formal verification (using interactive theorem proving) is unsustainable due to the rapid growth in code size and functionalities. Hence, we resort to semi-formal verification of critical components and use automated verification and verification-guided testing to enhance the code quality.

Amplification of hardware failures/bugs due to the scale effects. We found that some low-probability hardware faults or bugs are relatively likely to occur when deployed at scale, significantly affecting user experience and potentially becoming fatal in safety-critical scenarios. *HM* mitigates these issues by isolating critical drivers in different LDCs, restarting stateless drivers in TEE, and creating watchdogs for monitoring. *HM*, as a microkernel, also provides opportunities to address these issues through architectural design in future work.

Big kernel lock is not scalable in emerging scenarios. While it is argued that a big kernel lock is sufficiently scalable for a microkernel [97], mainly due to the short duration of most syscalls, we found that it still faces scalability issues on phones. First, phones have a high syscall frequency (61k/s, Figure 1f), causing *significant contentions*. Moreover, emerging scenarios demand some *complex functionality with long durations*. Examples include `poll`, which requires synchronizing a large number of states within the shim (IC0), and energy-aware scheduling [115], which involves frequent and costly calculations of power consumption for each scheduling decision due to the short-running nature of threads on phones.

8 Conclusion and Future Work

HongMeng is a commercialized general-purpose microkernel that retains microkernel principles while providing structural supports to address compatibility and performance challenges in emerging scenarios. It also facilitates future exploration of microkernels' benefits in production. For instance, its flexibility offers opportunities to accommodate the increasing hardware heterogeneity that Linux fails to address [104], and to achieve fault tolerance for improving availability.

Abstract

In this paper, we make a case for providing job completion time estimates to GPU cluster users, similar to providing the delivery date of a package or arrival time of a booked ride. Our analysis reveals that providing predictability can come at the expense of performance and fairness. Existing GPU schedulers optimize for extreme points in the trade-off space, making them either extremely unpredictable or impractical.

To address this challenge, we present PCS, a new scheduling framework that aims to provide predictability while balancing other traditional objectives. The key idea behind PCS is to use Weighted-Fair-Queueing (WFQ) and find a suitable configuration of different WFQ parameters (e.g., queue weights) that meets specific goals for predictability. It uses a simulation-aided search strategy to efficiently discover WFQ configurations that lie around the Pareto front of the trade-off space between these objectives. We implement and evaluate PCS in the context of scheduling ML training workloads on GPUs. Our evaluation, on a small-scale GPU testbed and larger-scale simulations, shows that PCS can provide accurate completion time estimates while marginally compromising on performance and fairness.

1 Introduction

Humans desire predictability in their daily lives [66]: from knowing how long their home-to-office commute will be to the arrival time of an Amazon package [80] or an Uber ride [7]. Fortunately, most real world systems (e.g., transportation, e-commerce, etc) meet this need by providing their users with a (reliable) prediction (e.g., estimated delivery date). As more and more of our lives move to the cloud (e.g., Metaverse [39, 73]), it begs the question of whether the cloud can offer similar predictability. More concretely, when a user submits a "job" (e.g., train a Machine Learning (ML) model) to the cloud, can the cloud provide a reliable job completion time prediction?

Such feedback can ensure a seamless experience and ease user frustration; perhaps more emphatically than simply making the cloud faster or fairer, according to studies in human psychology [22, 43] and systems usage [50]. It can also empower users to decide between different cloud platforms and services within a cloud based on the provided estimate, or be integrated with emerging inter-cloud brokers (e.g., SkyPilot [97]). In light of this, we advocate for the need to provide reliable job completion time predictions as a *core* primitive in today's cloud, akin to real world systems we interact with.

Several aspects of the user-cloud ecosystem can impact the (lack of) predictability of a job's completion time (e.g., failures [49], shared vs. dedicated resources [50], knowledge of individual job sizes [27, 58], workload characteristics etc.). The focus of this paper is on understanding the unpredictability stemming from the *scheduling* mechanism used by the cloud (sub)systems (e.g., FIFO vs. Fair Sharing vs. other policies). We situate our work in the context of ML workloads running on multi-tenant GPU clusters (e.g., PAI [89], Philly [49], etc). This is an important scenario as scheduling delays matter and can be highly variable due to the ever growing demand for GPUs by emerging AI applications such as those powered by Large Language Models (LLMs) [4], while other sources of unpredictability are minimal (e.g., workloads are predictable [49, 54, 62, 76]). It is also a challenging scenario because unlike the public cloud setting where users pay for dedicated (and hence predictable) GPU resources, these clusters are best-effort and heavily rely on intelligent scheduling mechanisms to determine how the underlying GPU resources are to be shared between ML applications or tenants (cluster users).

Our key observation is that a scheduling policy's use of *unbounded preemption* results in its inability to provide reliable Job Completion Time Predictions (JCTpred). Preemption is a key enabler for existing GPU scheduling proposals that optimize for metrics like minimizing average and/or tail job completion times (JCT) (e.g., Tiresias) [37, 76], fairness and resource efficiency (e.g., Themis) [14, 44, 62, 79, 93, 105], and meeting deadlines (e.g., Chronus) [30, 36, 59]. While crucial for achieving their respective objectives, the extensive use of preemption leads to unpredictability (i.e., prediction error) in a job's completion time due to (repeated) preemptions from future jobs. On the other hand, non-preemptive scheduling policies, such as First-In-First-Out (FIFO), are predictable (as future arrivals do not impact current jobs) but can result in extremely poor performance and a lack of fairness due to Head-Of-Line (HOL) blocking [26, 28, 37, 70].

This observation highlights an inherent trade-off between offering predictability and optimizing for other metrics, such as minimizing JCTs. Existing scheduling solutions typically occupy extreme points on this trade-off spectrum. They are either highly unpredictable due to the use of unbounded preemption or impractical because they do not employ preemption at all.

In light of these limitations, an important question arises: Are there intermediate points on this trade-off spectrum that can provide a balance between predictability and practicality? Specifically, can these intermediate solutions be achieved by controlling the extent of preemption used? Furthermore, the cluster operator may desire to operate at potentially any one of these intermediate trade-offs depending on their *relative* preferences. The trade-off space can be vast, and some points may be inherently less desirable than others. In such scenarios, how can we enable operators to express their preferences and efficiently explore the trade-off space?

To address these questions, we propose a novel scheduling framework called Predictability-Centric Scheduling (PCS) that aims to provide reliable JCTpred (predictability) while balancing other practical goals (flexibility) such as performance and fairness. PCS exposes a high level bi-directional preference interface which allows cloud operators to express the objectives they are interested in (e.g., avg JCTs vs. avg prediction error). To facilitate cloud operators in making an informed choice based on their *relative* preferences, PCS provides a *set* of Pareto-optimal trade-offs. Each Pareto-optimal trade-off improves one objective (e.g., predictability) while marginally sacrificing on other objectives (e.g., performance and/or fairness). This is unlike other tunable schedulers [52, 64, 71] which typically return a single solution.

At its core, PCS leverages Weighted-Fair-Queuing (WFQ) as a basic building block [23]. Our use of WFQ is motivated by the fact that it uses bounded preemption and offers direct control over the extent of preemption used. WFQ maps incoming jobs to a fixed number of queues, uses FIFO to schedule jobs within a queue and assigns a guaranteed resource share (weights) to each queue. These properties bound the preemptions and reordering experienced by jobs. Furthermore, the number of queues and their assigned weights are tunable parameters of the WFQ policy. This allows direct control over i) predictability (e.g., by creating limited number of queues), ii) performance (e.g., by assigning a higher weight to queues with smaller jobs), and iii) fairness (e.g., by assigning equal weights), motivating its flexibility and ability to achieve Pareto-optimal trade-offs.

Finding Pareto-optimal WFQ configurations is challenging because the space of possible configurations is large, with some trade-offs not feasible (e.g., optimal performance and maximum predictability) or beneficial (e.g., more unpredictable and unfairer than existing schemes). To address this challenge, PCS uses a highly-parallel simulation-based search strategy with an intelligent parameterization of WFQ using heuristics, to efficiently find suitable and feasible (Pareto-optimal) WFQ configurations. For example, we use the variation in job-sizes to determine the number of queues and thresholds as opposed to trying out arbitrary combinations. We show that Pareto-optimal trade-offs can be discovered for realistic workloads in a timely manner (§5.4).

A key benefit of PCS is that it is a generic scheduling framework, which can accommodate various types of jobs (e.g., network flows, DNN training jobs), allowing it to be realized in various multi-tenant scheduling scenarios. It only requires knowledge of a job's demand function, which can either be provided by the user or reliably estimated by the system [13, 50, 62]. This requirement is typically satisfiable for ML workloads and we later discuss the broader applicability of PCS to other scheduling scenarios in §6. PCS uses these demand functions to generate a completion time prediction as well as balance considerations for performance and fairness (e.g., when dealing with sub-linear scaling jobs) to be competitive with efficiency based schedulers (e.g., AFS [44]), as we show in §5.

We implement and evaluate PCS for realistic ML training workloads on a small-scale GPU cluster as well as large scale simulations. Our evaluation shows that PCS can successfully discover Pareto-optimal WFQ configurations to meet varying trade-offs. For example, PCS can reduce the prediction error by 50-800% while being within 1.1-3.5× of performance and fairness optimal schemes (§5).

Overall, we make the following contributions:

- We show that state-of-the-art GPU scheduling policies which optimize for performance and fairness [37, 44, 62] result in unpredictability. Our analysis shows that these policies typically lie on extreme points of predictability-performance or predictability-fairness trade-offs (§2).

- We design PCS, a generic job scheduler, which uses WFQ in a unique and novel way to achieve predictability and flexibility (§3.1).

- We provide a simple but expressive bi-directional interface to be used by cloud operators, enabling them to specify different high level objectives and giving them the ability to choose between trade-offs — a property existing scheduling systems fail to provide (§3.2).

- We implement a prototype of PCS in Ray [67] and evaluate it on a testbed and in simulations for realistic ML training workloads (§4 §5).

PCS is a step in providing predictability in today's cloud systems. It opens up important questions which we discuss in §6. Finally, we build upon and benefit from a large body of prior work in scheduling systems, which we discuss in §7. The code for PCS is made available at https://github.com/TuftsNATLab/PCS.

2 A Case for Predictable Scheduling

In this section we motivate the need for predictable scheduling to be a core primitive in today's cloud, and show how it is different from deadline-based scheduling. We provide several use-cases of predictable scheduling in the context of multi-tenant GPU clusters and draw analogies between real-world systems and the cloud. While this discussion has broader applicability in various scenarios (e.g., CPU scheduling, network bandwidth scheduling), we situate it in the context of multi-tenant GPU clusters and discuss the opportunities and challenges in supporting predictable scheduling in that context.

2.1 Why provide JCT predictions (JCTpred)?

A scheduling system that provides JCTpred can have two broad benefits: (1) Alleviating User frustration. Several studies on real-world systems (e.g., online retail [78], airlines [11]) show that providing a timeline to users can help ease frustration in the face of long and variable waiting times [43, 45, 99]. JCTpred can offer a similar role in the context of multi-tenant GPU clusters where users can suffer from large and unpredictable delays, inevitably leading to a poor and frustrating experience [22, 42]. Measurements on Microsoft's GPU cluster (Philly) show that ML training jobs can face up to 100 hours of queuing and preemption related delays [49], hinting that organizational GPU clusters are heavily oversubscribed. Research shows that users are often trying to guess when their training jobs will complete and that user-driven predictions can be off by more than 100%, with some users finding it *impossible* to make any meaningful predictions [30]. With the paradigm of AutoML, jobs that spawn hundreds of DNN trials [57, 62], and LLMs (e.g., GPT4 [4]) becoming mainstream, these issues will only exacerbate [9]. Additionally, predictability expectations are higher for users submitting repetitive jobs [50] and according to one study, 60% of training jobs exhibit DNN architecture similarity [54], emphasizing the need to provide JCTpred in such scenarios.

(2) Enabling decision making. In real-world systems, if the predicted timeline is long, customers may elect to perform other tasks or seek alternatives [63]. For example, estimated delivery dates can help shoppers decide between e-commerce platforms (e.g., Amazon [2] vs Temu [6]) and even between sellers within a platform. Today's cloud users have similar choices to make and JCTpred can enable them to make these choices in a more informed way. For example, it can help users decide between different cloud systems to run their ML workloads on, each option potentially offering a different cost-JCTpred trade-off. As a forward looking avenue, JCTpred can facilitate the growing eco-system around inter-cloud brokers which orchestrate seamless access to multiple clouds with low user effort (e.g., SkyPilot [19, 46, 84, 97]). Within a cloud, JCTpred can facilitate users in selecting between different model variants/pipelines to train, based on the expected accuracy-JCTpred trade-off [12, 20, 95, 101].

Why are Deadlines not the answer? One may wonder how the predictability metric is different from deadlines (and the large body of work on deadline-based scheduling for GPUs and beyond [16, 17, 30, 56]) where a user provides a deadline along with their job and the system tries to satisfy it. The fundamental difference is that in the deadline-based context, the burden lies on the *user* to provide a timeline to the system, with the system deciding the user's fate. We posit that it should instead be the *system* that provides the user with a timeline (i.e., a JCTpred), empowering them to decide whether it is acceptable or not. Our approach is analogous to real-world systems like ride-sharing where most users request a ride, wanting it ASAP (i.e., no deadline) while the system comes up with the expected arrival time of the ride.

Even if we try to shoehorn predictability into deadlines, it will be challenging for two reasons. First, coming up with a reasonable deadline is hard because the slowdown of a job is highly dependent on: i) cluster load (which can be highly variable and bursty at short timescales) and ii) underlying job-to-resource mapping which is (dynamically) determined at run time [50] and can result in significant variation due to heterogeneity in the underlying resources (e.g., low vs. high end GPUs [14, 71, 89], RDMA vs. TCP [31, 77], etc.,). Second, unless there is an inherent difference in user requirements (and hence deadlines), users have the incentive to specify a small deadline (i.e., to act greedy), which limits any prioritization the system can enable. In both the above cases, the lack of reasonable deadlines will render the system ineffective.

Feasibility of providing JCTpred. Computing JCTpred requires the knowledge of a job's size and its demand function (i.e., how its execution time will change based on the allocated GPUs). Fortunately, several attributes of ML workloads allow us to (approximately) estimate these. (1) Intra-job predictability. DNN training and inference jobs [37, 49, 62] exhibit intra-job predictability; the time it takes to run an inference job [38] or train a DNN for a specified number of epochs is fairly deterministic [62]. By profiling [44, 71, 74, 79] or modelling [31, 62, 76, 96, 105] the job's throughput and combining it with the provided job information (e.g., total number of epochs, convergence criteria, budget), its size and demand function can be estimated. (2) Recurring jobs. ML workloads are known to contain recurring jobs [24, 54, 90]. This can make history [75] and sampling [47] based strategies highly effective in estimating job sizes.

2.2 Limitations of Existing Schedulers

Reliably predicting the completion time of a user's job requires the underlying scheduling system to be predictable [30]. In this section, we highlight and analyze why existing schedulers used by GPU clusters today are either not amenable to reliable completion time predictions or are not practical.

Unbounded Preemption: the Price of Fairness and Performance. Performance and fairness-oriented schedulers frequently utilize *unbounded preemption* to prioritize and distribute resources among jobs. Preemption collectively refers to when some or all of the resources assigned to a job are reallocated or when its position in the queue is altered because of another (future) job. Although preemption is essential for achieving the goals of these schedulers, it can lead to unpredictability in a job's completion time [50]. Under preemptive scheduling policies, the arrival of future jobs can affect the completion times of current jobs by preempting the resources (e.g., GPUs) they are using.

Preemption manifests in today's cloud systems in the following ways: (1) Prioritization. When a higher priority job arrives and needs to be scheduled, running jobs are paused or waiting jobs are pushed further back in the queue. Several schedulers use prioritization to minimize JCTs and meet deadlines [8, 17, 30, 37, 56, 59, 76]. (2) Elastic Sharing. Jobs may need to be multiplexed together to achieve fairness and efficiency [14, 32, 44, 62, 93]. As new jobs arrive, the GPU share of existing jobs is reduced, stretching their completion times [50] or the scheduler takes away GPUs from existing less-efficient jobs and assigns them to new jobs that can utilize them more efficiently [13, 44].

Takeaway: Unbounded preemption results in unpredictability, making it challenging to provide a reliable JCTpred. A scheduler which utilizes bounded preemption will be more predictable.

Fixed Trade-offs. The other option is to use non-preemptive schedulers such as First-In-First-Out (FIFO) [86] and reservation based schemes [49] which are highly predictable as they guarantee resource allocation throughout the lifetime of a job — future job arrivals do not impact current jobs in the system. However, such schemes suffer from well known performance issues such as Head-Of-Line (HOL) blocking in the case of FIFO [26, 28, 37, 44, 70] and poor utilization for reservation based schemes [49, 89, 94]. There is no clear way to tune these schedulers that lie on extreme ends, to offer different trade-offs between predictability and other objectives. This is an issue because different cluster operators may want to settle for different (intermediate) trade-offs rather than switch between these two extremes.

Takeaway: Existing schedulers offer a fixed trade-off: predictable but high/unfair JCTs (non-preemptive) or low/fair but unreliable JCTs (unbounded preemptive). A scheduler which offers different trade-offs between these competing objectives is more practical.

Motivating Example. We use a simple toy example (Fig. 1a) with four jobs (J1-J4) to demonstrate these limitations. We analyze the performance of three schedulers — FIFO, Tiresias, and Themis — on reducing JCTs, unfairness, and unpredictability. FIFO is the default scheduler used in YARN [86]. Tiresias [37] prioritizes DNN training jobs with smaller remaining service times, while Themis [62] strives to minimize peak unfairness.[1] Tiresias and Themis are representative of a large space of policies which either use size based or fair scheduling, respectively. Unpredictability is captured as $\text{Pred}_{err} = \frac{JCT_{true} - JCT_{pred}}{JCT_{pred}}\%$, while unfairness is captured as the additional time it takes for a job to complete compared to its Fair Finish-Time (FFT) [15, 62] in percentage terms. JCTpred is computed at the time of a job's submission and is defined as the time it takes for a submitted job to complete given a scheduling policy and the current cluster state (i.e., GPU allocations to existing jobs). We provide a practical way to compute it for all scheduling policies in §4.

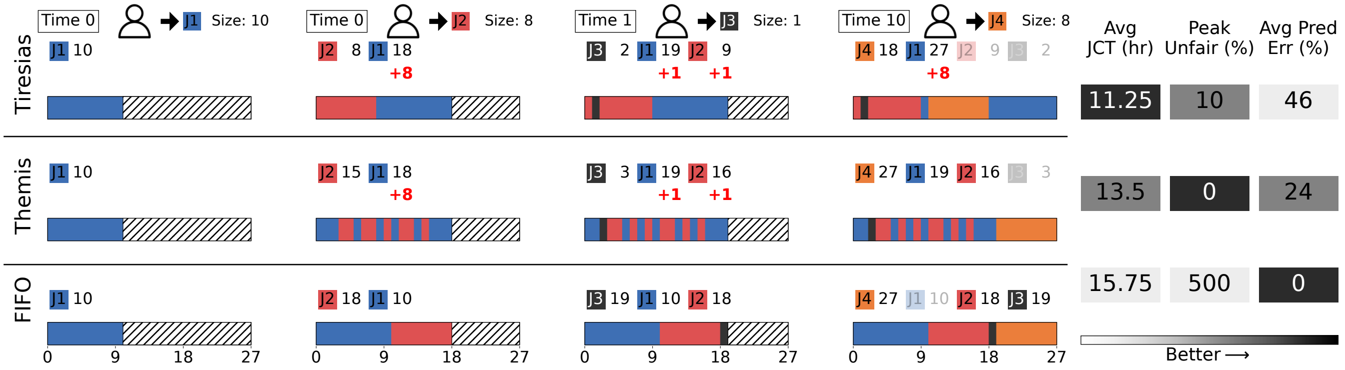
As new jobs arrive (moving left to right in Fig. 1a), both Tiresias and Themis result in a change in completion times of previous jobs. For instance, in Tiresias (top row), when J2 and J4 arrive in the system (second and fourth column), there is an eight time unit increase in J1's predicted JCT each time. While Tiresias achieves the minimum average JCT, it results in the highest average prediction error — 46% Pred_{err} in our example. Similarly, in Themis (middle row), the scheduler's multiplexing of J1 and J2 causes J1's predicted completion time to increase by eight time units (second column). While Themis ensures all jobs finish before their FFT (unfairness of 0) and also avoids HOL blocking, it has an avg Pred_{err} of 24%. The FIFO scheduler (bottom row) achieves a prediction error of 0 as it is non-preemptive, but is the most unfair strategy and has the highest average JCT. Figure 1b summarizes these outcomes.

We now discuss PCS, a generic resource scheduler that attempts to offer predictability while being flexible in balancing performance and fairness related objectives.

3 Predictability-Centric Scheduling (PCS)

Requirements. Our analysis in the previous section reveals that a scheduling policy with *no preemption* (i.e., FIFO) results in maximum predictability. However, this comes at a high cost in terms of performance (i.e., JCTs) and fairness, which makes it an *impractical* option. On the other extreme, there are scheduling policies that have *unbounded preemption* (e.g., Fair-Share, Shortest Job First, etc.). In these policies, an influx of future arrivals can arbitrarily stretch the completion

[1] We use a lease duration of 1 time unit for Themis and assume job size information is known for all schedulers



(a) Impact of future arrivals on scheduling

(b) Summary

Figure 1: Toy example with 1 GPU, demonstrating the limitation of existing strategies. (a) shows how the scheduling order changes as jobs arrive over time under the Tiresias [37], Themis [62], and FIFO [86] schedulers. Time moves from left to right with a new job arriving in each column. The expected finish times for the current jobs are displayed above the current schedule. Jobs that are finished are grayed out. (b) summarizes the results for performance, fairness, and predictability for these policies.

time of an existing job, making them unsuitable for providing predictability.

This insight distills into the following two requirements that a scheduling policy must satisfy in order to provide predictability while being practical:

- R1 Predictability Requirement: a scheduling policy must have *bounded preemption*. This is essential in order to provide reliable JCT predictions.

- R2 Flexibility Requirement: it should be able to approximate maximum predictability, optimal performance, and maximum fairness. Most importantly, it should be able to achieve Pareto-optimal trade-offs between these. This is essential for practicality.

PCS Overview. Our solution to this end is PCS, a generic scheduling framework (Fig.2), which captures these requirements using a high level preference interface (§3.2), and meets them by using the well-known Weighted-Fair-Queuing (WFQ) [23] policy in a novel way. The inherent properties of WFQ, careful selection of various WFQ parameters (number of queues, weights, etc) along with how each job is mapped to a queue and processed within it, allow us to meet our objectives (§3.1). Specifically, WFQ creates a fixed number of queues, assigns each of them a guaranteed share of the resource capacity (weights) and schedules jobs within a queue in FIFO order – this allows WFQ to satisfy our predictability requirement (R1). Similarly, the number of queues, weights, and how jobs are mapped to each queue are *tunable*, allowing it to offer the desired flexibility (R2).

A key component of PCS that enables the above functionality is the *preference solver* (§3.3), which translates the specified high level objectives into a set of Pareto-optimal WFQ configurations using a simulation-based search strategy.

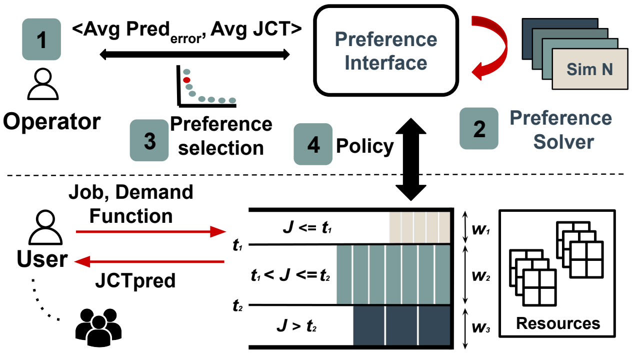


Figure 2: Key components of PCS: The preference framework can be used by operators to specify high level objectives. The preference solver uses a simulation-based search strategy to find Pareto-optimal WFQ configurations that are then shared with the operator. On the critical path, users submit their jobs along with the job's demand function and are given a JCTpred.

The simulation based search strategy is *not* on the critical path of a submitted job; it operates at coarser timescales, aligned with changes in workloads. Since ML workloads are fairly stable, expending the time to search for Pareto-optimal WFQ configurations is feasible. While the space of possible configurations is large, we use an intelligent parameterization of WFQ (e.g., coefficient of variation of job sizes within a queue) to navigate it in a feasible manner. Once a particular WFQ configuration is selected, it can be used to schedule submitted jobs as they arrive.

An important benefit of PCS is that it is a generic scheduling policy – it operates on the notion of a *job* which could be a network flow or a DNN training job etc. To deal with the varying needs of these different scenarios, in PCS, a job is defined using a demand function. The demand function is a mapping between the job's execution time and the resources allocated to it i.e., $demand(n) \mapsto T_{exec}$ and has a minimum ($demand_{min}$) and maximum ($demand_{max}$) resource allocation bound, denoting the execution time under the lowest and highest possible allocation. For ML workloads, in particular DNN training, the demand function is sophisticated, as different models can have different speedups based on the GPU type and affinity and is estimated on the users behalf, as discussed in §4. For scenarios like network (co)flow scheduling [18, 26, 28], the demand function is simpler, as we discuss in §6.

Finally, the user submits their job, optionally including its demand function. PCS then computes and returns the predicted completion time (JCTpred).

We now explain in detail, our choice of using WFQ as a building block (§3.1), followed by preference solver and interface.

3.1 WFQ under PCS

We begin by motivating why WFQ is a useful starting point and then share PCS's careful usage of WFQ in meeting our objectives. Our observation is that a lack of preemption, as in FIFO, and a non-zero guaranteed resource share for jobs is crucial for predictability. WFQ uses FIFO scheduling within each queue and across queues the resources are shared according to, strictly positive, queue weights, helping us satisfy the predictability requirement. To highlight the flexibility of WFQ, we show how it can be configured to optimize for extreme points in the trade-off space of maximum predictability, performance and fairness.

- **Maximum Predictability:** WFQ with a single queue is exactly FIFO scheduling which achieves a prediction error of 0
- **Near-optimal Performance:** Shortest Job First (SJF) is near-optimal in minimizing avg JCT for a single bottleneck [83]. WFQ can map each job to its own queue and give a higher weight to queues with smaller jobs, approximating SJF as shown by prior work [18, 88].
- **Max-Min Fairness:** If each job is mapped to its own queue and each queue gets an equal weight, WFQ can emulate Max-Min fair allocation which minimizes unfairness for a single bottleneck [33].

As our analysis in §2 reveals, a combination of these objectives is more practical. WFQ offers the necessary baseline flexibility in the queue creation, job mapping and weight assignment strategy. This motivates that we can achieve a combination of these objectives as well, which leads to PCS's preference interface §3.2.

Beyond vanilla WFQ. Our core idea is the novel use of WFQ to meet our objectives. First, PCS intelligently chooses the number of queues, weights and the job-to-queue mapping strategy to find various Pareto-optimal configurations, including extreme points, such as FIFO, SJF and Max-Min Fair Share. In PCS, jobs are mapped to different queues based on their size and a set of thresholds ($t_i^{\prime}s$), while strictly positive weights (w_i's) dictate the guaranteed resource share for each queue. For example, jobs with size $> t_k$ and $\leq t_{k+1}$ will be mapped to the k^{th} queue.

Second, within a queue, PCS deviates slightly from a strict FIFO schedule in favor of improving performance and fairness. In PCS, a job's demand function is used to cap the resources allocated to it. For example, a job at the head of its queue may not be assigned all of the guaranteed resource share of its queue (as in strict FIFO); instead, some of the resources may be allocated to the jobs behind it. This allows PCS to handle jobs that exhibits diminishing speedup w.r.t. increase in allocated resources, such as ML training jobs (§4).

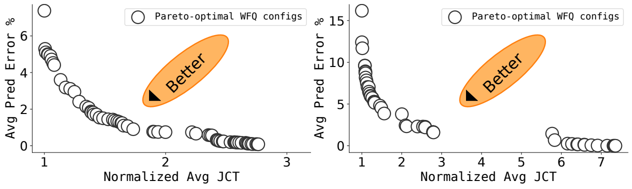
Finally, to ensure work-conservation, any residual allocation is then redistributed first within a queue in FIFO order by incrementally relaxing the cap on each job's demand function and then across queues proportional to their weights. We expose the weights, thresholds and the demand capping criteria to the preference solver which searches over the space of possible choices of these parameters in order to discover Pareto-optimal configurations (§3.3).

Pred$_{err}$ in PCS. Since PCS is work-conserving, a job may get a higher resource share compared to its guaranteed share. For example, if a job arrives when no other job is present, it will be allocated all the available resources (up to $demand_{max}$). This can lead to prediction errors (Pred$_{err}$) if in the future, other jobs arrive and occupy different queues.

In PCS, we bound these errors in a few ways. Firstly, a job's worst-case completion time is strictly bounded, irrespective of the number of future arrivals in other queues or its own queue. This is possible because each queue is assigned a strictly positive weight and uses FIFO scheduling (both properties of WFQ). By bounding the worst-case completion time of a job, the number of preemption events a job will experience during its lifetime is bounded, resulting in bounded Pred$_{err}$. Second, we exploit the fact that cloud systems are typically highly loaded [37], and by limiting the queues created we can reduce the likelihood of sudden and drastic changes in queue occupancy due to future arrivals. Furthermore, the exact load of a queue is controlled by the thresholds and weight assignment strategy. These observations guide us in discovering Pareto-optimal WFQ configurations.

3.2 Preference Interface

PCS exposes a simple yet expressive bi-directional interface that allows operators to specify high level objectives and present Pareto-optimal trade-offs (WFQ configurations) to choose from. This is unlike other tunable systems [52, 64, 71] which assume operators are aware of the trade-offs involved



(a) Trace #1

(b) Trace #6

Figure 3: Pareto front of the trade-off between Pred$_{err}$ and normalized average JCT for workload-2 (§5). *Better* indicates WFQ configurations that achieve a tight bound on average/tail Pred$_{err}$ while incurring the smallest possible increase in average JCT.

i.e., PCS *actively* tries to help the operator in making an informed choice. Our decision to use Pareto-optimal choices, as a way to support informed decision making, is grounded in fundamental literature on multi-objective decision making [34, 72], which maps neatly to the problem PCS is trying to address: predictability while being practical.

The preference interface itself, is general enough to be used in scenarios beyond predictability as well. For example it can be used to strike a balance between fairness and performance (e.g., Carbyne [35]) and between minimizing average and tail JCTs [26, 28, 35, 70]. The preference interface exposes the following API:

```
void SetPreference(
    Obj1 <Metric, Measure>,
    ...,
    ObjN <Metric, Measure>
);
List<WFQConfig> UpdateParetoFront();
void SetWFQConfig(WFQConfig config);
```

The current PCS API supports three `Metrics`: Performance (*JCT*), Fairness (*unfairness*), and Predictability (Pred$_{err}$). The `SetPreference()` method is used to specify the list of objectives; repeated entries are allowed to support exploring trade-offs across *different* measures of the *same* metric. For each objective, `avg(.)` or a particular `percentile(p)` needs to be specified as a `Measure`.

We envision the following API usage life cycle from an operators perspective: (1) Upon cluster deployment or drastic workload changes, the operator uses the `UpdateParetoFront()` method to kick-start the preference solver (§3.3). (2) The preference solver uses the updated workload information and preferences to discover the set of Pareto-optimal WFQ configurations. (3) Once complete, the operator can choose a specific WFQ configuration (`WFQConfig`) to be used by invoking the `SetWFQConfig()` method.

`UpdateParetoFront()` requires PCS to passively collect job size information and maintain a workload history. When bootstrapping, PCS starts with a default WFQ configuration, which can be any one of the extreme points in the trade-off space (e.g., FIFO) described in §3.1. When sufficient workload information is gathered, the preference solver is initiated.

We now show how the API is used to target scenarios covered in our evaluation.

Average JCTs *vs.* Average Pred$_{err}$: Minimizing average JCTs is a popular performance objective and has been a focus of several scheduling policies [37, 76]. To explore the trade-off between performance and predictability, one can specify it as `SetPreference(<JCT, avg>, <Pred`$_{err}$`, avg>)`. We use this for evaluating PCS for workload-1 and workload-2 in §5.

Average JCTs *vs.* Tail Pred$_{err}$: Prediction error can be tightly bound by specifying the tail Pred$_{err}$ (e.g., p99) as a measure of predictability. In such a case, the objectives would stay the same as in the above example, however, the measure for Pred$_{err}$ would change from `avg(.)` to `percentile(99)`. PCS uses this specification for workload-3 where low p99 Pred$_{err}$ is challenging to achieve with other policies.

Pareto Fronts. Figure 3 shows the set of Pareto-optimal WFQ configurations generated by PCS for two realistic DNN training workloads.

3.3 Preference Solver

The preference solver is responsible for finding Pareto-optimal WFQ configurations for the objectives specified. It uses a multi-objective search algorithm to navigate the space of possible WFQ configurations. The optimization parameters consist of the (1) number of queues, (2) queue weights, (3) queue thresholds, and (3) resource allocation cap. These parameters are deemed relevant as they directly control the different trade-offs involved between the objectives considered by PCS. For example, the number of queues influence the degree of preemption and hence predictability, while the resource allocation cap influences the overall efficiency and hence performance. Other common scheduling dimensions, such as explicit priorities or deadlines, are not considered as they relate to objectives beyond performance, fairness and predictability. For example, some systems may want to prioritize a longer running job. This conflicts with the goal of minimizing JCT; which is rather achieved by assigning a low priority to such jobs. Catering to such scenarios is beyond the scope of PCS.

Finding Pareto-optimal configurations is challenging due to the combinatorial nature of the configuration space. The solver intelligently parameterizes each configuration to make the search process feasible. It uses a simulation-based approach to evaluate the performance, predictability and fairness of a particular WFQ configuration. These are fed to the search algorithm, which decides the configurations to keep, try out next, and discard.

Intelligent Parameterization. To reduce the number of optimization parameters we use the following heuristics:

- **Creating Queues and Thresholds:** Large variation in job-sizes within a queue can lead to HOL blocking but creating too many queues increases preemption events and deteriorates predictability. In PCS, queues are created based on the squared coefficient of variation (C^2) in the job-sizes, as done by prior work [28]. We use a tunable parameter $0 < \mathcal{T} < C^2_{max}$ to ensure that queues are created such that C^2 of job-sizes within each queue is $\leq \mathcal{T}$, where C^2_{max} is the C^2 of the entire job size distribution. A larger (smaller) $\mathcal{T}$ results in fewer (more) queues created.

- **Systematic Weight selection:** Higher weights given to queues with smaller jobs improves performance for most workloads. On the other hand, a balanced weight assignment strategy may improve fairness instead. Based on this, we constrain the weight for the i^{th} queue to be $w_i = e^{-i \times \mathcal{W}}$. $\mathcal{W}$ is a tunable parameter which controls the relative weights for each queue. A higher (lower) value of $\mathcal{W}$ leads to a greater (lesser) disparity in weights among the queues. For heterogeneous deployments, containing several resource types (e.g., k different GPU types) we use $\mathcal{W}_1 \ldots \mathcal{W}_k$.

- **Finding Demand caps:** The resource efficiency of a job is used to decide its allocation cap and it is computed as $\zeta(n) = \frac{demand_{min}}{n \times demand(n)}$, where $demand_{min}$ is a job's execution time under its minimum possible allocation (e.g., 1GPU) and it is a non-increasing function of the allocated resources. For linear scaling jobs, $\zeta = 1$, while for jobs that scale sub-linearly, $0 < \zeta \leq 1$. Instead of a fine-grained efficiency comparison between all jobs, we introduce a tunable threshold ζ_{min} to be used for all jobs, to reduce the search parameters. Using this, a job's resource allocation is capped at k such that $\zeta(k) \geq \zeta_{min}$. Intuitively, a low (high) ζ_{min} means the scheduler is more (less) tolerant towards inefficient jobs. Our evaluation in §5 shows that this heuristic is competitive compared to the approach taken by other efficiency based schedulers (e.g., AFS [44], Themis [62]).

Using these heuristics, WFQ($\mathcal{T}, \mathcal{W}, \zeta_{min}$) becomes the succinct parameterization of each configuration. Different values for these parameters results in different trade-offs between the objectives specified by the operator. For example, setting ($\mathcal{T} = C^2_{max}, \zeta_{min} = 0$) achieves maximum predictability (i.e., strict FIFO) as only one queue is created and no allocation cap is enforced.

Simulation-based Search. We use a simulation based approach to discover Pareto-optimal WFQ configurations. Our methodology utilizes a simulator, which accepts a WFQ configuration (denoted by ($\mathcal{T}, \mathcal{W}, \zeta_{min}$)) as input. The simulator evaluates the provided configuration under a random sample ($\approx$ 1000 job arrivals) of the collected workload (i.e., size distribution and average arrival rate) and outputs the resulting JCT, FFT and JCTpred metrics. The results are then fed to the search algorithm.

The search algorithm samples the search space of possible WFQ configurations and interacts with the simulator to converge to Pareto-optimal solutions. We use SPEA2 as our choice of the search algorithm. It is based on evolutionary search and supports optimizing over multiple objectives [106]. Other multi-objective optimization algorithms can also be used as an alternate, in a plug-and-play fashion. To improve the robustness of each discovered WFQ configuration, it undergoes multiple evaluations under different random samples of the workload to increase its likelihood of being Pareto-optimal.

While we don't have any theoretical basis for the convergence and optimality properties of our approach, it works well in practice and can timely ($\approx$ 1hr) discover the Pareto front for a reasonably sized GPU cluster. Our evaluation confirms that Pareto-optimal configurations found using simulations follow the same trade-offs on the testbed experiment (§5.2). We micro-benchmark the feasibility of the simulation-based search strategy in §5.4.

4 PCS for GPU Scheduling

We now describe the realization of PCS for DNN scheduling on GPU clusters, highlighting important differences and how our abstraction of a job and demand function handles these differences.

DNN Jobs. A job is either a single DNN training job or a collection of DNN trials being run as part of a hyper-parameter tuning task (i.e., AutoML). The demand function for such workloads can be complicated. Modern DNNs require distributed training (e.g., data parallelism) on multiple GPUs. They are known to have sublinear speedup w.r.t to the (1) number, (2) type and (3) locality of GPUs allocated to them [44, 62, 71, 79]. PCS relies on existing techniques, such as throughput modelling and profiling, to estimate a job's demand function. As described in §3, the demand function describes how the job's execution time changes with different resource allocations. Since allocations have three dimensions: locality, GPU type and number of allocated GPUs, the demand function takes as input different combinations and returns the corresponding execution time. This is akin to the notion of bids in Themis [62] and throughput in Gavel [71].

Role of Demand Functions. PCS uses $demand_{min}$ as a job's size to map it to its respective queue. The demand function is also used to cap the maximum GPU allocation for DNNs that exhibit sub-linear speedup. Allocating GPUs up to the maximum demand ($demand_{max}$) for such jobs can result in poor performance. We evaluate this approach and show that it works for DNN workloads consisting of jobs that scale sub-linearly (§5.3). As described in §3.3, the allocation cap is a tunable parameter for the preference solver and can be adjusted for different trade-offs and workloads.

Implementation. We implement PCS as a central coordinator in Python and use the Ray cluster manager [67] for GPU allocation enforcement as well as for general cluster management tasks such as fault tolerance. Each job is either a single trial or consists of multiple trials as part of a hyper-parameter tuning algorithm provided by RayTune [60]. We use a custom `ray_trial_executor` to control starting, stopping and preempting individual trials based on the allocations computed by PCS. To determine the remaining service requirements of running jobs, we use various callbacks (e.g., `on_step_start`) exposed by RayTune to get the exact number of iterations completed by each job and multiply it with the profiled time per iteration.

In addition to the central coordinator, PCS consists of an agent, which uses information about running jobs to provide a prediction interface. This interface returns a JCTpred in real time to the user whenever they submit their jobs. The agent computes JCTpred by "virtually" playing out (i.e., in a simulated setting) the current snapshot of the cluster state (e.g., running jobs, available GPUs etc.), accounting for preemption overhead and demand functions of other jobs, to determine the time at which the job will end. This approach is inspired by prior work [29, 82], which use a simulator to compute a job's duration under different resource allocation strategies.

5 Evaluation

We evaluate PCS on a 16 GPU cluster with a realistic AutoML style workload to validate our observations. We also cover additional workloads at a larger scale using an event-based simulator. Our evaluation covers different application workloads (e.g., heavy-tailed vs. light-tailed, AutoML apps vs single DNNs), different scheduling schemes (e.g., Tiresias [37], Themis [62]) and different metrics (e.g, avg, p99).

Our evaluation attempts to answer the following key questions:

- **How does PCS perform in terms of Pred$_{err}$ compared to other schemes?** Our testbed results reveal that PCS configurations achieve significantly lower Pred$_{err}$ (20%) while being within 10% of high performing schemes on the performance side.

- **Does PCS work well across different workload types?** The flexibility and predictability provided by PCS holds across different workloads and across preference specifications. PCS can discover configurations that bound the tail Pred$_{err}$ to be within 100% compared to AFS [44] and Tiresias [37] which suffer from $\geq$ 300% error at the tail.

- **Are PCS configurations fair?** PCS configurations that are optimized for the performance vs Pred$_{err}$ trade-off do not necessarily suffer from unfairness because each queue is guaranteed a GPU share which helps in avoiding starvation.

- **Is the search process feasible?** Our micro-benchmark reveals that the search process can complete within O(hr), making it practical to use, and PCS configurations discovered using the simulation based search-strategy observe the same trade-off *trends* on the testbed.

	Testbed (16 GPUs)	Simulations (64 GPUs)	
Workload	Workload-1	Workload-2	Workload-3
Job Type	AutoML	DNN	DNN
DNN/job	1-20	1	1
GPUs/DNN	1	1-52	1-8

Table 1: Summary of the settings used to evaluate PCS

5.1 Experimental Setup

Testbed. Our testbed cluster consists of 16 1-GPU c240g5 machines in the Wisconsin Cloudlab cluster [3]. Each machine has one NVIDIA P100 GPU with 12GB GPU memory.

Simulation. We use an event-based simulator to cover workloads that contain jobs requiring O(100) GPUs on a homogeneous 64 GPU cluster. We have verified the fidelity of our simulator with trace results from Microsoft [49] and our testbed results with the difference being within 5%.

Pareto Search. The Pareto-optimal configurations for our workloads are discovered by the preference solver §3.3 running on a cluster of 10 c220g5 machines in the Wisconsin Cloudlab cluster [3]. It is important to note that these configurations are discovered and evaluated on different sampled subsets of the workload i.e., there exists a notion of training set vs testing set.

Workloads. Table 1 summarizes the characteristics of our candidate workloads. We now discuss these workloads in detail.

- **Workload-1:** We borrow this workload from Themis [62] (referred in their work as *Workload-1*). For our testbed evaluation we scale down the maximum number of trials per app to 20 and the maximum service time to 2 GPU-hours. The maximum number of GPUs per trial is set to 1. Each trial tunes a different hyper-parameter (learning rate and momentum) of popular vision models from the VGG family [81].

- **Workload-2:** We use traces from 6 virtual clusters from Philly [5] containing the largest number of jobs. In contrast to other workloads, jobs in these traces exhibit sub-linear scaling. We use the scaling data shared by Hwang et al. on Github [1]. More details are in the attached artifact appendix A.

- **Workload-3:** This is borrowed from Gavel [71] (referred in their work as *continuous-multiple*). It is a heavy-tailed workload, with a large number of very small jobs and few long running jobs. We run this workload at a job arrival rate of 4 jobs/hr.

A common characteristic of these workloads is that the minimum requirement of any job is 1 GPU i.e., as long as there is at-least one GPU available, a job can start. This also holds true for RayTune apps which we use in our testbed evaluation.

Scheduling Policies. We compare PCS against FIFO and recently proposed GPU scheduling systems (Themis [62], Tiresias [37], AFS [44]). All scheduling policies considered in our evaluation are "work-conserving" and elastic i.e., they redistribute unused GPUs amongst other jobs according to the policy. For example for FIFO if a job only needs k GPUs and n are available, where $n > k$, then $n-k$ are attempted to be allocated to the next-in-line jobs.

We now describe our implementation of Themis, AFS, and Tiresias that we use in our evaluation.

- **Themis** [62]. On every resource change event and lease duration expiry, in-progress jobs report their fair-finish-time and we allocate GPUs to jobs in descending order of the reported number. We do not consider the scenario where jobs could lie and thus do not require the partial allocation mechanism. The lease duration is set to 10 minutes as per the recommendations of the authors.

- **Tiresias** [37]. Since we assume complete knowledge about job sizes, here Tiresias emulates the Shortest-Remaining-Service-First (SRSF) policy.[2] As such, GPUs are first allocated to jobs with the lowest remaining service times on every resource change event.

- **AFS** [44]. This scheduler tries to minimize avg and tail JCTs while maximizing resource efficiency. On every resource change event we compute each job's allocation using the AFS-L algorithm.

PCS Configurations. We use three configurations for PCS: (1) PCS-pred, (2) PCS-JCT, and (3) PCS-balanced. Each configuration makes a different trade-off. PCS-pred has the highest JCT but the lowest Pred$_{err}$ amongst the three. For each workload and objective the set of WFQ configurations are different and are discovered using the preference specifications described in §3.2.

Comparison Criteria. We evaluate the merit of PCS on three fronts:

1. Job Completion Times (JCTs): A commonly used metric to evaluate the performance of scheduling policies.

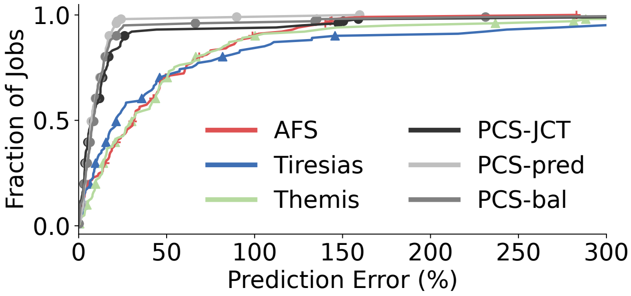


Figure 4: [TESTBED] Distribution of Pred$_{err}$ showcasing three configurations of PCS discovered by PCS — performance oriented, predictability oriented and balanced compared to other schemes.

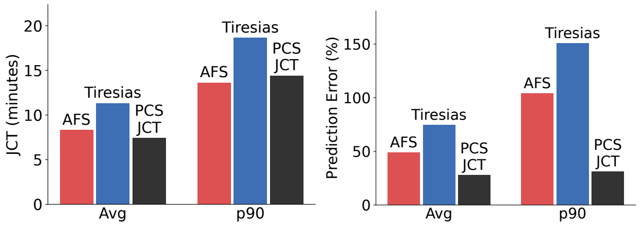
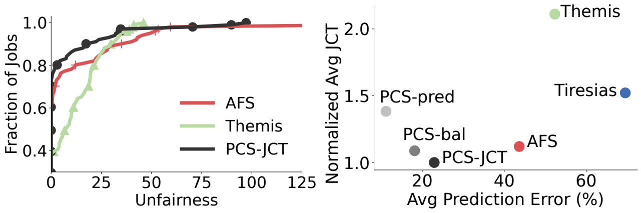


(a) JCTs **(b)** Pred$_{err}$

Figure 5: [TESTBED] Zooming into the trade-off between performance and predictability. PCS is within 1.1× AFS at p90 JCT, with significant improvement to predictability.



(a) Distribution of unfairness **(b)** Pareto font

Figure 6: [TESTBED] (a) shows the CDF of unfairness showcasing that PCS does not significantly compromise on fairness compared to a policy that optimizes for it. (b) highlights the Pareto-optimal configurations discovered in a simulated environment observe the same trend on the testbed evaluation.

2. Unpredictability (Pred$_{err}$): A proxy to capture the error in JCTpred.

3. Unfairness: It captures the extra time taken by a job to complete, compared to its fair-finish-time (FFT) and is 0 for jobs that complete before their FFT.

We consider all important statistics such as the average and tail (e.g., p99 Pred$_{err}$, avg JCTs) for all objectives. For each objective, a lower value is better.[3]

[2] Referred to as Tiresias-G in their paper

[3] The testbed result is an average across 3 seeds while simulation results are an average across 5 seeds

5.2 Testbed Experiment

For our main experiment we compare three PCS configurations, discovered by the preference solver for workload-1, against other schemes.

A tight bound on Pred$_{err}$. Figure 4 shows the CDFs of Pred$_{err}$ achieved by different scheduling schemes and the three PCS configurations. We observe that all PCS configurations are able to achieve significantly lower Pred$_{err}$. At p90, the difference is an 80% lower error achieved by all configurations compared to other schemes. At higher percentiles, PCS-pred provides the lowest worst-case Pred$_{err}$ of 150% while other schemes have a long tail. PCS-JCT still has a lower Pred$_{err}$ up until p95.

Negligible performance sacrifice for high predictability. Figure 5 zooms into the performance versus predictability trade-off achieved by PCS-JCT compared to AFS and Tiresias which aim to minimize JCTs. We see that PCS-JCT achieves equivalent performance to AFS and Tiresias for the average JCTs. It is within 1.1× of AFS at p90, however this trade-off results in significant improvement on the predictability front, where Tiresias and AFS suffer. Pred$_{err}$ under PCS-JCT is within 20% for average and p90 Pred$_{err}$ while AFS and Tiresias have $\geq 40\%(\geq 100\%)$ prediction error at the average (p90). This signifies that PCS-JCT trades off negligible performance to significantly improve predictability. Another source of improvement we observe is that since PCS makes limited use of preemption, overheads associated with preempting running jobs are reduced compared to other schedulers. This is the reason behind PCS outperforming performance oriented schedulers (i.e., AFS and Tiresias).

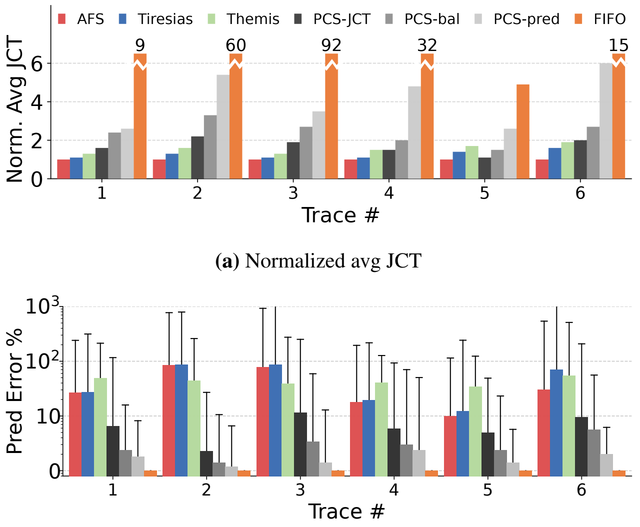
Unfairness. Figure 6a compares the unfairness for PCS-JCT compared to AFS, which optimizes for average JCT, and Themis, which minimizes unfairness. PCS achieves lowest unfairness till p95 and has the worst-case unfairness $\leq 100\%$ compared to AFS which has a worst-case unfairness $> 200\%$. Not surprisingly, Themis offers the tightest bound on the worst-case unfairness of less than 50%.

Pareto-optimality. Finally, figure 6b shows different PCS configurations that achieve different trade-off points in the space of avg JCT vs avg Pred$_{err}$. As expected, PCS-JCT has the lowest avg JCT, while PCS-pred achieves the lowest average Pred$_{err}$.

5.3 Simulation Experiments

We now consider different workloads at a larger scale in simulations and show the trade-offs achieved by suitable PCS configurations compared to performance and fairness optimal schedulers.

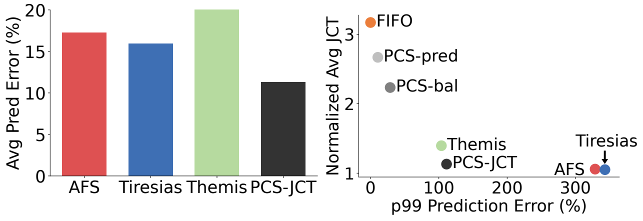
Workload-2. Figure 7 compares the performance and predictability of PCS with other schedulers for workload-2. For such workloads, AFS achieves the lowest possible avg JCT by giving more GPUs to jobs with higher efficiency. Despite its conservative approach in dealing with sub-linear scaling jobs, PCS remains within 1.5 to 4× of the optimal scheme for minimizing avg JCT, while drastically reducing the avg and tail Pred$_{err}$. For example, PCS-JCT reduces the average Pred$_{err}$ from 80% to 1% for Trace #2 and PCS-pred reduces the p99 Pred$_{err}$ from 900% to 10% for Trace #3.



(a) Normalized avg JCT

(b) Predictability

Figure 7: [SIM]: PCS for workload-2. a) Most PCS configurations are within 1.5-4× of the performance optimal policies while b) shows that they drastically reduce the average and tail Pred$_{err}$. In b), the bar height (line) represents average (p99) Pred$_{err}$ and the y-axis follows a logscale.

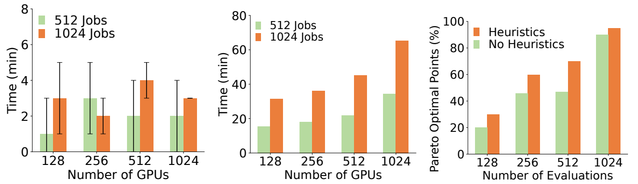


(a) Prediction Error

(b) Pareto front

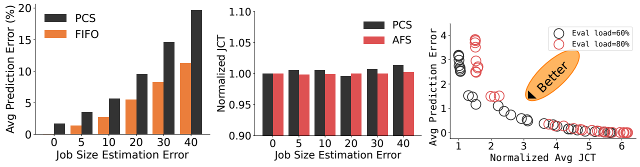
Figure 8: [SIM]: Showing that schemes that optimize for average JCTs for workload-3 also have a small average error. For such workloads, the tail Pred$_{err}$ becomes an important metric.

Workload-3. Figure 8 compares the different schedulers for workload-3. For this workload, we observe that schedulers optimized for performance, including PCS-JCT achieve reasonably low average Pred$_{err}$. This is because for workload-3, majority of the jobs are small and similar in size. For such workloads, tail Pred$_{err}$, becomes important owing to some jobs being starved under priority schedulers. With the appropriate preference specification, PCS discovers configurations



(a) Single sim time **(b)** Search time **(c)** Heuristics

Figure 9: Feasibility of the simulation-based search strategy. (a) captures the time to run a single simulation, (b) shows the time it takes to discover the entire Pareto-front. (c) highlights that intelligent parameterization helps in discovering more Pareto optimal points for a given evaluation budget.



(a) Pred_{err} **(b)** Avg JCT **(c)** Sensitivity

Figure 10: Shows the effects of error in job size and load estimation. a) compares the average Pred_{err} using PCS and FIFO [86] with varying job size estimation error. b) compares the avg JCT of PCS and AFS [44] under the same error. c) shows sensitivity of WFQ configs to load changes.

that can drastically reduce the p99 Pred_{err}. For example, PCS-JCT reduces the Pred_{err} from $\geq 300\%$ to $\approx 100\%$ while being within $1.1\times$ of performance optimal schemes (Fig. 8b).

5.4 Micro-benchmarks

Feasibility of the Search Strategy. Figure 9a shows that PCS takes $O(minutes)$ to run a single simulation for a given load (number of jobs) and cluster size (number of GPUs). PCS extensively leverages the underlying parallelism to discover the Pareto-front – requires running ≈ 1000 simulations– in approximately 60 minutes (Fig. 9b). Figure 9c shows that PCS benefits from the heuristics (discussed in §3.3) to speed up the search and improve the quality of the Pareto-front by discovering new points faster than searching on the unparameterized search space.

Error in Job Size Estimation. Figure 10 shows the impact of estimation error in job-sizes on the predictability and performance of PCS. As job-size estimation gets poorer, the impact on avg Pred_{err} follows the same trend as the Pred_{err} under FIFO (Fig. 10a). Figure 10b, compares the avg JCTs of AFS with no error in job-size estimation to PCS with varying estimation error. PCS is still within $1.05\times$ of AFS. This is because as long as the job is mapped to the correct queue, the error in estimating its size has limited impact on performance.

Sensitivity of Pareto-optimal configurations. To evaluate the sensitivity of Pareto-optimal configurations, we evaluate configurations discovered for workload-1 assuming 60% load on a system actually running at 80% load. Figure 10c shows that while the exact trends do not hold when the estimated workload is a mismatch, 75% of the configurations are within 10% of the closest Pareto-optimal point.

6 Discussion

Generalizability of PCS. In this paper, we realized PCS for ML workloads, however, it is designed as a generic job scheduling framework and the core insights (e.g., utilizing WFQ to realize multiple trade-off points, bounded preemption to provide predictability, etc) still hold across different scheduling scenarios. We tease apart different aspects of PCS's current realization and discuss their broader applicability. (1) Providing JCTpred. JCTpred can be computed if a job's demand function or simply put, its size is either known or can be estimated. There are several scheduling scenarios, beyond ML, where this requirement holds. Prior work has looked at estimating job sizes for requests in microservice deployments [51, 102], network flows [27, 58], compute tasks in data processing clusters [13, 21, 50] and I/O requests in storage clusters [40, 41]. In some scenarios, like network (co)flow scheduling, the demand function is simple: $\frac{\text{estimated (co)flow size}}{\text{allocated bandwidth}}$, while in other scenarios it may be more complicated and costly to determine. (2) Search process. The current simulation-aided search process is meant to be triggered on coarser timescales, assuming workloads are stable and predictable on shorter timescales. This is true for ML workloads as highlighted in §2 but also for some workloads beyond ML [48, 50]. If workload changes are highly dynamic, the search process may not be able to keep-up. This opens up an interesting avenue for future research to tailor the search process for such workloads.

Resource Heterogeneity. To handle resource heterogeneity (e.g., different GPU types), PCS can reuse an existing solution: Gavel [71], which makes a GPU scheduling policy heterogeneity-aware. It supports hierarchical policies with weighted-fairness across entities and FIFO scheduling within an entity. The different parameters of WFQ (e.g., number of queues, weights etc.) map elegantly to these primitives. Once an operator chooses a WFQ configuration, PCS can convert it into an optimization problem that Gavel can solve for.

Sophisticated prediction techniques. Using more complicated prediction techniques is orthogonal work. We posit that future arrivals, the main source of unpredictability, may be difficult to take into account in the prediction decision given that various attributes about them are unknown. For instance, a future job's demand function and its arrival time cannot be determined before it actually arrives. Our emphasis is on making scheduling *predictable* and rely on a simple prediction strategy instead.

Other use-cases of JCTpred. In addition to the use-cases discussed in §2, JCTpred can be used to co-design AutoML app schedulers (e.g., Hyperband [57]) with the underlying system; based on the predicted completion time, the app scheduler can decide to prioritize certain DNNs/trials over another. This can be framed as a bi-level optimization problem where the end goal is to find the most promising DNN hyper-parameters in the quickest time. This will require widening the prediction interface to allow users the option of cancelling and making shadow reservations. Beyond ML workloads, JCTpred can facilitate user applications in i) replica selection strategies (e.g., MittOS [40]), and ii) optimizing the right parallelism and placement for network-bound data processing tasks [29, 69].

Deciding between Pareto-optimal choices. Exposing trade-offs as Pareto-optimal choices can help operators to make informed choices by narrowing down the possibilities. We still, however, rely on the operator's ability to decide between them. One potential strategy is to elicit user preferences via surveys and averaging them to come up with a cluster wide trade-off point. Allowing individual users to pick different preferences on a per job basis, however, can result in cross-user conflicts which may be difficult to resolve. We leave picking preferences on a per-job basis as future work.

7 Related work

Scheduling Systems. A large body of work emphasizes on intelligent GPU scheduling for DNN workloads, considering metrics such as minimizing average job completion times [37,44,55,87,98], maximizing fairness [14,62,93], cluster efficiency [44,55,94] and average DNN accuracy [76,100]. They use preemption based techniques to achieve their objectives; we show in this paper that preemption is detrimental to predictability.

PCS can benefit from system-level techniques, such as elastic scaling [44,74], efficient GPU preemption [85,92–94], DNN throughput profiling [61, 79], job/AutoML app size estimation [62, 76], and sharing-safety [103] used in these systems. However, in contrast to them, PCS focuses on predictability by limited use of preemption and offering flexibility to cluster operators in choosing various trade-off points between predictability and other traditional objectives. Gavel [71] also translates different scheduling policies to optimization objectives but does not cover predictability and only finds a point solution for each objective while PCS allows operators to choose from a range of Pareto-optimal choices.

Multi-queue Scheduling. A broad category of schedulers use the idea of queue-based scheduling [10, 18, 25, 26, 28, 37, 68, 70] in different contexts to achieve performance related goals. We borrow ideas from these techniques. For example, like 2D [28], we also create queues based job size variation within a queue. Similarly, our limited use of multiplexing is inspired by the FIFO-LM scheduler [26]. However, these techniques opt for a fixed strategy in creating queues, mapping jobs to queues and assigning weights (e.g., Baraat [26] and Tiresias [37] only use 2 queues) and will be limited to offering a fixed trade-off between objectives.

Adaptive Schedulers. There are multiple recent examples of empirical, adaptive cluster management. For example, Self-Tune [52] applies reinforcement learning techniques to automatically update the cluster management policy based on periodic cluster status updates. Decima [65] uses simulations to learn optimal scheduling algorithms for data processing. SWP [104] uses a simulation guided approach to find optimal bandwidth scheduling decisions. These works show the efficacy of using simulated environments to learn system decisions. Our strategy is inspired by them.

Predictable Scheduling. Predictable scheduling and delay guarantees has been studied in broader contexts. Weirman et al [91] classify different scheduling policies based on the variation in the slowdown experienced by jobs. Other studies [22, 43] look at the benefits of providing delay information to users and understand how much delay is tolerable. CFQ [15] defines predictability as a job's FFT, similar to Themis. However, FFT is prone to variation itself as new jobs arrive [50].

8 Conclusion

In this paper, we called for providing predictability as a first order consideration in GPU scheduling systems. Our inspiration comes from real-world systems that provide their users with predictions (e.g., estimated delivery dates). Our solution, PCS, provides predictability while balancing other considerations like performance and fairness. It comprises of a bi-directional preference interface to empower cloud operators in making informed trade-offs between multiple objectives. To realize these trade-offs, PCS uses WFQ in unique way coupled with a simulation-based strategy to discover Pareto-optimal WFQ configurations. Our results show the flexibility of PCS in achieving a wide range of operator objectives, offering a first step towards predictable scheduling in a practical way.

A Artifact Appendix

Abstract

We have open sourced our implementation of PCS at https://github.com/TuftsNATLab/PCS/tree/osdi24-artifact. The repository contains jupyter notebooks to recreate figures from the paper as well as scripts to simulate schedulers used in the paper including PCS, FIFO, Tiresias, Themis, and AFS. There are also instructions for running the testbed on Cloudlab.

Artifact Checklist

- **Algorithms:** Both the simulator and testbed implement PCS as well as FIFO, Tiresias, Themis, and AFS.
- **Hardware:** Experiments on a physical cluster require 16 type c240g5 nodes on CloudLab. The nodes should be running Ubuntu 22.04.
- **Setup Instructions:** Setup instructions are available in TESTBED.md and the system prerequisites and setup sections of README.md. TESTBED.md provides instructions on setting up PCS on a CloudLab cluster as noted above as well as setting it up locally, provided the system has CUDA compatible GPUs.
- **Runtime** The testbed experiments take approximately a day (multiple hours per configuration) and the simulations take < 1 hr.

Description

Hardware Dependencies

We ran experiments on 16 c240g5 type nodes on CloudLab. We tested our system on Ubuntu 22.04 with Python 3.10.12 that should be accessilbe with `python3`. For more details, see TESTBED.md and the system prerequisites section of README.md.

Software Dependencies and Hardware Configuration

Software dependencies and hardware configuration can be installed using a script provided in the artifact. For details, see TESTBED.md.

Datasets

Experiments use either job workloads to generate traces, or directly use traces. Workloads consist of a distribution of arrival times, service times, min/max GPUs, and number of jobs per application. These are in the workloads and traces folders respectively. Traces from 6 virtual clusters (vc id's: 0e4a51, b436b2, 6214e9, 6c71a0, 2869ce, and ee9e8c) from Philly [49] are used in some simulator experiments. PCS configurations (PCS-JCT, PCS-bal, PCS-pred) used for each experiment can be found in the PCS_configs folder.

The testbed experiment train a VGG16 model using the CIFAR-10 dataset [53] which is automatically downloaded when the testbed experiment is started.

Experiment workflow

There are two kinds of experiments in the repo - simulation and testbed. For each of these experiments there are additional jupyter notebooks for plotting the results and creating the graphs used in this paper. The data needed to generate graphs used in the paper can be created with shell scripts described in the README of the respository.

Simulation experiments are run from a workload that is generated by a known distribution of job characteristics. We sample from these distributions and generate a workload that matches the provided cluster load, number of GPUs, and number of apps. The workload is then run through the simulator using a selected scheduling strategy.

The testbed is run on CloudLab using a ray cluster that has been modified to implement PCS.

Running Additional Simulations

We provide in the artifact the ability to choose and evaluate different PCS configurations, beyond the ones covered in the paper, for a set of workloads and traces. The user can also modify different experiment parameters (e.g., number of GPUs, number of apps, load). For more details, see reproduce.py and sim.py.

Optimizing Resource Allocation in Hyperscale Datacenters: Scalability, Usability, and Experiences

Meta Platforms

Abstract

Meta's private cloud uses millions of servers to host tens of thousands of services that power multiple products for billions of users. This complex environment has various optimization problems involving resource allocation, including hardware placement, server allocation, ML training & inference placement, traffic routing, database & container migration for load balancing, grouping serverless functions for locality, etc.

The main challenges for a reusable resource-allocation framework are its usability and scalability. Usability is impeded by practitioners struggling to translate real-life policies into precise mathematical formulas required by formal optimization methods, while scalability is hampered by NP-hard problems that cannot be solved efficiently by commercial solvers.

These challenges are addressed by Rebalancer, Meta's resource-allocation framework. It has been applied to dozens of large-scale use cases over the past seven years, demonstrating its usability, scalability, and generality. At the core of Rebalancer is an expression graph that enables its optimization algorithm to run more efficiently than past algorithms. Moreover, Rebalancer offers a high-level specification language to lower the barrier for adoption by systems practitioners.

1 Introduction

In Meta's private cloud, millions of servers are deployed to host tens of thousands of services, powering dozens of products that serve billions of users. In such a complex environment, we routinely encounter a wide variety of resource allocation problems. The following are some real examples:

- *Hardware placement* [30]: Decide when and where to add or remove server racks in a datacenter while balancing competing goals such as staff work schedule, power budget, spread across fault domains, and colocation for proximity, e.g., ML training servers requiring high-bandwidth network.
- *Service placement* [32]: Decide on the allocation of servers to services while spreading each service across fault domains and optimizing the matching between services and server generations, as different services exhibit varying performance across server generations.
- *Service sharding* [25]: For sharded services like databases, determine how to migrate data shards both within and across datacenter regions in response to real-time load changes, while ensuring spread across fault domains and preventing too many concurrent changes that could destabilize the system.
- *Traffic routing* [5]: Route traffic from billions of users to geographically distributed datacenters while optimizing network latency and datacenter load.
- *Locality groups* [35]: Intelligently partition serverless functions into groups, with each server executing functions exclusively within its designated group. The objective is to enhance locality, maximize hits in the JIT code cache, and balance CPU and memory usage across servers.

All these problems have a common pattern where we want to *assign* a set of *objects* to a set of *bins* in a way that optimizes specific *objectives* while meeting certain *constraints*.

Mixed-Integer Programming (MIP) is a well-known technique that can be used to solve such assignment problems. In this approach, assignment variables, denoted as v_{ij}, take the value of 1 if object i is assigned to bin j, and 0 otherwise. A MIP solver determines optimal values for these variables, optimizing the specified objectives while adhering to the given constraints.

While MIP is conceptually straightforward and has been explored in systems research [11, 21, 41], reports of its usage in large-scale production systems are limited. For instance, in the context of load balancing for sharded services, Google's Slicer [2] relies on hand-crafted heuristics, and Azure Service Fabric [21] unsuccessfully experimented with MIP before eventually adopting simulated annealing. Meta's own sharding system, Shard Manager [25], initially used hand-crafted heuristics for several years, but it became too complex to add new features. Eventually, it adopted the framework described in this paper.

The limited adoption of MIP in solving large-scale systems problems is primarily due to its two major limitations: usability and scalability.

Usability. Despite MIP's conceptual simplicity, most systems practitioners lack the training to translate real systems' complex, and sometimes ad hoc, policies into MIP's precise mathematical formulas. To address this usability gap, DCM [38] enables developers to express constraints using familiar SQL statements, while Wrasse [34] employs a domain-specific language for the same purpose. However, industry adoption of these approaches is yet to be reported, and thus, their generality remains unverified. Moreover, they do not sufficiently address the scalability challenge described below.

Scalability. Recall that assignment variables v_{ij} represent whether object i is assigned to bin j. Therefore, an assignment problem has $|\mathbb{O}| \times |\mathbb{B}|$ variables. Here, $\mathbb{O}$ is the set of objects, $\mathbb{B}$ is the set of bins, and $|\mathbb{O}|$ and $|\mathbb{B}|$ are their sizes. Although one can define assignment variables differently to reduce their number, the overall input size of a MIP problem formulation is still $\mathcal{O}(|\mathbb{O}| \times |\mathbb{B}|)$; we omit the details here. In our large-scale private cloud, assignment problems involve up to several million objects and 100,000 bins. However, even approximate MIP solvers would struggle with $\mathcal{O}(10^{11})$ assignment variables, not to mention that most assignment problems are NP-hard.

1.1 Overview of Rebalancer

To address the usability and scalability challenges, we have developed Rebalancer, a generic assignment problem solver. Over the past seven years, it has been applied to dozens of diverse use cases, demonstrating usability, scalability, and generality.

There are three core issues in designing a solver: *model specification*, *model representation*, and *model solving*. To address the scalability challenge, Rebalancer represents the model as a directed acyclic graph (DAG), reducing the model size from $\mathcal{O}(|\mathbb{O}| \times |\mathbb{B}|)$ to $\mathcal{O}(|\mathbb{O}| + |\mathbb{B}|)$. Moreover, the graph representation is a fundamental reason why Rebalancer's optimized local search can solve the model more efficiently than past local search algorithms [1]. To address the usability challenge, Rebalancer supports declarative model specification through intuitive APIs, automatically translating high-level specifications into the graph representation for efficient processing. We discuss each of these topics below.

Model specification. To address the usability challenge, Rebalancer employs a three-step approach to incrementally elevate the level of abstraction for ease of use. First, it introduces essential modeling constructs, such as *dimensions* (representing objects and bins' attributes like CPU and memory) and bin *scopes* (representing server, rack, datacenter, etc). Next, it provides an *expression API* to expose commonly used expressions (e.g., Max and Sum) for transformations on these constructs, as well as recursively on other expressions. Finally, leveraging these expressions, it exposes a high-level *spec API* implementing dozens of common objectives and constraints.

The high-level spec API enables developers to effortlessly construct assignment problems (see Figure 1). For example, CapacitySpec allows developers to specify constraints such as memory usage on a server with 64GB memory, and GroupCountSpec can be used to specify that each server rack can host at most one replica of a database shard, ensuring spread across fault domains.

If no existing high-level spec meets a developer's needs, they can always utilize the expression API to define a new spec, which can then be exposed for other developers to reuse in the future. In practice, across dozens of use cases supported by Rebalancer, 85% of their constraints and objectives are implemented by directly reusing existing specs, without resorting to the expression API. Moreover, we demonstrate that it is relatively easy to define a new spec using the expression API.

Model representation. After a developer leverages the specs to define an assignment problem, Rebalancer translates it into an *expression graph* $\mathcal{G}$. Each node in $\mathcal{G}$ represents an expression constructed from its child expressions. Due to careful choices in model constructs and common expressions, the size of $\mathcal{G}$ is scalable, $\mathcal{O}(|\text{objects}| + |\text{bins}|)$, as opposed to $\mathcal{O}(|\text{objects}| \times |\text{bins}|)$ in the MIP problem formulation.

Model solving. Since the class of assignment problems are in general NP-hard, our goal is to find a high-quality solution within a reasonable amount of time. For small problems, Rebalancer translates the expression graph into a MIP model and solves it with commercial solvers. However, large problems at Meta are either too large for commercial solvers or have tight deadlines, e.g., due to real-time load balancing requirements. To address these limitations, Rebalancer implements an optimized local search algorithm. The graph representation is the fundamental reason why this algorithm is more efficient than past local search algorithms [1, 29, 33, 34].

Contributions. This paper makes the following contributions.

- **First of a kind.** To our knowledge, Rebalancer is the first framework that solves a wide range of assignment problems and has been extensively validated through production usage in hyperscale infrastructure.

- **Model specification.** Seven years of hands-on experience with dozens of use cases has allowed us to iteratively improve and arrive at the current modeling constructs and high-level specification API. Although other usability-enhancing abstractions have been proposed before, their generality has not been validated through widespread production usage.

- **Model representation.** Due to careful choices in model constructs and expressions, the size of the expression graph is scalable, $\mathcal{O}(|\text{objects}| + |\text{bins}|)$, as opposed to $\mathcal{O}(|\text{objects}| \times |\text{bins}|)$ in the MIP problem formulation.

- **Model solving.** The expression graph is also an important distinction that enables us to design a highly scalable algorithm for model solving, utilizing optimized local search on top of the graph.

In subsequent sections, we will describe model specification, model representation, and model solving, in that order.

2 Model Specification

Rebalancer allows developers to easily specify an assignment problem as a composition of a predefined set of high-level *specs*. Figure 1 shows such an example.

2.1 Modeling Constructs

To ensure reusability of the specs, Rebalancer defines a set of modeling constructs that can flexibly represent user requirements:

- **Dimensions.** A *dimension* is a mapping of each object and bin to a number. For example, the memory dimension of a server (a bin) specifies the server's memory capacity, while the memory dimension of a task (an object) specifies the amount of memory needed to run the task. Dimensions can also represent complex relationships. For example, we can define a prohibitedObjects dimension, where an object takes a value of 1 or 0, depending on its assignability to a bin.
- **Bin hierarchy.** Rebalancer uses *scopes* to represent the hierarchical structure of bins. For example, the *datacenter* and *rack* scopes represent servers in a datacenter or rack. A scope divides bins into sets called *scope items*. For example, under the *rack* scope, the scope items $rack_1$ and $rack_2$ represent the set of servers in those specific racks.
- **Object hierarchy.** Similar to scopes and scope items for bins, an *object partition* is an aggregation of objects, which may not be necessarily disjoint. Each set in the partition is referred to as a *group*. For example, in the context of cluster management, all tasks are *partitioned* into jobs and a job is a *group* of tasks that run the same executable.

As a concrete example of using these constructs, Figure 1 defines two dimensions, CPU and storage, to model resources; a rack scope as a fault domain; and a job partition where each group comprises tasks that run the same executable.

2.2 Definition of Utilization

Next, we describe an important concept called *utilization* of bins or scope items. It encompasses, but is more general than the intuitive concept of a server's CPU or memory utilization. Formally, given an object-to-bin assignment and a dimension D, the *utilization* of a bin b_j with respect to D, denoted $\mathsf{util}(b_j, D)$, is defined as the sum of dimension values of all objects assigned to the bin. That is,

$$\mathsf{util}(b_j, D) = \sum_{o_i \in \mathbb{O}} D(o_i) \cdot v_{ij}, \tag{1}$$

where $D(o_i)$ is the dimension value of object o_i, and v_{ij} takes value 1 if o_i is assigned to b_j and 0 otherwise.

```
// Do not exceed CPU and storage capacity.
addConstraint(CapacitySpec(
    scope="server", dimension="CPU"))
addConstraint(CapacitySpec(
    scope="server", dimension="storage"))

// A rack hosts no more than one task per job.
addConstraint(GroupCountSpec(
    scope="rack", dimension="ObjectCount",
    partition="job", limit=1))

// Balance CPU and storage usage across servers.
addObjective(BalanceSpec(
    scope="server", dimension="CPU"))
addObjective(BalanceSpec(
    scope="server", dimension="storage"))
```

Figure 1: Using Rebalancer's high-level specs to specify the objectives and constraints for assigning tasks (objects) to servers (bins).

For example, a bin's utilization with respect to the ObjectCount dimension is simply the number of objects assigned to it. Note that utilization can also be defined for a scope item with respect to a group of objects. For example, $\mathsf{util}(\mathsf{rack}_r, \mathsf{job}_j, \mathsf{ObjectCount})$ counts the number of job_j's tasks deployed on servers in rack_r.

Flavors of utilization. The basic definition of utilization in Eqn 1 is inadequate for certain intricate scenarios. For instance, in the process of migrating a data shard from a source server to a destination server, it may be necessary to first load the shard on the destination, ensuring its healthy operation, before removing it from the source. Throughout this transition period, which might be prolonged when involving substantial data copying, the shard consumes resources on both the source and destination servers. Another scenario involves modeling system stability requirements, such as restricting the number of objects moved in and out of a bin.

To accommodate these complexities, we introduce additional utilization variants. Utilization of bin b_j is the sum of contributions from a set of objects. In Eqn 1, this set consists of objects *currently* assigned to bin b_j, referred to as AFTER. Additionally, we define sets like INITIAL, representing the objects initially assigned to b_j, and $\mathsf{STAYED} = \mathsf{INITIAL} \cap \mathsf{AFTER}$, denoting the initial objects that remained in bin b_j. Extending the notation to include the *temporal* set of objects contributing to utilization as $\mathsf{util}(b_j, D, \mathsf{TIME})$, we refer to it as $\mathsf{TIME}_{\mathsf{util}}$, where TIME can be AFTER, STAYED, or INITIAL. Concretely, expressions like $\mathsf{INITIAL}_{\mathsf{util}}$, $\mathsf{AFTER}_{\mathsf{util}}$, and $\mathsf{STAYED}_{\mathsf{util}}$ capture the utilization by the sets of INITIAL, AFTER, and STAYED objects, respectively.

Through set operations on these base definitions of util, we can create derived definitions such as:

- $\mathsf{NEW}_{\mathsf{util}} = \mathsf{AFTER}_{\mathsf{util}} - \mathsf{STAYED}_{\mathsf{util}}$ which captures the utilization of *new* objects that moved into bin b_j.
- $\mathsf{OLD}_{\mathsf{util}} = \mathsf{INITIAL}_{\mathsf{util}} - \mathsf{STAYED}_{\mathsf{util}}$ which captures the uti-

lization of *old* objects that moved out of bin b_j.

- $\mathsf{ANY_{util}} = \mathsf{INITIAL_{util}} + \mathsf{AFTER_{util}} - \mathsf{STAYED_{util}}$ which captures the utilization of objects that were in bin b_j at any point in time. Note that subtracting the STAYED term avoids double counting for objects that stayed in b_j.

These utilization variants help capture complex scenarios. For instance, $\mathsf{ANY_{util}}$ can model double occupancy, while $\mathsf{NEW_{util}}$ and $\mathsf{OLD_{util}}$ can model system stability.

Internally, Rebalancer translates these utilization variants into their mathematical forms. $\mathsf{AFTER_{util}}$ is simply Eqn 1 using v_{ij} determined by the current assignment. $\mathsf{INITIAL_{util}}$ is a constant value that can be pre-computed from Eqn 1 using the initial assignment. To implement $\mathsf{STAYED_{util}} = \mathsf{util}(b_j, D, \mathsf{STAYED})$, a new dimension named D_j^{init} is introduced for each bin b_j. This dimension takes the value $D(o_i)$ for all objects initially assigned to b_j and zero otherwise. We can again use Eqn 1 with the fact that $\mathsf{util}(b_j, D, \mathsf{STAYED}) = \mathsf{util}(b_j, D_j^{\mathsf{init}}, \mathsf{AFTER})$.

2.3 Common Specs

Over the past seven years, through the process of supporting dozens of large-scale use cases, we have iteratively developed the common specs shown in Table 1. On average, an assignment problem uses seven specs, with a maximum of 14.

Table 1 highlights the reuse of many specs, with six used only once, suggesting they are developed when needed initially. The high-level spec API prioritizes ease of use, while the low-level expression API offers extensibility for new spec development. It provides different flavors of util expressions, mathematical operators (Max, Sum) for aggregation, and transformation operators (Step, Ceil, Log, and Power). Besides being user-friendly, this API enables modeling of non-linear properties, providing a more convenient alternative to crafting a MIP problem formulation from scratch. Overall, the expression API facilitates the implementation of simple specs in dozens of lines of code, and even the most complex specs can be implemented in a few hundred lines of code.

Consider, for example, the introduction of UtilIncreaseCostSpec to prioritize moves to servers with CPU utilization less than a specified threshold T_0. When all servers have CPU utilization over T_0, it favors the one with the least utilization. Using the expressions API, this is modeled in just 65 lines of code by adding the penalty expression $\mathsf{Power}(\mathsf{excessUtil}_i,\ 2)$ to the objective for every server *i*. Here, $\mathsf{excessUtil}_i = \mathsf{Max}(0,\ \mathsf{util}(\mathsf{server}_i, \mathsf{CPU}, \mathsf{AFTER}) - T_0)$.

3 Case Studies of Model Specification

In this section, we describe how to model several real world assignment problems using Rebalancer's spec language.

3.1 Hardware placement

To provide context, we first outline our infrastructure hierarchy: datacenter region→datacenter→suite→main switch board (MSB)→server row→server rack→server. Globally, there are tens of datacenter regions and each region has multiple datacenters within a few miles' radius. Each datacenter consists of four large rooms called suites. Each suite has three MSBs, each supplying power to 10K to 20K servers laid out as rows of server racks. Each rack hosts tens of servers.

A datacenter undergoes continuous evolution with the addition of new server racks and the removal of existing racks for maintenance or decommissioning. The hardware-placement problem involves computing an optimized weekly schedule for these operations, considering the staff's work schedule, ensuring hardware spread across fault domains, and adhering to capacity constraints on power, network, etc.

We model racks as *objects* and *(week, position)* pairs as *bins*, where a *position* is a physical location in the datacenter. We introduce *scopes*, such as *MSB* and *week*, where each *scope item* is a collection of bins associated with the same MSB and week respectively. Similarly, an *object partition* of racks can be defined, where each group consists of racks of the same type. In the following, we outline a small subset of objectives and constraints for hardware placement.

- **New racks.** Initially, all new racks belong to a special bin called *unassigned*. Applying ToFreeSpec on that bin ensures that new racks are assigned to certain *(week, position)*.

- **Power and network constraints.** This is achieved by using CapacitySpec at different *scopes* of the infrastructure hierarchy such as position, MSB, and suite.

- **AI Zone.** AI server racks must be placed in an *AI zone*, which is a special section of the datacenter connected by a high-bandwidth network. To enforce the placement of AI racks in the AI zone, we introduce a new dimension AiRack, which takes the value 1 for AI racks and 0 otherwise. Similarly, this dimension has a limit of 1 for AI zone positions and 0 otherwise. We then apply CapacitySpec with the AiRack dimension over the *position* scope.

- **Place certain racks in the same week.** This is achieved by putting those racks into a *group* and applying ColocateGroupSpec to the group over the *week* scope.

Overall, as rack changes occur incrementally over time and we compute a solution for each datacenter region separately, the hardware-placement problem is relatively small in size, involving hundreds of objects and thousands of bins. For these small problems, Rebalancer translates the expression graph into a MIP problem formulation and employs a MIP solver, instead of a local-search solver, to ensure high-quality results.

3.2 Service Placement

Hardware capacity in datacenters are allocated to teams responsible for different products in the form of quotas called *reservations*. Whole servers or fractions of a server's resources are assigned to reservations while adhering to all kinds of constraints. While reservations can be either global

Spec name	Description	Usage count	Lines of code
CapacitySpec	Enforce that the utilization of a scope item is within specified limits.	19	340
GroupCountSpec	Restrict utilization by objects of a group placed in the same scope item, commonly used to enforce the spread of objects across scope items. For instance, a job can have at most one task in a rack.	17	480
AvoidMovingSpec	Do not move any of the specified list of objects.	16	120
BalanceSpec	Balance utilization across scope items.	12	250
MinimizeMovementSpec	Minimize the number of objects that move into or out of a scope item.	12	90
MovesInProgressSpec	Objects specified as moving from one bin to another by the previous solver run must finish the move.	10	65
NonAcceptingSpec	Specify scope items that are not accepting incoming objects.	9	100
MinimizeBinsSpec	Minimize the number of bins utilized.	8	105
AssignmentAffinitiesSpec	Indicate that specific objects prefer specific bins.	6	90
ToFreeSpec	Free up certain bins. For example, move services out of servers that will be decommissioned.	5	70
ColocateGroupsSpec	Place objects of the same group in the same scope item, e.g., placing a job's tasks in the same rack.	5	100
GroupMoveLimitSpec	Limit how many objects of the same group (e.g., a database's replicas) can move concurrently.	4	95
AvoidAssignmentsSpec	Prevent assignments of certain objects to scope items. For example, in hardware placement, an AI zone in a datacenter only accepts AI server racks.	4	60
GroupDiversitySpec	Every scope item must get objects from at least (or at most) K different groups.	4	80
SingleGroupFailureBufferSpec	Provide additional buffer objects when a group of objects fails together. Used in service placement to ensure that services have enough servers even when a fraction of a datacenter fails.	2	145
DrainCapacitySpec	Allow draining objects from a faulty bin to other bins while respecting capacity constraints.	1	80
MoveGroupSpec	Move objects in the same group together across bins.	1	75
MinimizeNthLargestUtilization	Minimizes the utilization of scope items with the n-th largest utilization	1	85
MaximizeAllocationSpec	Maximize utilization on a set of scope items	1	65
UtilIncreaseCostSpec	Prefer moving objects to underutilized scope items.	1	65
Logical Or/And Specs	Perform a logical OR/AND of certain specs.	1	55

Table 1: List of 21 most frequently used specs out of a total of 28 specs currently supported by Rebalancer. Remaining specs are specific to their respective usecases and their descriptions involve defining concepts beyond the scope of this paper.

or regional, our discussion focuses on regional ones for simplicity. A regional reservation can comprise servers from any datacenter within the same region but not across regions. Our cluster management system treats each reservation as a dynamic virtual cluster and deploys the owner team's jobs on it.

In this service-placement problem [32], we model servers as *objects* and reservations as *bins*. Moreover, we group servers by *MSB*, *rack*, and hardware *type*, which become object partitions. Below, we describe some used objectives and constraints.

- **Capacity sufficiency.** If a reservation specifies a demand of X units for a server type Y, we fulfill it by utilizing CapacitySpec with the count dimension for each server type. The variability in performance among services on various server types can be represented as a dimension. Thus, we can optimize for assigning servers of a specific type to services that can extract optimal performance from them.
- **Spread.** GroupCountSpec ensures that servers allocated to a reservation are spread across *MSB* and *rack* partitions.
- **Stability.** As new reservation requests emerge or existing ones are updated, we run the solver to update both old and new reservations. Recomputing solutions for old reservations is necessary, as it enables the relocation of servers from old reservations to new ones, facilitating global optimization. However, moving many servers out of an old reservation, even if those servers are replaced with new ones, would cause churns to services running on those servers. We use MinimizeMovementSpec to minimize churns.
- **Fault tolerance.** For each reservation, we allocate additional buffer capacity to ensure that in case any single MSB in a datacenter region goes offline due to failure or maintenance, there is still sufficient capacity in the reservation. This requirement is modeled using SingleGroupFailureBufferSpec.

A large service-placement problem involves up to 700K servers (objects) in a datacenter region and 6K reservations (bins). We solve one such problem per region every hour. The solve frequency and associated downstream actions necessitate that Rebalancer must finish solving the problem within 10 minutes. Initially, Rebalancer converted the expression graph to a MIP problem and solved it with a MIP solver. However, recently we switched to using the faster local-search solver due to both the growing problem size and the desire to reduce the solve time to fulfill capacity change requests faster. This experience demonstrates one advantage of Rebalancer—it can take the same problem specification and flexibly decide which solver to use based on the problem size and time limit.

3.3 Service Sharding

Sharded services, such as databases, are prevalent at Meta and account for 68% of the total RPC traffic [25, 36]. They often host about 100 shards per Linux process for improved efficiency, and shards are dynamically migrated across these Linux processes to balance the load. For simplicity, we refer to each such Linux process as a "*server*", assuming one process per server. To ensure redundancy, each shard has multiple replicas, which are grouped together using *object partitions*. This problem assigns *shards* (objects) to *servers* (bins) while meeting various requirements, some of which are described below.

- **Capacity limit.** We use CapacitySpec to ensure that servers are not overloaded. Given that cross-server shard moves are not instantaneous, we use $\mathsf{ANY}_{\mathsf{util}}$ to account for double occupancy (§2.2).
- **Limit churns.** To cap the number of moves per server or per shard, we use CapacitySpec with *ObjectCount* as the dimension and $\mathsf{NEW}_{\mathsf{util}}$ and $\mathsf{OLD}_{\mathsf{util}}$ as the utilization (§2.2).
- **Region preference.** Certain shards prefer servers in specific datacenter regions because the users accessing those shards are close to those regions. This preference is modeled using AssignmentAffinitiesSpec with the *region* scope.
- **Load balancing.** To ensure that the load is balanced across servers, we use BalanceSpec with the *bin* and *region* scopes for regional and global load balancing, respectively.
- **Fault Tolerance.** To ensure that a shard's replicas are spread across various fault domains, such as rack and MSB, we use GroupCountSpec with *replica* as the partition and *rack* or *MSB* as the scope.

The largest sharding problems involve 1.8M objects and 27K bins and have a solve time limit of five minutes. Rebalancer's local search algorithm has scaled well to produce high-quality solutions for such large problems.

3.4 Message Queue Placement

Many people use Meta's messaging products. On the server side, a message queue is created for each user to store messages intended for delivery. Placing the message queue in a datacenter region close to the user reduces latency. This problem is to assign user queues (objects) to datacenter regions (bins). However, treating each user as an individual object is inefficient, so we aggregate users objects with common properties into a bundle and treat each bundle as an object. The bundles are computed offline based on properties such as proximity and connectivity of users within a bundle. The following are some supported requirements:

- **Minimize latency.** Every user bundle has a numerical affinity to each datacenter region. The affinity is equal to the negative of the average network latency to a region for users in the bundle. Utilizing AssignmentAffinitiesSpec as an objective with these affinities minimizes the total latency.
- **Colocate related user bundles.** If two bundles' users frequently communicate with each other, colocating them in the same region would reduce both latency and cross-region traffic. ColocateGroupSpec achieves this purpose, where each *group* is a set of related bundles.
- **Buffer capacity for disaster recovery.** One service level objective is that any single datacenter region can go offline without causing disruption to users. For this purpose, a traffic matrix with elements t_{ij} specifies that in the event of region i failure, a fraction t_{ij} of region i's traffic will be redistributed to region j. Rebalancer must ensure that each region has enough spare capacity to absorb the incoming redistributed traffic. This is achieved by using DrainCapacitySpec to enforce that the peak utilization of a bin with the worst case spillover traffic must be within its capacity limit.

The message-queue problem typically involves tens of thousands of objects and tens of bins, and is solved only once a week. Because of the small scale and lenient solving deadline, Rebalancer translates it into a MIP problem. The traffic-routing problem described in §1 shares some commonality with this problem, but it needs to update the global edge-to-datacenter traffic matrix every few minutes. Hence, it utilizes local search to achieve a low average runtime of 5 seconds.

3.5 Kubernetes Scheduler

When evaluating the flexibility of Rebalancer's specs using the use-case examples above, a question naturally arises: do the specs inherently cover these examples because they are designed to support them? To showcase Rebalancer's flexibility, we implement Kubernetes' scheduling policies using Rebalancer's existing specs. While Rebalancer handles load balancing of containers across machines in production, it does not handle the Kubernetes-like initial container placement in our fleet. This function was implemented in Meta's cluster manager using heuristics similar to those in Kubernetes years before introducing Rebalancer and is still in active use.

Specifically, to prepare for a direct comparison with DCM [38] in performance evaluation (§6), we implemented Kubernetes' scheduling policies listed in Figure 2 of the DCM paper. To improve usability, DCM uses SQL statements to express allocation policies and internally translates these SQL statements into a constraint satisfaction problem, which is then solved using the Google OR-tools CP-SAT solver.

In Kubernetes, container *pods* are scheduled on *nodes* (machines). We represent pods as objects and nodes as bins. Similar to DCM, our implementation schedules a batch of pods together. All unscheduled pods of the current batch are placed in a special *unassigned* bin, and we impose a ToFreeSpec constraint on that bin, forcing Rebalancer to place them on certain nodes. Resource limits, such as CPU and memory, are enforced using CapacitySpec. Affinity of pods for specific nodes is specified using CapacitySpec with a custom dimension representing affinity. Inter-pod anti-affinity for replica groups is modeled using GroupCountSpec. Fixing certain pods to nodes is achieved with AvoidMovingSpec, and so forth.

Overall, we are able to model Kubernetes' scheduling constraints using Rebalancer's existing specs in about 500 lines of code, which is comparable to 550 lines of SQL-based specification in DCM. This demonstrates that Rebalancer is flexible and its usability is comparable to DCM. We will compare the performance of DCM and Rebalancer in §6.

3.6 Other Use Cases

In addition to the examples described above, Rebalancer supports dozens of use cases at Meta, including Linux container rebalancing across servers [39]; routing traffic from globally distributed edge datacenters to main datacenters [5]; grouping serverless functions to improve locality [35]; balancing online ML training workloads across regions while considering the priority of ML workloads; minimizing the number of replicas for ML inference models or databases deployed across geo-distributed datacenters, while adhering to latency SLO and meeting varying user request rates; various sharding systems that have requirements different from the one in §3.3; assigning work tickets to engineers; and so forth.

4 Model Representation

Once an optimization problem is specified using specs, Rebalancer materializes them into an expression graph. Recall that Rebalancer's expression API supports operators such as Max and Sum for aggregation, and Step, Ceil, Log, and Power for transformation. For example, $\mathsf{Step}(x)$ evaluates to 1 if x is positive and 0 otherwise. We translate the specs into a recursive composition of expressions that reuses common expressions to obtain a compact expression graph.

4.1 Translating Specs into Expressions

We use several examples to illustrate how to translate specs into expressions. *CapacitySpec* enforces that the utilization of a resource is within specified limits. For instance, with a CapacitySpec applied to the scope server and dimension CPU, Rebalancer creates $|\mathbb{B}|$ constraints (one per server) in the form of $\mathsf{util}(\mathsf{server}_i, \mathsf{CPU}, \mathsf{AFTER}) \leq L_i$, where L_i represents the CPU limit of server_i. To model double occupancy, CapacitySpec would use ANY instead of AFTER.

MinimizeMovementSpec minimizes the movement of objects into or out of a scope item. Rebalancer adds the expression $\mathsf{util}(S_{\mathrm{out}}, \mathsf{count}, \mathsf{NEW}) + \sum_j \mathsf{util}(S_j, \mathsf{count}, \mathsf{NEW})$ to the objective, where S_{out} represents the set of bins that do not belong to any scope items, such as the *unassigned* bin in the hardware-placement example (§3.1). Note that each moving object is only counted once. Specifically, the first term captures the objects that move out of all the scope items, while the second term captures objects that move within the scope items.

GroupDiversitySpec ensures diversity in the set of objects assigned to a bin. For example, the servers (objects) assigned to a service's global reservation (bin) must come from at least k datacenter regions so that in the event of a region failure, there is at least some capacity available for the service. In this case, assuming objects are partitioned into groups G_i based on their region, Rebalancer adds $|\mathbb{B}|$ constraints (one per service) in the form of $\sum_i \mathsf{Step}(\mathsf{util}(b_j, G_i, \mathsf{count})) \geq k$. Note that the inner Step expression evaluates to 1 if bin b_j contains objects from group G_i and 0 otherwise.

4.2 Reducing Model Size

In the previous section, we discussed how to translate specs into mathematical formulas using expressions such as util. However, the direct representation of util as shown in Equation 1 is inefficient as it would lead to a problem representation size of $\Theta(|\mathbb{O}| \times |\mathbb{B}|)$. To address this scalability challenge, Rebalancer implements several efficient custom expressions that help reduce the problem's model representation to $\Theta(|\mathbb{O}| + |\mathbb{B}|)$. Below, we describe one such expression called Lookup, which is used to efficiently implement util.

Object Lookup. The insight behind Lookup is that, in most cases, an object's dimension value remains unaffected by the bin to which it is assigned. For instance, a task consumes the same amount of memory irrespective of the server on which it runs. This allows representations of utilizations for different bins and scope items to share and reuse these dimension values, reducing the problem input size by a factor of $\Theta(|\mathbb{B}|)$, resulting in an overall input size of $\Theta(|\mathbb{O}| + |\mathbb{B}|)$.

Specifically, for each such static dimension D, we establish an *object-vector*, denoted as V_D, representing a mapping from objects to their dimension values. Given an *object-vector* V_D and a scope item S_i, a Lookup represents an efficient aggregation operation over the (object, bin) pairs for bins in S_i. For example, $util(S_i, D) = \mathsf{Lookup}(S_i, V_D)$ simply aggregates the utilization across all bins in S_i with respect to D through lookup. Note that the memory usage of Lookup itself is of constant size since it only keeps references to S_i and V_D, while the representations of S_i and V_D, with sizes $\mathcal{O}(|\mathbb{B}|)$ and $\mathcal{O}(|\mathbb{O}|)$, respectively, are shared and reused across all expressions. This leads to an overall problem size of $\Theta(|\mathbb{O}| + |\mathbb{B}|)$.

Expression graph. Since constraints in Rebalancer are inequalities in the form of $f(\cdot) \leq 0$, they can be combined using the Max expression. For example, although a CapacitySpec results in $|\mathbb{B}|$ constraints (one per bin), it can be simplified into a single constraint by rewriting it as

$$\mathsf{Max}_i(\mathsf{Lookup}(b_i, V_D) - L_i) \leq 0.$$

As each constraint and objective can be written as a recursive composition of expressions, we can encapsulate an assignment problem's all constraints and objectives in a DAG $\mathcal{G}$. The nodes of $\mathcal{G}$ correspond to expressions, and each objective or constraint in the problem is a subgraph of $\mathcal{G}$; see Figure 2 for an example. For a node $v \in \mathcal{G}$, we use $\mathsf{children}(v)$ to denote the set of all nodes w such that $v \to w$ is an outgoing edge from v. The $\mathsf{type}(v)$ of a node (e.g., Max) is its mathematical operator, and $\mathsf{children}(v)$ represent its inputs. The DAG $\mathcal{G}$ is obtained from a recursive composition of these operators.

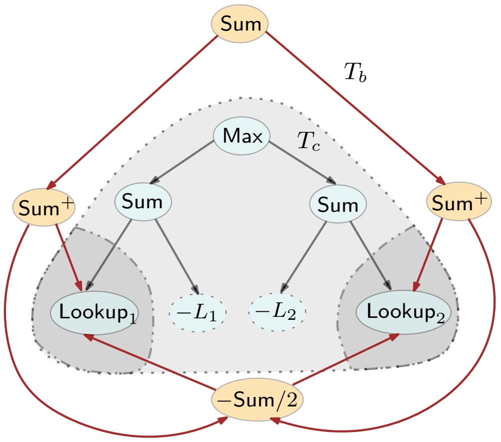

Figure 2: This *expression graph* represents a simplified version of the task-allocation problem shown in Figure 1. It aims to balance the CPU utilization across two servers, server$_1$ and server$_2$. It uses BalanceSpec on the CPU dimension as the objective (subgraph T_b) and CapacitySpec on the CPU dimension as the constraint (tree T_c). Nodes in the intersection of T_b and T_c namely Lookup$_1$ and Lookup$_2$ are reused. Constant nodes are shown in dashed circles. L_i is the CPU limit of server$_i$, Lookup$_i$ represents the lookup for the CPU dimension on server$_i$, meaning server$_i$'s CPU utilization. Sum$^+$ is a shorthand for $\max(0, \text{Sum})$

5 Model Solving

After representing an assignment problem as an expression graph $\mathcal{G}$, the next step is to solve the problem. For small problems, Rebalancer translates it into a MIP problem and solves it with a MIP solver. For large problems, Rebalancer implements its own optimized local search. The existence of the expression graph is a fundamental reason why Rebalancer's local search is more efficient than existing local search algorithms.

5.1 Using MIP Solver

To translate an expression graph into a MIP problem, each expression implements a recursive mipTranslate operation. This operation, based on the expression's type, converts it into a linear combination of binary assignment variables v_{ij} that indicates whether object i is assigned to bin j. Invoking mipTranslate on the root nodes of an expression graph yields a MIP model, which can subsequently be solved using a commercial solver. Note that the MIP model's input size is $\mathcal{O}(|\mathbb{O}| \times |\mathbb{B}|)$, which is not scalable. Therefore, we only use the MIP solver for relatively small problems.

5.2 Graph-Assisted Local Search

In contrast to the MIP solver's all-or-nothing approach to finding the *optimal* solution, local search [1] incrementally generates a set of object *moves* that improve upon the initial assignment but without guaranteeing optimality. Each move

Algorithm 1 Local search using expression graph $\mathcal{G}$

```
while exit-conditions are not met do
    $\mathcal{L} \leftarrow$ generate_candidate_moves($\mathcal{G}$)
    for local change $\delta$ in $\mathcal{L}$ do
        obj$_\delta \leftarrow$ evaluate_moves($\mathcal{G}, \delta$)
        if obj$_\delta > 0$ then
            discard $\delta$    ▷ violates constraint or worsens objective
        end if
    end for
    $\delta^* \leftarrow \min_{\delta \in \mathcal{L}}$ obj$_\delta$    ▷ best local change
    apply_moves($\mathcal{G}, \delta^*$)
end while
```

(o_i, b_s, b_d) corresponds to reassigning object o_i from its source bin b_s to its destination bin b_d.

Although local search has been applied to assignment problems before [19, 33], the uniqueness of our approach, as highlighted in Algorithm 1, lies in its exploration of the expression graph for all its main steps: (1) generating candidate moves, (2) evaluating them, and (3) applying the best moves. In the rest of this section, we describe the main ideas that enable our algorithm to scale to millions of objects and bins.

5.2.1 Generating Candidate Moves

Because each object can potentially be moved from its current bin to any other bin, there are a total of $|\mathbb{O}| \times (|\mathbb{B}| - 1)$ candidate moves to consider. Obviously, it would be too expensive to evaluate all of them. There are two natural ways to reduce the candidate set: (1) restricting the search space to one bin at a time and finding the best moves involving that bin, or (2) restricting the search space to one object at a time and finding the best moves for that object. Rebalancer takes approach (1) because the number of bins is usually much smaller than the number of objects. With this settled, we still need to decide in which order to evaluate bins and, given a bin, how to propose candidate moves. We discuss these topics below.

Bin selection. Our insight here is to first evaluate *hot bins* that potentially can have the biggest impact on the overall objectives by moving objects into or out of these bins. The structure of the expression graph already captures what objectives are affected by which bins and by what amount. Intuitively, for example, if there is a directed path from a node v to a Lookup on bins b_1 and b_2, moving objects in and out of these bins will improve node v's value. The idea is to process the leaf nodes of $\mathcal{G}$ (such as Lookup) in a *greedy order* of their contribution to the objective. This ordering of leaf nodes gives us a sequence of sets of bins $S_v, S_w, \ldots, S_z$ and we can use these sets to infer the *hottest bin*.

Move strategies. After identifying a hot bin, Rebalancer explores different *move strategies* to move objects into and out of it. For example, the SINGLE move strategy considers moving every object in b_s to every other bin b_d exhaustively and accepts the best move. There are also variants of SINGLE, such as SINGLE_GREEDY, which accepts the first improving move, and SINGLE_RANDOM, where b_d belongs to a small sample of randomly chosen bins. A commonly used effective strategy is to first use SINGLE_RANDOM for some period of time when opportunities for improvement are abundant and later switch to using SINGLE_GREEDY when opportunities for improvement become scarce.

In addition to variants of the SINGLE strategy, Rebalancer also supports more complex strategies such as swapping objects between two bins, and using the Kernighan–Lin algorithm to identify the move-destination bin; see details in the Appendix. Finally, Rebalancer also supports custom strategies that exploit domain knowledge. For example, Shard Manager [25] uses Rebalancer to move shards (objects) across servers (bins) to balance the load. If a hot server has many small shards and a few large shards, going through the shards sequentially may spend most of the time evaluating moving small shards that have little impact on the objective. Instead, Rebalancer evaluates large shards earlier, which not only accelerates the search but also reduces the number of shard moves.

5.2.2 Evaluating and Applying Moves

The remaining components of Rebalancer's algorithm are *evaluating* and *applying* moves. When given a candidate move (o_i, b_s, b_d), a naive way to evaluate its impact is to apply the move to the initial assignment to obtain the new assignment. Then, we compute the new assignment's objectives from scratch through a full graph traversal. However, since we already have the value of every graph node under the initial assignment, few nodes might be affected by applying the candidate move. We can significantly speed up the computation by only recomputing the values for these affected nodes.

Bottom-up change propagation. To only recompute the changed nodes, we preprocess the leaf nodes in the expression graph to build a map from objects to the leaf nodes that reference them. Similarly, we build a map from bins to the leaf nodes that they affect. Given a move candidate, we use the two maps to identify a set of leaves affected by the change. We then traverse from those leaves to the roots, and the reached nodes along the way are the set of nodes whose values need to be recomputed.

Minimal computation during a node update. When recomputing the value of a changed node, iterating over all its child nodes is often unnecessary, as only a small fraction of them likely have changed. Depending on the type of the node, we can store additional information to speed up the recomputation. Below, we provide an example for the Max node, while similar optimizations exist for other node types.

For the Max node, we separately compute the maximum value of its changed child nodes (denoted as z_1) and the maximum value of its unchanged child nodes (denoted as z_2). Then, the new value of the node is simply $\max(z_1, z_2)$. To compute z_2 efficiently, we maintain a sorted list of child nodes ordered by their decreasing node value. We iterate over this list and stop at the first child node that is unchanged. This child node's value is z_2. Note that the runtime of this algorithm is proportional to the number of changed child nodes c instead of the total number ℓ of child nodes. This algorithm incurs the overhead of $\mathcal{O}(c \log \ell)$ to update the sorted child list, but it only occurs when a move is accepted and applied. In practice, the number of evaluated but rejected candidate moves often dominates.

Parallelizing Move Evaluations Since move evaluations do not affect the current state, we can use multiple threads to evaluate candidate moves in parallel before we pick the best candidate to *apply*. This improves the number of evaluations per second (evals/s) by an order of magnitude enabling local search to make faster progress. Although the exact number depends upon the problem instance, we are able to obtain roughly 150k evals/s for most large instances. For example, for a large sharding problem, parallel move evaluations resulted in 170k evals/s and 12k applied moves within the time limit of 300s. In contrast, sequential move evaluations result in 25k evals/s and 2k applied moves in the same time limit. In this case, local search was able to progress six times faster due to parallelization of move evaluations.

5.3 Identifying Equivalent Objects

In addition to focusing on hot bins to reduce the search space, for certain commonly used objectives and constraints, we can identify objects that are equivalent from a modeling perspective, thereby effectively reducing the number of objects. This optimization can be applied to both local search and MIP solvers. For example, in the problem of placing tasks on servers, all tasks that belong to the same job are equivalent since they all affect the constraints and objectives in the same way. For a set of equivalent objects, we only need to explore moves with at most one of those equivalent objects, which reduces the search space. In Rebalancer, we employ a recursive algorithm that exploits the expression graph to compute sets of equivalent objects. Various additional details about our solver algorithm can be found in the Appendix.

6 Evaluation

In this section, we evaluate Rebalancer's scalability and solution quality, and compare it with alternative approaches, such as DCM [38] and MIP partitioning techniques similar to POP [31]. Additionally, we assess the efficacy of local search techniques such as hot bin ordering.

Figure 3 shows the statistics of the problems solved by Rebalancer in production during a typical week. These tens of millions of solves span diverse use cases outlined in §3. The largest cases involve service sharding (1.8M shards, 27k servers) and service placement (700k servers, 6k reservations). We will use these application scenarios in evaluation.

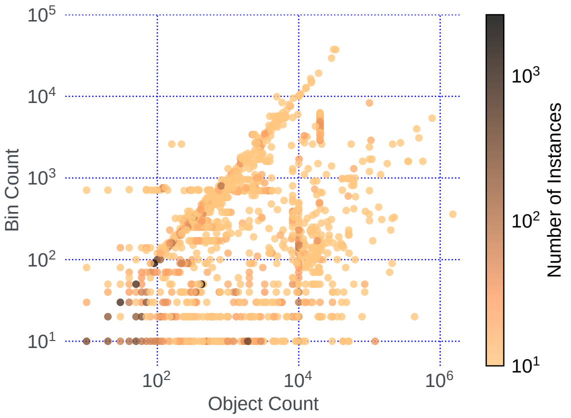

Figure 3: Samples of production problems solved by Rebalancer. The P99 (99th percentile) solve time is 16s with a problem size of 65k objects and 5k bins.

6.1 Comparison with DCM

In the context of cluster management, DCM [38] uses SQL to express policies for placing *pods* on *nodes*. It translates these SQL statements into a constraint satisfaction problem, which is then solved using the Google OR-tools CP-SAT solver. DCM's scalability bottleneck is the CP-SAT solver, which has computational intractability similar to MIP solvers.

We replicated DCM's implementation of Kubernetes scheduler in Rebalancer (§3.5). To stress-test our implementation, we impose inter-pod anti-affinities for all replica groups, a condition known to increase scheduling difficulty. Similar to evaluations in the DCM paper, we use the Azure dataset [27]. All experiments are conducted on a machine with 40 CPU cores and 256 GB of RAM.

We will quote numbers from the DCM paper instead of conducting measurements on our machines because DCM's open source code cannot run on our production machines due to the security setup of those machines. We also cannot run Rebalancer on third-party machines due to its dependencies on tools only available in our production environment. Despite the inability to directly compare their absolute performance on the same machine, their scalability trends are evident from their respective evaluations using the same dataset and implementing the same Kubernetes scheduling algorithm.

We also compare local search's SINGLE_GREEDY move type, which evaluates placing an unscheduled pod on every node, with the SINGLE_RANDOM move type, which randomly selects a fraction f of nodes as targets. If unsuccessful, it repeats the process with the remaining unexplored nodes.

Scalability. We evaluate Rebalancer under two scales: the *DCM-scale*, scheduling 50 pods per batch on clusters with 1k, 5k, and 10k nodes (similar to that in the DCM paper); and the *hyperscale*, scheduling 500 to 5k pods per batch on clusters with 10k, 50k, and 100k nodes. Using larger pod batches in the hyperscale setup is motivated by the fact that the arrival rate of pods typically increases with the cluster size. As shown in Figure 4, the P99 (99th percentile) per-pod scheduling latency of SINGLE_GREEDY is less than 35 ms for instances up to 10k nodes. However, beyond 10k nodes, SINGLE_GREEDY becomes progressively slower, while SINGLE_RANDOM continues to scale well. We have found a sample size of $f = 10\%$ (capped at 1k bins) to offer a good trade-off between solution quality and runtime.

Overall, Figure 4 demonstrates Rebalancer's significant scalability advantage over DCM. Due to inherent scalability limitations in DCM's CP-SAT solver, the largest problem tackled in the DCM paper involved scheduling 50 pods in a 10k node cluster, with close to 30 ms scheduling latency per pod. In contrast, even with a cluster size of 100k nodes (10 times that of the DCM experiment) and a batch size of 5k pods (100 times that of the DCM experiment), Rebalancer with SINGLE_RANDOM achieves a per-pod latency of 14ms.

Solution quality. We compare Rebalancer's local search with an optimal MIP solver in an experiment that places 10k pods from the Azure dataset on 500 nodes, with the objective of maximizing the number of placed pods. As shown in Table 2, neither MIP nor local search can place all pods due to their aggregate resource demand surpassing the capacity of 500 nodes. While SINGLE_RANDOM places 1.4% fewer pods than MIP when nodes are full, its runtime is 5.2 times faster.

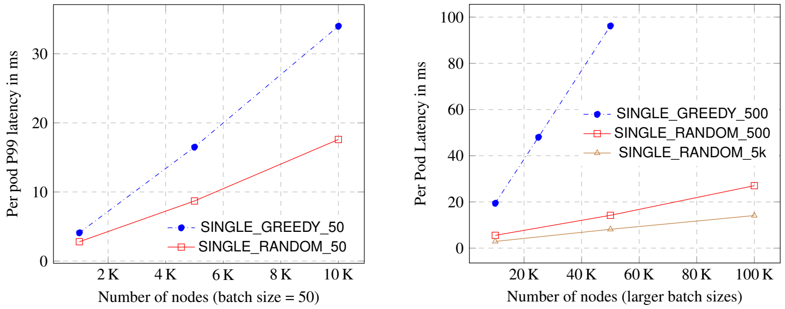
Test case	Optimal MIP solver	SINGLE GREEDY	SINGLE RANDOM
Azure dataset	94.6% (31ms)	92.8% (8ms)	93.2% (6ms)
Pathological N=10	100% (209ms)	97.1% (0.6ms)	97.8% (0.9ms)
Pathological N=100	N/A (timed out after 600s)	97.4% (26.5ms)	97.7% (22.4ms)

Table 2: Percentage of placed pods and the scheduling latency.

To evaluate local search in a scenario where it is unlikely to perform well, we design a pathological case parameterized by N, with $31N$ pods and $50N$ nodes, each with 32GB memory. Pod memory requirements follow an exponential distribution over 5 groups: the first $16N$ pods with 2GB memory, the next $8N$ with 4GB, the next $4N$ with 8GB, the next $2N$ with 16GB, and the last N pods with 32GB. The only way to schedule all pods is when the total used memory on every node is precisely 32GB. Due to the nature of local search, finding this uniquely optimal solution is unlikely. As shown in Table 2, local search can place more than 97% of the pods, while being over 200 times faster than MIP. Additionally, as depicted in Figure 5, Rebalancer finds a solution where the memory usage across nodes is well balanced.

6.2 Comparison with Partitioned MIP

POP [31] improves scalability by partitioning a large MIP problem into smaller ones and solving them independently, coordinating solutions as needed. We have implemented a



(a) DCM-scale problems. (b) Hyperscale problems.

Figure 4: Per-pod scheduling latency of our Kubernetes implementation.

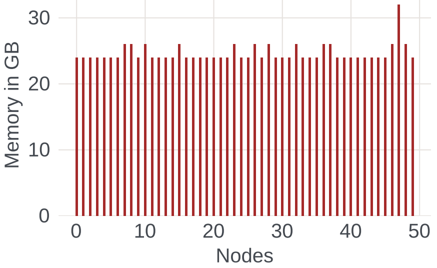


Figure 5: Memory usage across 50 nodes for the pathological case.

POP-like partitioned-MIP solver in Rebalancer in addition to its existing local-search and MIP solvers.

In Table 3, we compare local search with partitioned MIP on the service placement problem (§3.2) using our production data. Here, local search uses a combination of move types, including SINGLE_RANDOM, SINGLE_GREEDY, and SWAP. Local search is up to four times faster, meeting all the service-level requirements such as spread and capacity sufficiency, while its solution quality is less than 0.6% worse than that of partitioned MIP. Due to local search's scalability, even though we used partitioned MIP in production for a period of time, we eventually switched to local search (§7).

Problem Size (objects × bins)	Local Search	Partitioned MIP	Relative Gap
700k × 5.7k	184s	376s	0.43%
710k × 4.8k	214s	350s	0.56%
568k × 4.7k	151s	455s	0.21%
645k × 4.5k	146s	557s	0.11%

Table 3: Problem sizes and runtimes of service placement. The "*relative gap*" denotes the difference in objective values between local search and partitioned MIP.

6.3 Local Search's Individual Techniques

Next, we evaluate local search's individual techniques.

Expression graph $\mathcal{G}$ scales linearly. We validate this using three production instances of the service sharding problem, with 71k, 152k, 289k objects each and roughly 1.5-2k bins. The expression graph's memory usage grows almost linearly from 1.7GB to 3.2GB and 6.2GB.

Move evaluations are fast. As can be seen from the pod scheduling example (Figure 4), evaluating all possible 50k moves for a pod takes only 100ms. This indicates that Rebalancer can evaluate up to 500k moves per second. The techniques detailed in §5, such as bottom-up traversal of changed nodes, help achieve this speed; without them, move evaluations would be an order of magnitude slower.

Hot bin ordering is effective. A *hot bin* is one that contributes the most to the objective, and Rebalancer processes bins in the order of their hotness. As shown in Figure 6, processing bins in the order of their hotness reduces the objective value more quickly. This results in higher solution quality when the search time is capped for large problems.

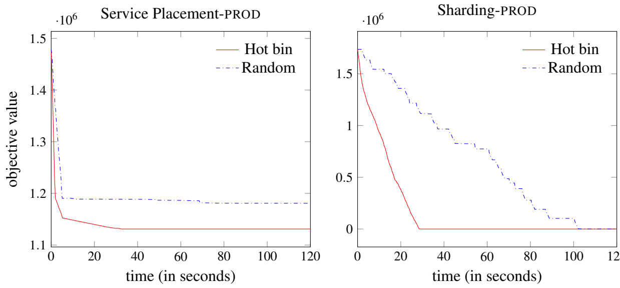

Figure 6: Comparing *hot bin* selection and *random bin* selection using service placement and service sharding.

7 Experiences and Limitations

In this section, we share some learnings from using Rebalancer and discuss its limitations.

7.1 Alternative Approaches for Optimization

We summarize three categories of approaches to solving optimization problems and make our recommendations.

Approach 1: *ad hoc heuristics*. This approach directly implements heuristics to support resource-allocation policies as code. It is the most widely used approach as it is easy to start with. However, as policies grow in complexity over time, adding new ones becomes increasingly difficult, and the solution quality tends to decrease due to the intricate balance required between different policies.

Approach 2: *formal problem specification solved by a formal solver*. Systems utilizing MIP, such as Flux [10], belong to this category, but there are other formal methods as well, such as network flow optimization. Rebalancer with a MIP solver in the backend also fits into this category. To address the challenge that most systems practitioners are unfamiliar with formal problem specification, a higher level of abstractions can be introduced, for example, DCM [38] using SQL and Rebalancer using a high-level specification language. However, a formal method's solver often lacks scalability, posing a hard barrier to its application at hyperscale.

Approach 3: *formal problem specification solved by a systematic-heuristics solver*. This category includes systems that formulate problems using MIP but solve them using simulated annealing or local search. Rebalancer using a local-search solver in the backend falls under this category. The usability issue can be solved by raising the level of abstraction, similar to that for Approach 2. While good scalability is a strength of this method, its weakness lies in producing suboptimal solutions compared to formal solvers.

Recommendation: Based on our experiences, we make recommendations as follows. First, systems requiring short and predictable latency in resource allocation decisions should use ad hoc heuristics, even though they are hard to maintain and evolve. Schedulers for high-throughput, short-lived batch jobs fall under this category. Second, systems needing high-quality solutions for small to medium-sized problems should leverage formal solvers for their optimal solutions. Lastly, for hyperscale systems not requiring real-time decisions, we recommend approach 3 over approach 1, because it is much easier to add or evolve resource-allocation policies with approach 3. One advantage of Rebalancer is its ability to support both Approaches 2 and 3 using the same high-level specification, and seamlessly switch the backend solver as needed, depending on the problem scale and solve time constraint.

7.2 Experiences with Alternative Approaches

Among the three alternatives described in the previous section, our choice for service placement (3.2) evolved from Approach 2 to Approach 3, while our choice for service sharding (3.3) evolved from Approach 1 to Approach 3. We discuss these experiences below.

Service placement. The service-placement problem [32] was initially modeled using Rebalancer's high-level specification language and solved with a MIP solver. This is because initially the problem size was still manageable for MIP, the 20-minute solve time service-level objective (SLO) was sufficient, and we were (overly) worried about the solution quality.

However, as more services and machines were added to the fleet, MIP's solve time became problematic. Meanwhile, the solve time SLO was reduced from 20 minutes to 10 minutes due to the need for faster reactions to capacity change requests. We continued optimizing the MIP solver, for example, by grouping equivalent objects to reduce the number of decision variables. These incremental optimizations bought us some time, but MIP still constantly fell behind on scalability. Other issues included the MIP solver having not only unpredictable execution times but also occasionally running into infeasibility due to numerical precision issues. Debugging and fixing these elusive problems in production under time pressure were recurring pain points for engineers.

To scale MIP, we implemented a POP-like [31] partitioned MIP solver (§6.2). Initially, it performed well in both solve time and reliability. Managing hundreds of smaller subproblems meant that a few failing MIP solves would not have a fleet-wide impact. However, new requirements, such as stacking more services on bigger machines, increased the problem scale by an order of magnitude. At this point, building a partitioned MIP model, which in the worst case uses $|\text{objects}| \times |\text{bins}|$ assignment variables, was no longer practical.

This finally forced us to explore local search. With some tuning, the local search solver achieved both good solution quality and fast solve times. As shown in Table 3, the solution-quality difference between local search and partitioned MIP is less than 0.6%. The lesson for us is that, despite having the local search technology, our unwavering faith in MIP's optimality led us on a lengthy detour to reach our current state.

Service sharding. While service placement started with Approach 2 and converged to Approach 3, the service sharding system Shard Manager, went through the opposite direction, switching from Approach 1 to Approach 3.

When Shard Manager started with ad hoc heuristics more than a decade ago, Rebalancer did not exist at that time. As Shard Manager became widely adopted by many applications, its load-balancing algorithm became overly complicated. For example, it supported multiple-dimension balancing across CPU, memory, and storage, enforced rate limiting, and considered regional and global locality. Unsurprisingly, this complexity led to frequent issues where some servers were overloaded while others were underutilized. Shard Manager struggled to balance the load because the heuristics implementing sometimes conflicting policy requirements were not robust.

The team started rewriting Shard Manager with yet another heuristic implementation. It represented the topology (region, datacenter, power domain, rack, server) as a tree and enforced resource constraints across all levels of the topology. However, achieving good load balancing proved challenging even with a clean implementation. Iterative tuning of the heuristics required constant code changes that might not lead to positive outcomes and often became dead code later.

Eventually, the heuristic-based new prototype was abandoned, and the team switched to exploring Rebalancer with local search. The usability benefits were immediate, as it was much easier to experiment with different load-balancing algorithms by changing a few lines of high-level specification in Rebalancer. The main challenges were solution quality and scalability when solving problems with millions of objects and tens of thousands of bins within the five-minute solve time SLO. These requirements are well met, and in production, 90% of the solves actually finish within 10 seconds.

7.3 Experiments with Simulated Annealing

Recall that Rebalancer's internal architecture decouples problem representation from problem solving. There is a common abstraction all solvers (e.g. local search, MIP) inherit from which can be extended to support experimentation with new kinds of solvers. In the past, we experimented with a solver based on the simulated annealing algorithm. One common problem faced by local search is finding a locally optimal solution that does not lead to a globally optimal solution. This happens when there is no sequence of moves which strictly improve the objective at each step. In order to get out of a local optimum, the sequence of moves would have to temporarily decrease the objective quality. This is not contemplated in local search, but is one of the features of simulated annealing.

However, we found our implementation of simulated annealing to not be practical at all for production-scale problems. It did not beat the performance of local search in any experiments, neither in terms of quality nor run time. At our scale, the number of possible object moves at any point is large (e.g. $\mathcal{O}(10^{11})$ combinations for a problem with several million objects and 100k bins), and the vast majority of these moves are not helpful. We found that it is important to exploit the structure of the objective function and aggressively prioritize which moves to evaluate. This is primarily done by the hot bins optimization in local search. Our implementation of simulated annealing did not exploit this structure, and blindly evaluated moves with equal probability, regardless of the shape of the objective. For this reason, we believe that further research into heuristics to reduce the search space would be needed to make simulated annealing practical. This is challenging because the heuristic would not only have to select *good* moves, but also the right *bad* moves which decrease the quality but are likely to lead to an improved quality later on.

Recall that to ensure allocation stability, it is often desired to limit or minimize the number of object moves needed to improve the assignment. We found this challenging to enforce in an algorithm such as simulated annealing, which greedily makes moves that barely improve or even decrease the quality of the objective. In contrast, local search is able to maximize the objective improvement at each individual step, finding a shorter and more optimized sequence of moves.

7.4 Evolution of Rebalancer as a Library

Originally, Rebalancer was designed as a standalone executable that took an input file describing the model in a custom format. This initial design quickly became hard to maintain as it required the service invoking Rebalancer to carefully craft the input. At that point, we decided to create a strongly typed API for programmatically defining models. As a result, with the help of the compiler and runtime sanity checks, the interface-related maintenance overhead drastically reduced. The implementation of this interface was an inflection point for the adoption of the project, as it became intuitive enough to be used by many teams at Meta.

There still remained a question of whether to make Rebalancer a service or a library. We decided to make Rebalancer a library for two main reasons. First, services invoking Rebalancer need to collect and feed Rebalancer with potentially a large amount of input data, which can be done more efficiently via a library API. Second, providing a multi-tenant service is difficult, as different Rebalancer use cases can heavily contend with each other due to their high memory and CPU usage. Currently, if a particular use case still prefers to operate Rebalancer as a single-tenant service, they could do so by wrapping the library with an RPC interface, but we have not seen that in practice.

Therefore, today Rebalancer is implemented as a library that gets compiled into each project that depends on it. The resulting binary has predictable behavior, which does not change unless it is recompiled with a newer version of the code. Different usecases have their custom logic to collect the input and setup an assignment problem using Rebalancer's specification language (See Figure 1 for an example). The usecases then specify the choice of solver (MIP or Local Search) and invoke the core solver which builds the expression graph, solves the problem and returns a solution.

7.5 Handling Multiple Objectives

Each objective specifies a weight and a priority. Rebalancer combines all objectives with the same priority using a weighted sum. Finding appropriate weights for competing objectives (e.g., objA, objB) is done by first normalizing them so that their values are comparable and then selecting multiplicative weights based on their relative importance in the problem domain. Some use cases provide strict priorities for objectives, and Rebalancer ensures that it does not regress on higher-priority objectives when solving for lower-priority objectives.

Recall that local search only makes moves that strictly improve the objective value and is generally more stable. However, when using MIP, if there are two solutions with exactly the same objective value, Rebalancer may choose one of them arbitrarily, causing instability across multiple solves. In such cases, we typically add a MinimizeMovement goal that disincentivizes moves which do not strictly improve the objective.

7.6 Debugging Solver Behavior

The majority of engineering time in setting up a model goes into debugging the behavior of the solver, which includes ranking the objectives by their importance, identifying conflicting constraints, etc. Without proper tools, this process requires a deep understanding of the internals of the solver, which only engineers working on the core of Rebalancer have. Over time we identified the common questions that helped modelers understand the solver's behavior and we built a specialized UI tool for answering them: Rebalancer-explorer. At a high level, Rebalancer-explorer can be compared to debugging tools such as Whyline [24] for post-facto analysis.

Under the hood, Rebalancer-explorer loads the expression graph representation in memory and reuses many of the algorithms mentioned earlier making it extremely fast to evaluate formulas on demand. At a high level, the UI consists of:

- *Table view* to inspect objects, bins, their dimensions and their membership in partitions and scopes.

- *Tree view* to inspect the underlying expression (sub)-graph corresponding to various user provided specs.
- *Solution comparison view* to inspect the goal and constraint values for different solutions. By default, it shows a comparison of initial and final solutions.
- *Timeline navigation view* to inspect the sequence of moves performed by local search at each step and the associated objective improvements.

One example scenario is to answer questions such as *why did solver not move an object to/from a given bin*. We can use the solution comparison view to compare the goal/constraint values between the solver-generated solution, and an ad hoc solution where a specific object is moved to/from the given bin. In this case, the UI gives real-time feedback of why that move is not good – perhaps it breaks a constraint, or makes the goal value worse.

7.7 Limitations of Rebalancer

Some problems can be modeled with MIP but cannot be modeled with Rebalancer because they do not fit the abstraction of assigning objects to bins. One such example is to assign network traffic flow to links, where Rebalancer cannot model a sequence of dependencies in the link topology. However, Rebalancer 's low-level expression API and expression graph are generic enough to support these problems while providing a significant boost for usability. Consequently, we extended the expression API and expression graph to create a more flexible framework, enabling the modeling of MIP problems beyond assignment problems.

8 Related work

There is a rich body of work in the systems research community that uses optimization problem formulations for different resource allocation settings (e.g. [2–9, 11, 13, 14, 16–18, 20, 22, 25, 28, 32, 34, 37–42]). Among these, Rebalancer shares design goals with Wrasse [34] and DCM [38] domain-specific language (DSLs) for resource allocation problems.

Comparison with existing DSLs. Wrasse [34] also uses an object-bin abstraction but their specification language is limited to a small set of properties such as resource capacity but for example does not support many other important properties listed in Table 1 such as spread, balance, affinities etc. Moreover, their GPU-based solver is tightly coupled with these properties making it hard to extend. On the other hand, DCM [38] allows a user to specify constraints and goals using SQL-like queries which are then fed into off-the-shelf solvers. As discussed before, DCM's ability to scale is limited by the intractability of underlying constraint solvers.

Other relevant systems. These systems fall in one of two categories. They either use some hand-crafted heuristics or use a commercial MIP solver. Examples which use heuristics include cluster management [4, 7, 43], application sharding [2, 25], and container reallocation [33]. The paper [33] uses variation of local search to move containers across physical machines but its scalability is limited by the fact that it uses $|\mathbb{O}| \times |\mathbb{B}|$ decision variables. Examples where commercial MIP solvers are used include capacity reservation [32] and in cluster managers [11, 41]. Rebalancer, through its specification language and its ability to translate to MIP models can help set up and solve (using Xpress and Gurobi) a version of many of the above problems at a comparable scale.

There also has been some recent progress on solving hyperscale allocation problems using MIP models. POP [31] presented a technique to decompose large scale assignment problems into small ones and combine their solutions to solve the bigger problem. However, POP requires that resources (objects) are *fungible* and clients (bins) should not prefer one object over others by a large amount. These do not always hold for assignments problems we encounter, for instance, in the case of service placement, it is common for services to request specific server types. This is the reason why our POP-like partitioned MIP solver required some additional techniques.

Work on the machine reassignment problem. A set of relevant work are the papers [12, 19, 26] from the 2012 ROADEF/EURO Challenge [29]. This challenge was designed to solve a *machine reassignment problem*, which is about reassigning processes to machines to satisfy some goals and constraints such as load balancing (see [29] for details). These papers design heuristics to solve such problems and there are some broad similarities with the ideas used in Rebalancer's local search. However, it is unclear if their techniques generalize beyond the relatively small scale and type of problems that were used in the contest.

9 Conclusion

In this paper, we discuss the design and implementation of Rebalancer, a generic framework that solves a diverse set of hyperscale assignment problems. Rebalancer decouples problem specification from optimization by defining a compact graph representation, simplifies problem specification with a high-level language, and designs a scalable optimization algorithm. Finally, we shared our experiences and lessons learned from evolving solutions for service placement and service sharding.

10 Acknowledgements

We acknowledge the contributions made by all past and present members of Algorithmic Optimization, RAS and Shard Manager teams at Meta towards evolution of Rebalancer over the last seven years. In particular, we would like to thank Aravind Narayanan, Raj Rajendran, Sahil Deshpande, Apurva Samudra and Pavan Kumar for their contributions to Rebalancer. We also thank all the reviewers and our shepherd Philip Levis for their insightful comments.

Appendix A Additional Details on Rebalancer's Local Search

The input to the local search algorithm that powers Rebalancer is an initial assignment $\mathcal{A}_0$ and the compact representation of goals and constraints as the expression graph $\mathcal{G}$. Furthermore, in the rest of this section, we assume that the following preprocessing steps have been done on $\mathcal{G}$.

- *Compute and store current values of each node*: This can be done by a simple recursive algorithm on all the roots $r_i \in \mathcal{G}$, where the value of a node Z_v is computed using the values of its children.
- *Compute and store the current upper and lower bounds for each node:* This can again be done by a simple recursive algorithm. For a node v, we use Z_v^{ub} and Z_v^{lb} to denote its upper and lower bounds, respectively.
- *Compute and store the potential of each node:* The *potential* of a node v is the difference between its current value and its lower bound (i.e., $Z_v - Z_v^{\text{lb}}$). Additionally, for each node $v \in \mathcal{G}$, we maintain a sorted order of its $\mathsf{children}(v)$, sorted by their potentials. We say that a subgraph rooted at v is *optimal* if v's potential is zero.
- *Compute and store the* affected bins *of each node:* Recall that a leaf node $\ell \in \mathcal{G}$ (such as ObjectLookup) is parameterized by a set of bins S_ℓ and changes to contents of S_ℓ will potentially change the value at node ℓ. We refer to the set S_ℓ as *affected bins* which can be recursively computed for all $v \in \mathcal{G}$ as $S_v = \{\bigcup S_w \mid w \in \mathsf{children}(v)\}$. (See also Figure 2).

A.1 Restricting the search space

One important step in any local search algorithm is to generate a neighboring set of candidate solutions. To get to a candidate solution, Rebalancer employs the notion of a *local change*, denoted δ, which is a set of ordered tuples (o_i, b_s, b_d) and where each tuple denotes the change in some o_i's assignment from some b_s to some other b_d (or alternatively, the "movement" of o_i from b_s to b_d). We refer to each tuple in δ as a *move*. So, δ is simply a set of moves. We will use the term *applying the local change* to describe the process of updating $\mathcal{A}$ with the moves in δ and denote it as $\mathcal{A} \oplus \delta$.

It is easy to see that given any two assignments $\mathcal{A}$ and $\mathcal{A}'$, there exists a set of moves δ such that $\mathcal{A}' = \mathcal{A} \oplus \delta$. So, now, the question remains as to how we can systematically generate candidate sets of moves. First, observe that even if we restrict ourselves to *single moves*—i.e., local changes where we explore moving a single object from some source to some destination bin—there are $\mathcal{O}(|\mathbb{O}| \times |\mathbb{B}|)$ choices. As discussed before, this is unacceptable for large problems, and so we must find another way to restrict the search space.

There are two natural ways to do this, *i)* restrict the search space to *one bin at a time* and find the best moves involving that bin, *ii)* restrict the search space to *one object at a time* and find the best moves for that object. Note that in both these cases the order in which we explore the bins (resp. objects) is extremely important or we may spend too much time exploring moves that yield little improvement. In Rebalancer, we restrict the search space at the *bin* scope. This decision is primarily motivated by the fact that the number of bins is usually much smaller than the number of objects, so restricting the search by bins makes faster local progress. Now, even with the choice of exploring one bin at a time, there still remains two main questions: *i)* What is the order of bins to consider, *ii)* Given a choice of bin, how to generate the set of local changes. We will answer the second question below and return to the first one in the next section.

A.1.1 Move Types

Given a bin b_s, we can generate local changes that move objects to and from b_s. To methodically generate them, we use the notion of a *move type* that describes the semantics of these changes. For example, a SINGLE move type considers moving every object in b_s to every other bin b_d. There can be other variants of SINGLE such as SINGLE_GREEDY which accepts the first improving single move, and SINGLE_RANDOM where b_d belongs to a small sample of randomly chosen bins. Although in our experience just using *single move types* often suffices, it is worth noting that the notion of a move type is highly customizable and can exploit problem-specific domain knowledge. In the following, we describe this in a greater detail.

Overall, each move type generates a set of local changes $\mathcal{L}$, evaluates each of the resulting candidate solutions (i.e., for each $\delta \in \mathcal{L}$, evaluates $\mathcal{A}' = \mathcal{A} \oplus \delta$), and if it exists, returns the δ that improves the objective the most. The logic to generate $\mathcal{L}$ varies based on the move type and the following are some commonly used ones.

- **SINGLE:** Given a source bin b_s, it tries moving every object in b_s to every other bin b_d. That is, $\mathcal{L}$ is the set of all $\delta_{i,d}$, where $\delta_{i,d} = \{(o_i, b_s, b_d)\}$ is a move set with exactly one move.
- **SINGLE_GREEDY:** Similar to SINGLE, but instead of evaluating moving every object in b_s to every other b_d, it considers the objects in some order and only considers the moves with the subsequent object if no improving move was found with the previous one.
- **SWAP:** For a source bin b_s and all other destination bins b_d, it tries swapping every object in b_s with every object in b_d .
- **KL_SEARCH:** inspired by Kernighan–Lin algorithm [23]. Given a source bin b_s, and for every possible destination bin b_d, construct the KL-move set δ_k iteratively as follows. Let $\delta_0 = \emptyset$ be an initially empty move set. The move sets at the end of i-th ieration δ_i is best of $\delta_{i-1} \cup m_i$ where m_i is a single move from b_s to b_d or from b_d to b_s. The iteration stops once moves involving all objects in b_s and b_d have been tried. The KL-move set δ_k is the best of all δ_i.

In fact, there are more complex move types in Rebalancer, but we do not go into its details here due to space constraints.

A.1.2 Identifying equivalent objects

In addition to restricting the search space to explorations from a bin, depending on the set of objectives and constraints, it might be possible to identify objects that are equivalent from a modeling perspective. For example, in the TASKS-ON-SERVERS example, all tasks that belong to the same job are equivalent, since they all affect the constraints and objectives in the same way. Observe that if we identify the sets of equivalent objects, then we can cut down the search space even further by only exploring moves with at most one object from an equivalence class. In Rebalancer, we employ a recursive algorithm that exploits the expression graph $\mathcal{G}$ to compute sets of equivalent objects.

Consider again the TASKS-ON-SERVERS example. There we would ideally want a solver to automatically identify that all tasks that belong to the same job are *equivalent*, since they all affect the objectives and constraints identically. In fact, such a feature can be quite powerful in further reducing the search space, since it allows us to discard moves that are equivalent while exploration (two moves are equivalent if they both move equivalent objects from a source bin to destination bin).

In Rebalancer, the intuition described above is formalized using the notion of *equivalent objects*. Formally, let $\mathcal{A}$ be any feasible solution of the given problem, and for two objects o_i and o_j, let $\mathcal{A}'$ be the assignment obtained by swapping their bins, i.e., $\mathcal{A}' = \mathcal{A} \setminus \{(o_i, \mathcal{A}(o_i)), (o_j, \mathcal{A}(o_j))\} \cup \{(o_i, \mathcal{A}(o_j)), (o_j, \mathcal{A}(o_i))\}$. Then, o_i and o_j are deemed *equivalent* if all constraints and objective expressions evaluate to the same value for both $\mathcal{A}$ and $\mathcal{A}'$. Alternatively, one can also, slightly informally, think of o_i and o_j as equivalent if, for every bin b and for a problem expressed in native form (i.e., using assignment variables), the modified problem that results from replacing every variable of the form $v_{i,c}$ with variable $v_{j,c}$ is mathematically equivalent to the original problem.

Ideally, we want compute an optimal set of equivalent objects (i.e., a set $P = \{I_1, \cdots, I_k\}$ of minimum size and where each object is part of one of the I_js and each I_j is a set of equivalent objects), however this is computationally hard. Hence, we use a greedy recursive algorithm which once again exploits the expression graph $\mathcal{G}$. The main component in our algorithm is for every node in $\mathcal{G}$ to maintain some information about what sets of objects are equivalent with respect to it. For example, in the case of ObjectLookup, two objects are equivalent w.r.t. it if they have the same value in the corre-

Algorithm 2 **Finding sets of equivalent objects**

```
$P \leftarrow \{\mathbb{O}\}$                    ▷ initially, all objects are considered equivalent
repeat for each node $v \in \mathcal{G}$
    if children($v$) is empty then,
        return set of equivalent objects w.r.t. $v$
    end if                           ▷ every leaf stores sets of objects eq. w.r.t. it
    for each child $w \in$ children($v$) do
        $P_w \leftarrow$ set of equivalent objects w.r.t. $\mathcal{G}_w$
        for each set $I \in P_w$, where $I \notin P$ do
            $\mathcal{E}_1, \ldots, \mathcal{E}_k \leftarrow$ sets in $P$ that intersect $I$
            Create $2k$ sets $O_1, \ldots, O_k$ and $N_1, \ldots, N_k$,
              where $O_i = \mathcal{E}_i \setminus I$ and $N_i = \mathcal{E}_i \cap I$
            $P \leftarrow \{O_1, \ldots, O_k, N_1, \ldots, N_k, \mathcal{E}_{k+1}, \ldots, \mathcal{E}_{|P|}\}$
        end for
    end for
until all nodes in $\mathcal{G}$ are explored
return $P$
```

sponding V. Once we have this information for every node in $\mathcal{G}$, we can then have an algorithm that starts by initially considering all objects as equivalent, and then recursively splits this set while ensuring that no two objects that are deemed non-equivalent by a node is part of the same set. Algorithm 2 describes how to do this. While it is possible to prove that this algorithm does produce a set of equivalent sets (although not necessarily of minimum size), a formal proof is beyond the scope of this paper.

A.2 Computing the hottest bin

While move types help in generating local changes, the more important question is: *what order of bins should one look for moves from?* To answer this, we introduce the notion of *hottest bin*. A bin is considered *hottest* when, given an objective and a current assignment, moving objects to or from this bin reduces the objective value the most. At a high-level, during each iteration we find the hottest (a.k.a. most broken) bin and attempt to fix it by making local changes as dictated by the *move types*, and continue the search until no progress can be made. Algorithm 3 describes the high-level local search algorithm used in Rebalancer. (Timeout handling has been omitted for simplicity.) Observe that there are three performance sensitive components in our algorithm, *i)* finding the hottest bin (line 7), *ii)* given a local change, evaluating the objective value (line 12), and *iii)* applying a local change (line 17). In the rest of this section, we describe each of these components in more detail.

Algorithm 3 Local Search Algorithm

Input: Objects $\mathbb{O}$, bins $\mathbb{B}$, expression graph $\mathcal{G}$, initial assignment $\mathcal{A}_0$

```
 1: $\mathcal{A} \leftarrow \mathcal{A}_0$                              ▷ set current assignment
 2: $anyProgress \leftarrow$ true
 3: while $anyProgress$ do
 4:     $anyProgress \leftarrow$ false
 5:     $explored \leftarrow \emptyset$
 6:     while $explored \neq \mathbb{B}$ do
 7:         $b_{hot} \leftarrow$ find_hottest_bin($\mathcal{G}$) $\notin explored$
 8:         $currProgress \leftarrow$ false
 9:         for $moveType$ in MoveTypes do
10:             $\mathcal{L} \leftarrow$ local changes using $b_{hot}$ and $moveType$
11:             for local change $\delta \in \mathcal{L}$ do
12:                 obj$_\delta \leftarrow$ evaluate_changes($\mathcal{G}, \delta$)
13:                 remove $\delta$ from $\mathcal{L}$ if it violates any con-
                    straint or worsens objective, i.e., obj$_\delta > 0$
14:             end for
15:             if $\mathcal{L}$ is not empty then
16:                 $\delta^* \leftarrow \min_{\delta \in \mathcal{L}}$ obj$_\delta$         ▷ best local change
17:                 apply_changes($\mathcal{G}, \delta^*$)
18:                 $\mathcal{A} \leftarrow \mathcal{A} \oplus \delta^*$                  ▷ update assignment
19:                 $currProgress \leftarrow$ true
20:                 $anyProgress \leftarrow$ true
21:                 break
22:             end if
23:         end for
24:         if $currProgress$ is false, then add $b_{hot}$ to ex-
            plored
25:     end while
26: end while
```

Intuitively, the hottest bin is one that can potentially improve the most from local moves, but it is not obvious how to find such a bin. Prior work explored the concept of *bin potential* which, for a bin b, is the difference in the current objective value and the value of the objective after removing all objects in b [19]. Although a reasonable metric, it only works for objectives that can be improved by moving objects out of a bin, but not when objects need to be moved in, such as what is required when enforcing minimum capacity. Moreover, finding a candidate bin can be expensive as it requires computing the contribution of every bin and taking the maximum.

The bin ranking algorithm used in Rebalancer exploits the expression graph $\mathcal{G}$ and works regardless of whether the objectives improve by moving objects in or out of them. Moreover, it does not need to compute the contribution of every bin and terminates as soon as the hottest bin has been established. Recall that each node $v \in \mathcal{G}$ directly (leaf nodes such as Lookup) or indirectly (internal nodes such as Max) affects a set S_v of bins. The idea is to process the leaf nodes of $\mathcal{G}$ in a *greedy order* of their contribution to the objective. This ordering of leaf nodes gives us a sequence of sets of bins $S_v, S_w, \ldots, S_z$ and we can use these sets to infer the *hottest bin*. Indeed, if each leaf node affected exactly one bin, the hottest bin would be the one corresponding to the first leaf in this ordering. However, leaf nodes such as ObjectLookup may affect many bins, so we need a way to break ties.

We do this by maintaining an initially empty list of *hottest candidates* in a data structure H called *incremental priority*

Algorithm 4 find_hottest_bin

```
1:  Incremental priority queue $H \leftarrow \emptyset$
2:  $iter \leftarrow$ objective root
3:  **if** valid cache exists, **then** restore $H$ and $iter$ from cache
4:  **while** $iter \neq end$ **do**
5:      $v \leftarrow$ node at $iter$
6:      **if** $H$ has a unique best element **then**
7:          **return** $\mathsf{top}(H)$ as the hottest bin
8:      **end if**
9:      **if** $v$ is a leaf or *does not need expansion* **then**
10:         $S_v \leftarrow$ affected bins at $v$
11:         $\mathsf{update}(H, S_v)$                ▷ update queue $H$
12:     **end if**
13:     advance $iter$ to the next node in pre-order
14: **end while**
15: **return** $\mathsf{top}(H)$ breaking ties at random
```

queue. The items in H are bins whose priority is defined using a *series of sets* of descending priority. Given two bins $b, b' \in H$ and the series of sets associated with each, b has a higher priority than b' if it appears in a set before b' does. If both b, b' appear for the first time in the same set, then the second set breaks the tie, and if the second is also the same, then the third is used, and so on. The series of sets can be fed into the data structure one set S at a time with $\mathsf{update}(H, S)$. One implementation of this data structure is to maintain a map of bins with the indices of the sets in which they appear. This map is sorted by a custom *compare* function which orders the bins in the right way. For example, if we had three sets $\{1\colon \{b_p, b_q\}, 2\colon \{b_p, b_q, b_r\}, 3\colon \{b_p, b_r\}\}$, the sorted map will be $b_p\colon \{1,2,3\}, b_q\colon \{1,2\}, b_r\colon \{2,3\}$. In this case, once all the sets have been processed, b_p will be the hottest bin.

Algorithm 4 describes how we compute the hottest bin by traversing the expression graph $\mathcal{G}$ in *pre-order*. We start with the objective root and process children recursively in the order of decreasing potentials and exit as soon as the hottest bin is found (line 7). We also perform some natural optimizations to reduce the number of nodes traversed. For example, we do not recursively expand nodes that have achieved their bound values, and also do not expand if every node in the subgraph rooted at it affects the same set of bins (line 9). Observe that the algorithm saves the progress each time and if possible resumes from a valid cached state. If we invalidate the cache after applying each local progress, then the ordering of hot bins is *dynamic*, otherwise it is *static*. Indeed dynamic ordering often leads to a better solution quality (at the cost of recomputing the ordering every time), but there are cases when a static ordering is sufficient.

A.3 Evaluating and applying candidate solutions

The remaining two important components of our local search algorithm are *evaluating* and *applying* a set of moves δ. A naive way of evaluating or applying a change δ would be to just recompute the modified assignment $\mathcal{A}' = \mathcal{A} \oplus \delta$ and recompute the value of all nodes by a full recursive traversal. Indeed this is quite inefficient as it requires traversing and recomputing values for all nodes of the graph $\mathcal{G}$ when the number of nodes affected by the change δ is likely quite small. Since every node of the graph already stores its value w.r.t. to the current assignment, if we can find a way to identify the child nodes whose values need to be recomputed and combine them with values that were not modified, we can significantly speed up evaluate and apply operations. Observe that *applying* of moves updates the internal state of graph $\mathcal{G}$ (namely node values, bounds, ordering of children by their potential), whereas *evaluating moves* does not modify the graph. This distinction is important as it allows us to achieve even faster running times for *evaluate* operations. Below, we describe some ideas that make this possible.

Bottom-up propagation of changes.

Once the expression graph $\mathcal{G}$ is built, we can also preprocess the leaf nodes to build a map $\mathcal{M}_o$ from objects to the leaf nodes that reference them. Similarly, we build a map $\mathcal{M}_b$ from bins to the leaf nodes that they affect. Recall that each local change δ is a set of moves (o, b_s, b_d) that denotes moving object o from b_s to b_d. Given this, we can iterate over the set of moves in δ, and use the maps $\mathcal{M}_o, \mathcal{M}_b$ to compute a set of leaves L affected by the change δ. Starting from the leaves in L, we traverse the graph bottom-up (from leaves to the roots) using the *incoming edges* at every node. The set of nodes reachable in this way is precisely the minimal set of nodes whose values need to be recomputed. (See also Figure 2.)

Minimal computation at a node v.

While recomputing value of a changed node v, iterating over all the nodes in $\mathsf{children}(v)$ can be unnecessarily expensive especially when only a small number of child nodes may have been updated. Depending on the type of the expression node, we can store some additional information that makes these updates significantly faster. Here we give an example for the Max node; similar optimizations exist for other node types. For a Max node, we maintain a *sorted list of children* by their value. We first iterate over all the *updated child nodes* and take the maximum of their new values; suppose that this value is z_1. Next, we iterate over the list of sorted children nodes and stop at the first node that was not updated. Let the value of that node be z_2. Now, it is not hard to establish that the updated value of this Max node is $\max(z_1, z_2)$. Observe that as a result of this process, updating the value of this node took $O(|Z|)$ time, where $Z \subseteq \mathsf{children}$ is the set of updated children, as opposed to $\mathcal{O}(|\mathsf{children}(v)|)$. However, this comes at the cost of a more expensive apply operation where we will need to update the list of sorted children. This trade-off is acceptable because the number of evaluations is typically several orders of magnitude larger than the number of apply operations.

A.4 Local search exit conditions

Recall that our local search algorithm terminates when it can no longer make any progress. In some cases, depending on the values of the objectives, it might be possible to determine if any future moves can result in an improvement, and if not end the search early. Below, we briefly describe the notions of *global* and *local* optimality that are used for this purpose.

Global Optimality

Recall that we had recursively computed the lower bounds for each node in $\mathcal{G}$. If the current value of the objective root note has reached its estimated lower bound, we say that the current assignment is *globally optimal* and we can terminate our local search algorithm.

Local Optimailty

Observe that in Algorithm 3, we maintain a list of *explored* bins, which are the set of bins for which no improving move was found. We leverage this information to compute a new *constrained lower bound* for each expression. To do this, assume that all the bins in *explored* are frozen (can neither move objects in or out) and compute the new value of each expression. For example, consider a Lookup node v such that all its affected bins S_v are explored. Since future moves cannot improve the value of this node, we can establish that its *constrained lower bound* is its current value. Once the bound of all leaf nodes are updated, we can recursively compute the updated constrained bounds of all the expressions. If we establish that the value of the objective root node is the same as its constrained lower bound, then we say that the current assignment is *locally optimal*, and if this happens, then we can terminate the inner loop of our local search algorithm (lines 6-25 of Algorithm 3).

A.5 Numerical stability of incremental apply

Please refer to the discussion in the main text around incremental application of small changes in local search. Observe that another challenge that we need to tackle is numerical stability of *apply* operations. This is more important for nodes of the graph $\mathcal{G}$ such as *Sum* that can accumulate numerical errors by performing arithmetic operations on values of children nodes. For example, let ε be the numerical tolerance for satisfying a constraint. That is, two values are considered equal if they are within ε of each other. Now suppose applying every change incurred an error of say $\varepsilon' = 10^{-3}\varepsilon$, we would accumulate an error of $K\varepsilon'$ after applying K moves. Say if $K = 10^4$, would incur an error of 10ε which is enough to invalidate a valid constraint. Although some amount of precision loss is unavoidable, apply operation for expressions in Rebalancer are designed to minimize precision loss as much as possible. In some cases, as shown below, there is a trade off between running time and precision loss and we need to use a slightly advanced data structure to achieve both.

For example, consider the Sum, where we have two alternatives for recomputing its value for a given change δ. Note that any floating point arithmetic often results in some loss of precision.

- *Case 1 : Slow with small precision loss and numerical stability.* Compute the value dynamically after every change by summing the values of children. This takes $O(|\mathsf{children}|)$ time. Even though there is some precision loss in this process, the resulting value is the same as the values are added in the same order.

- *Case 2: Fast with high precision loss and numerical instability.* Let z_0 be the current value of the total sum, and z_p, z_n respectively be the sum of prior and new values of the *changed children*. Then the updated value of this node after applying the change is $z_0 + z_n - z_p$. Note that this takes $O(|\delta|)$ time but we would likely accumulate some additional precision loss by subtracting two approximate numbers z_n and z_p. Moreover, this problem is encountered per update, and it adds up across many incremental updates. Finally, this also results in numerical instability because the result depends on the order of applying updates.

We can address this problem by building and maintaining *segment tree* structure over the children values that supports computing sum of values in a given range as well as value updates in logarithmic time. Therefore applying the change δ takes $O(|\delta| \log |\mathsf{children}|)$ time but incurs smaller precision loss and better numerical stability.

Appendix B Additional Details on Rebalancer's MIP Based Solver

In the previous section, we described a local search based algorithm for solving assignment problems. However, for problems that are not too big or where the solution quality is extremely important, we can use commercial Mixed Integer Programming (MIP) solvers such as Gurobi [15] and Xpress [45]. As we will soon describe, here again we use the flexibility of the expression graph $\mathcal{G}$ to translate all or part of the problem to a MIP model, which in turn enables us to combine the strengths of MIP solvers with our local search algorithm for applications that need them.

B.1 On-the-fly translation to a MIP model

Recall that the standard MIP model for an assignment problem consists of *binary* assignment variables v_{ij} for every object bin pair (o_i, b_j). In Rebalancer, we reuse the notion of *equivalent objects* briefly described in Section A.1 to succinctly combine assignment variables of objects that belong to the same equivalence class. To see how, first, let $\mathbb{O}_d$ be the collection of equivalent sets of objects; each element $\mathbb{O}_d^i \in \mathbb{O}_d$ is a set of equivalent objects. Next, we introduce the notion of *dynamic bins*, denoted $\mathbb{B}_d$. A bin is dynamic if objects can move in or out of it. Note that depending on the constraints, some bins may not be able to do either (i.e., they are frozen). Given this, the assignment variables in our MIP model are defined as follows.

1. For each eq. object set $\mathbb{O}_d^i$ and dynamic bin $b_j \in \mathbb{B}_d$, create an *integer* variable v_{ij} that represents the number of objects of type i that are assigned to b_j. Set the lower bound of v_{ij} as 0 and upper bound as $|\mathbb{O}_d^i|$.
2. For each $\mathbb{O}_d^i$, add an *object integrality constraint*: $\sum_j v_{ij} = |\mathbb{O}_d^i|$ which ensures that all the equivalent objects in a set are assigned.

Note how the above reduces the number of variables from $\mathcal{O}(|\mathbb{O}| \cdot |\mathbb{B}|)$ to $\mathcal{O}(|\mathbb{O}_d| \cdot |\mathbb{B}_d|)$. In our experience, this optimization can sometimes be the difference between being able to solve the problem using a MIP solver and otherwise.

Given the assignment variables above, similar to *evaluate*, and *apply* operations, every Rebalancer expression implements a mipTranslate operation, which knows how to correctly translate the expression based on its type into a linear combination of assignment variables. Below we show a couple of examples (see [44] for details on translating many other expressions including some non-linear types).

- For a leaf node v of type Lookup, we can implement the mipTranslate similar to the native representation of util defined in Equation 1.
- For a node v of type Max, we can use standard techniques of translating a max function to MIP model. For simplicity, consider the easy case when v is minimized by some objective. In that case, we add a new variable z to the model, for all $w \in \mathsf{children}(v)$, add constraints $z \geq \mathsf{mipTranslate}(w)$, and return the expression z.

With mipTranslate operation of each node in place, we can build the MIP model M for the entire problem by recursively calling mipTranslate on the objective root obj_r and all the constraint roots, ctr_r^i. Once we have the MIP translation, the objective in the MIP model is to minimize $\mathsf{mipTranslate}(\mathsf{obj}_0)$ and the constraints are $\mathsf{mipTranslate}(\mathsf{ctr}_r^i) \leq 0$ for all ctr_r^i and the ones that are added during the mipTranslate calls on a node (like in the case of Max node described above).

B.2 Solving the model

We can use the aforementioned translation algorithm parameterized by dynamic bin set $\mathbb{B}_d$ to generate the MIP model and solve using commercial solvers. If the problem is small enough, we can solve the full problem with $\mathbb{B}_d = \mathbb{B}$. Otherwise, we can use the hottest bin ranking from Algorithm 4 to select an appropriately sized subset $\mathbb{B}_d \subset \mathbb{B}$ of dynamic bins and solve only part of the problem. This technique can in turn be useful if we want to combine our local search algorithm with MIP solvers.

μSlope: High Compression and Fast Search on Semi-Structured Logs

Rui Wang[†] Devin Gibson[†⋆] Kirk Rodrigues[†] Yu Luo[†‡⋆]
Yun Zhang[‡] Kaibo Wang[‡] Yupeng Fu[‡] Ting Chen[‡] Ding Yuan[†⋆]

YScope[†] *Uber* [‡] *University of Toronto*[⋆]

Abstract

Internet-scale services can produce a large amount of logs. Such logs are increasingly appearing in semi-structured formats such as JSON. At Uber, the amount of semi-structured log data can exceed 10PB/day. It is prohibitively expensive to store and analyze them. As a result, logs are only kept searchable for a few days.

This paper proposes μSlope, a system that losslessly compresses semi-structured log data, and allows search without full decompression. It concisely represents the schema structures, and only keeps this representation stored once per dataset instead of interspersing it with each record. It further "structurizes" the semi-structured data by grouping the records with the same schema structure into the same table, so that each table is also well structured. Our evaluation shows that μSlope achieves 21.9:1 to 186.8:1 compression ratio, which is at least a few times higher than any existing semi-structured data management systems (SSDMS); The compression ratio is 2.34x as high as Zstandard and the search speed is 5.77x of the other SSDMSes.

1 Introduction

In the past two decades we have witnessed an explosive growth of log data from Internet-scale systems. Conventionally, logs were only in the form of unstructured, free text (e.g., output from `printf()`). However, they increasingly appear in semi-structured format, such as JSON [12] or Protocol Buffers® [9]. [1] These data models have a tree-structure, where each node (except for the root) is a key-value pair. The value may include non-primitive data types such as nested values.

Different records may have different schema structures. This is why they are referred to as *semi*-structured. For example, JSON and YAML [15] formats are schema-less, meaning that records may have arbitrarily different schemas. This flexibility allows programmers to easily log common data types in high-level programming languages, such as C struct, class, hash table, array, etc. Although Protocol Buffer and other formats require users to declare a schema to be used on all records, they allow a field to be optional. As a result, different records may still have different structures.

The dynamic schema structure imposes challenges for data management. For example, naively extending conventional relational databases would require creating one column for each *possible* key. This results in a sparse table (i.e., each row may have many NULL values), and it is challenging to handle polymorphic typing (the value of the same key might have different types).

Some existing semi-structured data management systems (SSDMS) use custom-designed data structures to store the schema structure of each record [2, 8, 20, 26, 29, 30]. These systems were initially designed for user-generated data which is relatively small (and they primarily focused on fast search speed). For example, most of the published works on SSDMSes use Twitter® datasets (i.e., Tweets in the Twitter data feed are in JSON) as their primary evaluation target [20, 26, 29, 30]. Twitter reports that in 2023 there are a total of 500 million Tweets per day [13], which results in 140GB of Tweet data per day (assuming 280 characters for each Tweet).

In comparison, logs with machine-generated data can be orders of magnitude larger. The size of JSON logs at Uber from all services exceed 10 Petabytes on a busy day, or 60PB/week, which is more than 70,000x the size of tweets. Managing data at this scale with existing SSDMSes is prohibitively expensive. These systems need to store one schema structure for each record, resulting in a large amount of duplication when a large number of records share the same schema. As a result, even if some systems can efficiently compress the data content [20, 30], the overall storage size is still large as it is dominated by the schema structures [20].

At Uber we have repeatedly suffered from scalability issues as Uber grew. Initially we used Elasticsearch® [21] to manage our JSON logs. It builds indexes for every word in a JSON document to support full text search, hence the index size is at the same order of magnitude as the original data and needs to be stored on SSD for fast search. The resource cost, together

[1] While we do not have global data on the prevalence of the semi-structured logs versus unstructured ones, in Uber, the size of semi-structured logs is about 10x of the unstructured. Part of the reason is that, even if some third-party or legacy applications emit unstructured logs, our log aggregation tools would wrap them in JSON. This is also a common practice outside of Uber. For example, Amazon CloudWatch® [1] also wraps unstructured log outputs in JSON. Grafana Loki® [5] tags unstructured logs essentially turning them into semi-structured logs for the purposes of search, and so on.

with other issues (§2), forced us to migrate away from it around 2019. Since then we have been using ClickHouse® [4], a columnar RDBMS with features for handling JSON data. Its overall compression ratio on our setup is less than 4:1, and it also requires SSD for fast search. Therefore the resource cost is still prohibitively expensive.

CLP [27] and LogGrep [31] are able to compress unstructured logs and allow users to search compressed data without full decompression. While effective on unstructured logs [2] they are limited on semi-structured logs. Fundamentally, their storage structure is not designed for the semi-structured format. For example, CLP parses an unstructured log into three components: timestamp, log type, and variables. The entire log dataset can be stored in a table consisting of these three columns: each log message is stored in one row, and all of its variable values are stored as a list in the variables column. Even if we extend CLP's parser to recognize the key/value structure (so the schema structure can be treated as the log type), the values of all the fields are intertwined in the same variables column of a single table. This hurts compression, but more importantly, querying any field requires tedious decompression and scan of the entire variables column. Indeed, real-world users who use CLP to manage JSON logs encounter poor search performance exactly for these reasons [10]. In addition, these tools only support a wildcard substring query model (like `grep`), but do not provide boolean algebra support to filter on multiple fields.

We propose μSlope[3], an SSDMS for semi-structured log data. μSlope focuses on storage efficiency by losslessly compressing the logs. And we show that fast search can be achieved with a careful system design without having to use an index (which would increase storage overhead). μSlope does not require any user annotation as it automatically handles the dynamic schema structures.

μSlope incorporates three novel designs. The first is its concise representation of the schema structures. Unlike existing SSDMSes that store separate schema information for each record, μSlope proposes (1) a *merged parse tree* to store the schema structures generalized for patterns specific to logs, and (2) a *schema map* to concisely represent each schema with a set of leaf nodes in the tree. Each unique schema structure is stored only once in the schema map, instead of per record, and it is decoupled from the storage of the value contents.

μSlope then partitions the records into *different* tables to store their values, where the records in the same table have the same schema. Therefore each table is now *perfectly* structured: all records have the same number of keys and each value is of the same type. This allows us to apply well-studied optimizations designed for relational tables. For example, we can store and compress each table in a columnar manner that maximizes the compression ratio and search speed [16].

Finally, μSlope uses a query processing algorithm that leverages the schema information and encoded tables. μSlope first builds an abstract syntax tree (AST) from the query, and systematically refines this AST by looking up the merged parse tree and schema map. This leads to early termination of queries that do not match any schema structures, and allows μSlope to decompress and scan data only when necessary.

μSlope's design was guided by a characterization study of Uber's semi-structured logs and queries (§3). We found that while records do have dynamic schema structures, there is enormous repetition as most records share a small number of common schemas. In addition, nearly one third of the queries that users performed can be terminated without table scanning because they do not match any of the schema structures.

We evaluate μSlope on a total of 21 semi-structured log datasets, and compare it with a number of widely used SSDMSes. Our result shows that μSlope achieves a compression ratio of 68.1:1 on average. This is at least 2.6x better any existing SSDMSes'. The compression ratio is even 2.34x of Zstandard's and 1.70x of LZMA's at the default compression level, even though they do not support search on compressed data. μSlope's search speed is 2.47x of ClickHouse's, 8.09x of PostgreSQL's, and 6.74x of MongoDB®'s.

This paper makes two contributions. First, it proposes μSlope, a resource efficient archival SSDMS that compresses semi-structured log data and enables fast search without full decompression. Second, we present an in-depth analysis of the characteristics of the semi-structured log data at Uber.

μSlope also has a few limitations. It is designed for semi-structured text logs, which are highly repetitive, instead of being a general-purpose SSDMS. If every record uses a different schema structure it won't work well on μSlope. Furthermore, μSlope uses an index-less design to optimize for storage efficiency; its search speed, however, may not be as fast as index-based search tools like Elasticsearch.

2 Background and Related Work

In this section we present the background information and related work. We explain (1) the semi-structured data model, (2) how prior SSDMSes manage the semi-structured data, and (3) commonly used compression algorithms.

2.1 Semi-structured Data Model

Semi-structured data have a tree structure, and its data model can be defined as follows:

$$\begin{aligned}
T_{root} &= T_{object} \\
T_{object} &= \{key_1 : T_{value1}, \ldots, key_n : T_{value_n}\} \\
T_{value} &= T_{object} | T_{array} | T_{primitive} \\
T_{array} &= [T_{value}, \ldots, T_{value}] \\
T_{primitive} &= string | number | boolean | null \\
key &= string
\end{aligned}$$

[2] CLP is deployed across Uber's various data and ML platforms to manage the unstructured logs.

}
```

Figure 1: Two example log records and their schema trees.

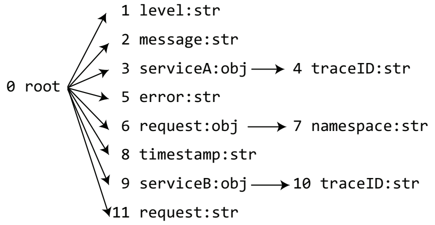

Figure 2: The merged schema tree of the two records.

Each semi-structured *log record*, or record for short, corresponds to a T_{root}. Figure 1 shows two sample records. A log dataset contains a number of such records. The *schema* of each record can be represented as a tree [30]. Figure 1 shows the two schema trees. Each node records a *field*, which consists of the name of the key and the type of its value.

Only the leaf nodes can have primitive value types in the schema tree. Any non-leaf nodes would have non-primitive value types, that is, either object or array.

If two records have the same schema tree, we say they have the same schema. The two nodes in their respective trees are considered to be the same if and only if both the key and the value type are the same. In a schema-less data format like JSON, a key could have "polymorphic" values, i.e., different value types in different records. For example, the "request" field in the two schemas in Figure 1 have different value types.

The schema trees of multiple records can be merged into a single tree [30]. We call it the *merged schema tree*, or MST. Specifically, given node N_1 and N_2 from two schema trees, we can merge them if and only if: (1) N_1 and N_2 have the same key name; (2) the value type are the same; and (3) all the predecessor nodes of N_1 and N_2 in their respective schema trees can be merged. Figure 2 shows the MST of the two schema trees in Figure 1.

2.2 Existing SSDMSes

Different semi-structured records may have different schemas, therefore we cannot naively store them in the RDMS table.

```
\x16\x00\x00\x00          // size (32-bit): 22 bytes
\x02                      // 0x02 = value type String
hello\x00                 // key name
\x06\x00\x00\x00world\x00  // size of value (6 bytes), value
\x00                      // 0x00 = 'end of object'
```

Figure 3: The BSON representation of {"hello": "world"}.

As a result, existing SSDMSes either use natively designed storage format or extend RDBMS in sophisticated ways.

Native Support for Semi-structured Data. These SSDMSes use custom data structures to represent the schema structure *of each record*. MongoDB uses a concise binary format called BSON (Binary JSON) [2]. Figure 3 shows the BSON representation of a simple JSON record {"hello": "world"} [3]. It stores the schema structure, including the type and size of each key/value pair, interspersed with the record content. The BSON records can only be stored in a row-oriented manner, which limits both the compression and search speed because it has to scan the entire record even when the user only searches for a specific key. Fast search can only be achieved via creating external indexes.

PostgreSQL®'s jsonb [8] and Oracle®'s OSON [26] are two other examples of custom schema structures. The former is similar to BSON, while the latter stores more metadata information, such as the number and offsets of nested keys.

Steed [30] proposes both row and column oriented storage methods. It operates on the merged schema tree (MST). Instead of storing the key name with each record, Steed only needs to store the node ID of the key in the MST. However, it still keeps one schema structure for each record in its row-oriented method. Keeping track of the schema structure is even more complex in its columnar method, as it splits the datasets into N independent columns where N is the number of keys, each column stores all the values of that key. Because the key/value pairs of a single record are now split, assembling the original record's schema structure requires even more complex data structures (2 additional columns for each key) and algorithms (finite state machine).

Scuba [17] is an in-memory SSDMS that keeps records in a compressed row-oriented format. Records are stored one after another in a table. Therefore it needs to scan all records in a table (and all the fields) during search. It stores the string values in a dictionary, and the dictionary is used as an index during search. However, unlike CLP, the entire string is stored as a single entry instead of being parsed into timestamp, log type, and variable values. It also has some restrictions on the data model, most notably it prohibits nested keys. Note that Scuba is designed for general-purpose data storage instead of narrowly focusing on logs.

Extending RDBMS. Sinew [29] uses a hybrid design that materializes a subset of the keys as separate columns, and stores the remainder using a binary format similar to BSON in a single RDBMS column. JSON Tiles [20] extends the idea of Sinew, reordering the records to group those with similar schemas into disjunct tiles. However, it still needs to keep a binary schema structure for each record. Although JSON Tiles applies compression to those separate columns, the compression ratio is around 1 because the large size of the per-record schema structure.

Some RDBMSes map semi-structured data into relational tables. For instance, Argo [19] proposed two methods. The first stores fields in a single table, while the second splits it to three where each is used for a primitive value type. However, the first method will result in sparse tables (many fields with NULL values). Both methods take up too much storage space due to repetitive key/values. Liu *et al.* proposed to store the entire JSON record in a single RDBMS column [25].

Elasticsearch and ClickHouse: Experiences at Uber. Elasticsearch [21] is a JSON document store that supports search. It assumes the type of the field will never change by default and cannot handle fields with dynamic types easily. (By default, Elasticsearch will drop records if a field has a different type than in a previous record.) It also struggles to handle the case where every record has new unique keys (e.g., using a UUID as a key) [18]. At Uber we used to use Elasticsearch, but migrated away (to ClickHouse) due to these issues as well as its excessive resource usage.

ClickHouse is a columnar RDBMS with features for handling JSON data. At Uber we built a layer to transform records before ingestion into ClickHouse. After experimenting with different storage formats, we settled on storing a handful of common fields in dedicated columns, and storing all other unique key-value pairs that are less than or equal to 3 levels deep in a pair of arrays per type. For instance, string-type fields were stored in two arrays, "`String.names`" and "`String.values`". To query a field, we first find the key in the `String.names` array, use the index of that key to index the `String.values` array, and finally compare the value against the query. We also keep a _`source` field that contains raw JSON and build inverted index on top of it. Finally, to improve query performance for frequently accessed fields, our abstraction layer temporarily extracts these fields into temporary dedicated columns (materialized columns). This setup results in a compression ratio lower than 4:1.

2.3 Compressors

General-purpose compressors like Gzip [23] and Zstandard [22] use a sliding window approach proposed by Lempel and Ziv [33]. They locate duplicates within a fixed-size sliding window, so they cannot detect duplications if the distance between the two duplicated patterns is larger than the size of the sliding window. Therefore storing duplicated patterns close to each other would maximize the compression ratio.

Searching, unfortunately, requires decompressing the entire data. These compressors typically encode duplicates in length-distance pairs [28, 33]. Starting from the current position, if the next L (length) characters are the same as the ones starting at D (distance) behind, the next L characters can be encoded with (D,L). This (D,L) pair is directly embedded in the compressed data, hence search requires decompression from the beginning.

Log compression and search. Existing log compression techniques focus only on unstructured (i.e., free text) logs. CLP [27] uses a custom-designed log parser to split each message into three components: timestamp, static text (i.e., log type), and variable values, structurizes logs into a table of three columns. CLP stores the static text and repetitive variable values into respective dictionaries, and the dictionaries also serve as coarse-grained index during search to minimize decompression and scan. It then compresses the three-column table in columnar order.

LogGrep [31] also compresses unstructured logs and allows search. It uses a training phase to identify the common patterns of messages. LogGrep identifies patterns in much finer granularity (e.g., a variable can be further divided into subcomponents if a different subcomponent is repetitive). Therefore a message is split into a larger number of subcomponents without clear mapping to program semantics, and it uses tables to store the complex mapping to assemble these subcomponents into the original log message.

3 Characterizing Semi-structured Log Data

We first provide a characterization study on semi-structured log data before describing the design of μSlope. While prior works have characterized semi-structured *user-generated* data [30], we are the first to provide an understanding of *machine-generated* semi-structured log data.

We collected 16 frequently used log datasets (LogA-LogP) from Uber and 5 log datasets from open-source software (Apache Spark™, MongoDB, CockroachDB®, Elasticsearch, and PostgreSQL). All of these datasets are in JSON format. We limit each dataset to 1,000,000 log records. We also provide a characterization of real-world queries on semi-structured log data by analyzing a total of 23,091 queries spanning twenty days from Uber; 7665 of them are unique.

Schema Variation. We first study the schema variation. JSON's schema-less nature means that the variation of schemas between records can range from zero (i.e. all records have the same schema) to 100% (i.e. all schemas are different). Recall from §2.1 that the schemas of two log records are considered the same if and only if their schema trees are identical. The degree of variation is a critical consideration to the design of μSlope and prior systems. If there is no variation, then one can easily store logs in an RDBMS by materializing one column for every leaf-node node.

Figure 4 shows the unique schemas for each dataset. All except two datasets have more than 1 unique schemas, with LogE having the largest variation (6,176 unique schemas). The median number of unique schemas of all datasets is 40.

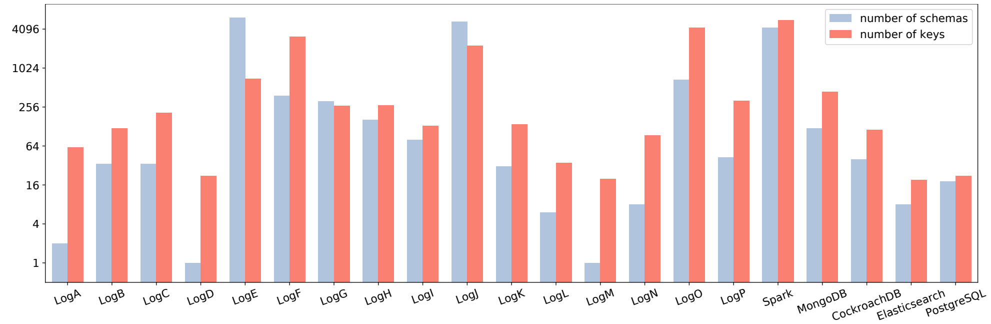

Figure 4: Number of unique schemas and keys for each dataset.

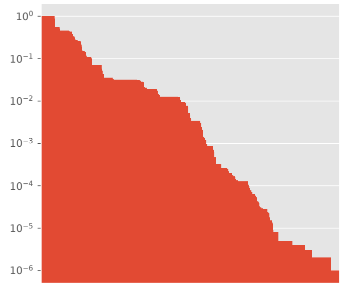

Figure 5: KF distribution of LogE

Despite the relatively large degree of variation, there also exists a large degree of *repetition*. On average, there are 25,000 records in each dataset with the *same* schema; if we increase the sample size, this repetition will be larger. Even for the most noisy dataset, LogE, there are still an average of 162 records per schema.

To understand the schema variation, we further measure the variation of individual keys. Figure 4 also shows the number of unique keys for each dataset. Two keys are considered the same if and only if their full name and value types are the same. A key's full includes all the nested keys (i.e., predecessor nodes in the schema tree). For example, "serviceA.traceID" is the full name whereas "traceID" is not. The median number of unique keys is 138, and it varies greatly. LogM has only 20 unique keys (and it has only 1 schema), whereas Spark logs have 5,627 unique keys.

This result suggests that the variation in schemas is likely due to the variation of individual keys instead of their combinatorial effect. In theory, a large variation in schemas could be the result of a small number of keys: n unique keys could result in 2^n different combinations, hence 2^n schemas. However, this is not the case with logs. In fact, in 18 out of 21 datasets the number of unique keys is larger than the number of schemas, showing the opposite of a combinatorial effect.

To get better understand how keys are distributed within a dataset, we measure the key frequency (KF). It is defined as

$$KF(x) = \frac{number\ of\ records\ that\ contain\ key\ x}{total\ number\ of\ records}$$

Figure 5 takes LogE as an example to show the distribution of KF. Each bar represents a key. LogE has 6176 schemas and 704 keys. There are a small number (21) of keys that have KF = 1.0, indicating that they appear in every record. These are the keys uniformly added by the logging library, such as "timestamp" and "level".

On the other hand, there is a long-tail in the KF distribution of LogE. 83.0% of the keys has a KF <0.1. Most of them are different data structures in the program that documents the program state relevant to a specific event. There are also cases where the variation in schemas is caused by a large variation in the name of a key, like Spark using the pathname as the key name, or some datasets using the UUID as the key name.

Type Composition. Next, we break down the value types. Recall from §2.1, the value type can be an object, array, or one of the primitive types. We further refine the types as follows. First, we break down the number type into integer and float. For strings, we separate single-word values from multi-word ones (using white space as word delimiter), because the former is likely a variable (e.g., an identifier) whereas the latter is free-text log. We call the former *variable* and the latter *log-text*.

Figure 6 shows the breakdown of the value types in each dataset. On average, 70.8% of the values in each dataset are variables (i.e. single-word strings). 10.8% are objects, i.e. non-leaf nodes in the schema tree leading to nested keys. In comparison, the percentage of boolean, float, null are low, averaging 1.74%, 1.21%, 0.22%.

The percentage of **array** fields are also low at 0.79%. In addition, only 28 of the 7,665 (0.4%) of the unique queries explicitly search on an array field. Furthermore, these explicit array searches only match 0.05% of the data on average.

Each log record contains an average of 1.6 log-text keys. In addition, 41% of the unique queries contain filters on log-text, so efficient search on log-text is important. In addition, a record contains 4.0 integer fields on average.

Repetitiveness of Variables. Next, we zoom into variable fields (i.e., single-word strings), because they dominate the composition of logs. The question we care about is: Are these values repetitive? We use the repetition ratio to measure the repetition of variable fields. It is defined as

$$repetition\ ratio = \frac{number\ of\ all\ variable\ values}{number\ of unique\ variable\ values}$$

A high repetition ratio means that unique variable values are much fewer and these fields are repetitive. Figure 6 shows the repetition ratio. The median repetition ratio is 37.8 and the average is 58.2 across all datasets. It can be as high as 433.4 (LogD) and even the minimum is still 9.29 (LogC). This means dictionary deduplication can be effective.

The variable fields are also frequently queried. The average query contains 3.450 filters with 2.663 of those being variable filters. For example, `level:"warn" OR level:"error"` is a query that has two string filters on the `level` key. The largest query has 93 string filters. Furthermore, filters that implicitly

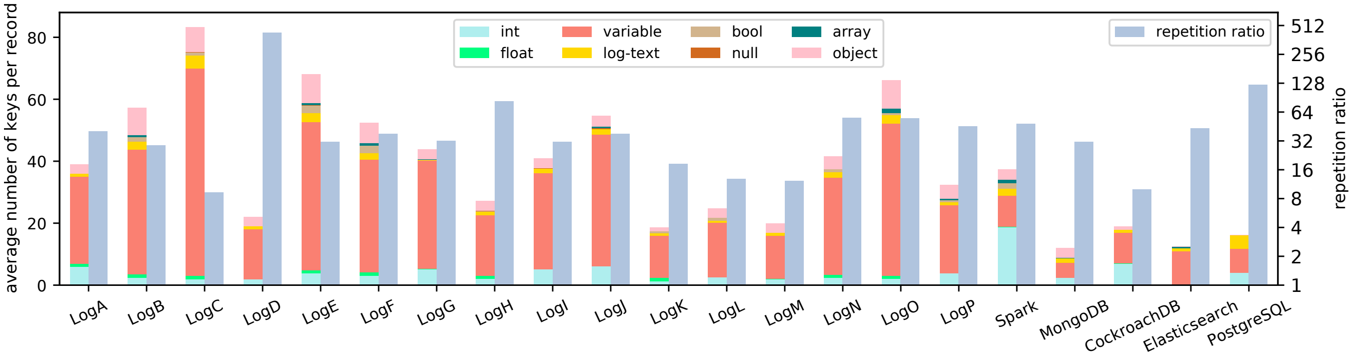

Figure 6: Average number of keys per record, broken down by different value types and repetition ratio of variables.

match all keys – "wildcard keys" – are common in practice. For example, `*:"aUUID"` matches any keys as long as its value is “aUUID”. Of the 7,665 unique queries 2,271 of them contain a wildcard key. These filters are easier to express for users of search, but pose a significant performance hazard. In the worst case such filters can impose scans over the entire record, eliminating much of the benefit of querying structured data. However, using a dictionary to store the variables would significantly speed up such queries as we only need to search the dictionary for matching values.

Importance of Schema Search. Nearly one third (29%) of the unique queries do not match any of the schema structures. That is, they can be returned without scanning the values. Examples include searching for a nonexistent key, the key exists but the value type does not match, or the conjunction of keys/value types do not exist. For example, engineers performs such search to regularly verify the nonexistence of certain error events. However, for existing SSDMSes (such as MongoDB and PostgreSQL) this opportunity is wasted, because the schema structure is interspersed with the values.

Summary and Takeaways. Schemas are dynamic, and those unstructured keys are frequently queried. Therefore simple extension of RDBMS to only materialize those structured keys as columns is insufficient, and we need to precisely track the schema of semi-structured data. On the other hand, a large number of records have the same schema, presenting opportunities to group them by the same schema so that each group is well-structured.

70.8% of the keys are single-word strings. They are highly repetitive, and commonly queried on. This indicates that storing them in a variable dictionary would effectively deduplicate them, and at the same time, speedup the search.

Finally, efficiently storing the schema structure and decouple it from the record value data would significantly speedup the 29% of the queries that can be completed only by querying the schema structure.

4 Overview of μSlope

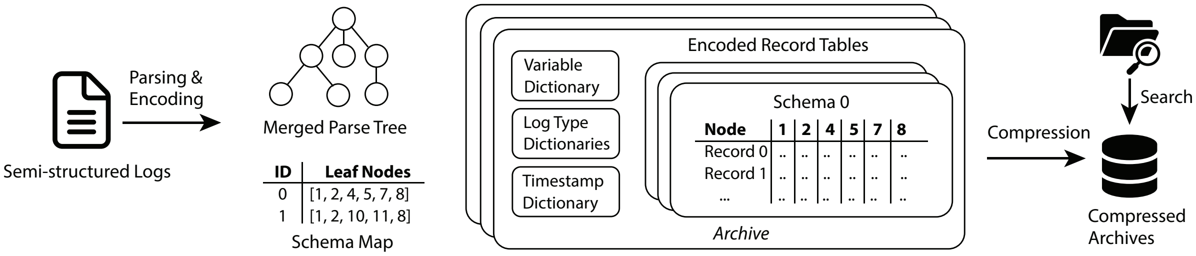
μSlope is a resource-efficient SSDMS that we designed from the ground-up. μSlope has three major designs that are novel compared to other SSDMSes: (1) Decoupling the storage of schema metadata from the storage of each record; (2) Grouping records by schema to store them into well-structured tables, and apply efficient encoding; and (3) Optimized schema metadata lookup to speedup search.

Figure 7 shows μSlope's architecture. When data is ingested, μSlope parses each record and extracts its schema. It uses two core data structures to track the schema structure: the merged parse tree (MPT) and the schema map. The MPT and the schema map are collectively referred as *schema metadata*. It is critical to keep the schema metadata as small as possible, yet still captures the highly repetitive structure of the log.

The MPT is a more general form of the merged schema tree (MST) as described in §2.1. It has four differences when compared to MST. First, the MPT can contain special unnamed nodes that mark the truncation of some key value pairs. Multiple rare keys can be mapped to the same unnamed node when the key names contain random data, such as UUID or file path. Including such non-repetitive key names would bloat the metadata. In contrast, sometimes the value of a key could be highly repetitive. For example, all the records from the same application would have the same value under the application-name key. Therefore, the MPT also allows a node to include the value (only if the value is highly repetitive).

The third difference is that MPT can encode the structure of strings with key-value pairs. This allows μSlope to capture more structural information from strings, improving compression and search. For instance, given a record `{.. "message": ".. latency=35, status=OK, type=READ, ..."}`, μSlope would create three nodes for “latency”, “status”, and “type” respectively as the children of the “message” key. This requires that schemas contain an *ordered* region where we maintain some leaf nodes in a specific order, because the order of the keys in a string needs to be preserved.

Another difference is that MPT stores more fine-grained string types. A string value could either be a timestamp, a single-word string, or a log-text. Storing fine-grained types



ID	Leaf Nodes
0	[1, 2, 4, 5, 7, 8]
1	[1, 2, 10, 11, 8]

Node	1	2	4	5	7	8
Record 0	..	..	..	..	..	..
Record 1	..	..	..	..	..	..
...	..	..	..	..	..	..

Figure 7: Architecture of μSlope.

enables more filtering opportunities on MPT, resulting in better search performance.

The *schema map* stores each unique schema in the log dataset in a hashmap. We make the observation that a schema can be unambiguously identified with the list of *leaf nodes* in the MPT. For example, the schema map in Figure 7 shows the two schemas of the two records in Figure 1, where the node IDs corresponds to the MST shown in Figure 2. (In this example, the MPT and the MST are the same.)

The MPT and schema map deduplicate the highly repetitive schema structures. Unlike prior SSDMSes §2.2 that store a schema structure for every record, each unique schema is stored only once. In practice, the schema metadata size is typically less than 0.0001% of the total compressed data size. This design also enables fast search: the succinct metadata can be efficiently searched, providing powerful filtering capability.

μSlope uses one table for each schema to store the values. Therefore each table only stores the values of the records that have the same schema. As a result, there can be thousands of tables, one for each schema. The advantage is that each table is now perfectly structured, as all records have the exact same keys and value types. μSlope essentially structurizes those semi-structured data.

The tables are called *Encoded Record Tables* (ERT), because instead of storing their raw value, μSlope performs type-specific encoding. For example, single-word string will be stored in a *variable dictionary*, so only an ID is stored in the ERT. The dictionaries serve two purposes at the same time: it effectively deduplicates the highly repetitive patterns, and it serves as coarse-grained index for search so μSlope only needs to scan the ERT that contains the matching record.

Each ERT is stored and compressed in a columnar order. This significantly improves both the compression ratio and search performance [16], because a column groups the semantically similar values together so it maximizes general-purpose compressors' ability to find repetitions, and during search we only need to decompress and scan the columns whose keys were searched for.

Log Type Dictionary

ID	Log Type
L0	Can't fetch flow \INT, cell \DICTVAR

Timestamp Dictionary

ID	Format
T0	yyyy-MM-dd'T'HH:mm:ss'.'SSS

Variable Dictionary

ID	Variable Value
V0	error
V1	cell_32
V2	abc-xyz
V3	Error404
V4	driver_onboarding
V5	def-uvw
V6	vehicle_compliance

Schema 0 Encoded Record Table

Node	1	2		4	5	7	8	
Values	V0	L0	6,V1	V2	V3	V4	T0	1..8

Schema 1 Encoded Record Table

Node	1	2		10	11	8	
Values	V0	L0	8,V1	V5	V6	T0	1..6

Figure 8: How μSlope encodes log records.

μSlope leverages the efficiency of metadata and dictionary lookup to optimize the search performance. It uses Kibana Query Language (KQL) as its query language, which is both concise and powerful. μSlope transforms a query into an abstract syntax tree (AST) to perform a number of optimizations, including determining if the query matches any schema and if the filter pattern matches any dictionary values. If not, μSlope will terminate query processing early. Otherwise, only relevant ERTs are finally decompressed and searched through.

Both compression and search are embarrassingly parallel. During compression, when parsing a new record μSlope extracts the key-value pairs of each log record. Corresponding key nodes are added to the MPT, with leaf node IDs collectively representing a schema. Values are encoded by various methods and are stored in the ERTs. Upon identifying a new schema, μSlope dynamically creates a new ERT to store the encoded values. All the ERTs, dictionaries and schema metadata will be buffered in the memory. Once the buffer reaches a certain size, they are compressed using Zstandard before stored to disk, creating what we call an *archive*. μSlope then clears the buffer and dictionaries before compressing newly arrived records. Therefore different archives can be compressed, searched, and decompressed independently in parallel.

5 Compression

We use simdjson [11] parser to parse the JSON structures. Other log formats representable by the data model in §2.1 can also be supported by integrating a parser to extract the key-value pairs from the records.

μSlope uses different encoding techniques on different value types. Next we describe them in turn.

Strings. μSlope treats string values differently depending on whether it is (1) a timestamp, and if not, (2) a variable, i.e. a single-word string, or (3) log-text. μSlope uses CLP's parser to parse a string value. It uses heuristics to detect if the string is a timestamp. If so, μSlope encodes it into a Unix® epoch time and stores the format pattern in the timestamp dictionary. As a result, each timestamp field is encoded into *two* columns in the ERT: a timestamp dictionary ID and a Unix epoch time. The ID column consumes negligible space after compression because most of the time there is only one timestamp format.

For a log-text, the CLP parser extracts the log type and variables. The log type is stored in the log type dictionary. Different types of variable values are encoded differently. Integers and floating point numbers are directly encoded in binary format. Other variables are encoded as a variable dictionary ID after storing them in the variable dictionary. Therefore a log-text also has two columns: a log type ID, and a list of encoded variables stored in a single column. We extend CLP's log parser [7] to allow users to specify rules to extract key/value pairs from log-text fields and store them as JSON fields. Therefore, if the log is in unstructured format (instead of JSON), or dominated by unstructured text log (i.e. majority of a record is an unstructured text message field with a few additional fields containing metadata like hostname, verbosity, etc.), μSlope essentially falls back to CLP encoding.

μSlope directly stores a single-word string in the variable dictionary and stores the dictionary ID in the ERT. The dictionary effectively deduplicates the repetitions in variables as we shown in §3. We use the same variable dictionary used for the log-text for maximum deduplication.

Figure 8 shows the contents of the dictionaries and encoded record tables for the example log records in Figure 1. Their MPT is the same as the MST shown Figure 2, except that the MPT keeps a fine-grained string type on each string field. The schemas are shown in Figure 7. We use different prefix and colors for the different types of dictionary IDs: log type ('L'), timestamp ('T'), and variable ('V'). For example, consider the first log record, which is stored in the ERT of schema 0. Four of its keys ("level", "serviceA.traceID", "error", "request.namespace") have single-word strings; they have the MPT node IDs 1, 4, 5, 7 respectively (Figure 2), and their values are encoded as V0, V2, V3, and V4 which are IDs into the variable dictionary. The "message" field (node ID 2) is a log-text. Its first column stores L0, which is the ID into the log type dictionary, and the second column stores the two encoded variables. Note that '\INT' and '\DICTVAR' in the log type are special placeholder bytes for variables (of integer and dictionary variable types respectively). The "timestamp" value is stored in the last 2 column (node 8); the value "1..8" is the encoded timestamp in Unix epoch time.

Integers, floating point, and boolean values are directly encoded in binary form in the same way as in CLP [27].

Arrays are stored as log-text strings by default, i.e., using CLP to parse it into a log type and a list of variable values. This means that arrays are typically searched by decoding and parsing their string representation. This is acceptable as §3 shows that arrays occur rarely and are seldom searched. Note that the log type parsed from an array string is stored in a separate log type dictionary to avoid polluting the regular log type dictionary for log-text. We also support fully parsing arrays and recording their structure in the MPT under a non-default configuration. This approach offers performance benefits for array searches, but typically results in growth in schema size due to the diverse internal structures of arrays.

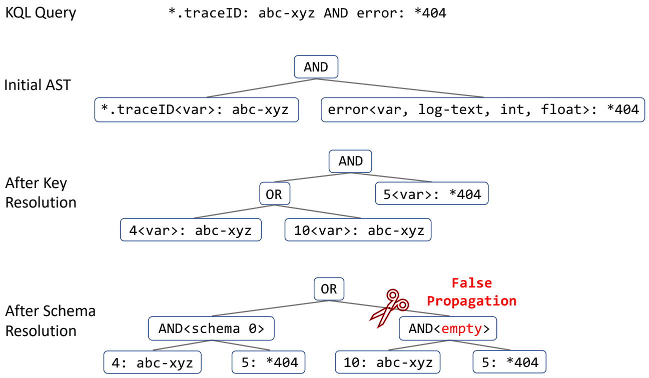


Figure 9: Example of query processing.

Preserving record order. Splitting the records into different tables means that we lose the order between records of different schemas. Using timestamp to order them is unreliable because records may have the same timestamp. To preserve the order, μSlope adds a column in each ERT to store the order of the record in the original log stream.

Random keys and invariant values. Recall that μSlope truncates the key name from the MPT if it is not repetitive, and includes values that don't change into the MPT. The heuristic we use is that if a key does not appear in more than 1% of the records of the archive, it will be truncated; whereas a value will be included in the MPT only if it never changes. We implement them by keeping counters for the keys and values as records are parsed and stored in the memory buffer; the decision to truncate a field or include a value in the MPT is made when we write the buffered data to disk (into the archive format). The structures of a truncated field and its successors (a truncated field may be a non-primitive type, in which case all the subfields will be recursively truncated) are encoded in a row-oriented format similar to BSON, and stored in a column that is mapped to a (special) MPT node located at the place of the truncated node.

6 Search

μSlope search accepts queries which combine filters on one or more keys. The key names in the query may contain wildcards and be of ambiguous underlying type. Search takes advantage of the MPT, *schema map*, and dictionaries to evaluate queries efficiently. This is a multi-step process, each step performs refinements and optimizations on a custom Abstract Syntax Tree (AST) μSlope built from the query. Next, we explain each step using an example shown in Figure 9.

Step 1: Constructing the initial search AST. Given a query μSlope transforms it into an AST where each leaf node specifies a filter on some key, and each non-leaf node is a logical AND or OR. Figure 9 shows an example KQL query. The query consists of two filters joined by AND. The key name in first filter contains a wildcard, meaning it can match any hierarchy of keys that end with "traceID". The second filter contains a wildcard in the value pattern.

μSlope parses this query into a search AST shown in Figure 9. Initially this AST contains two nodes, each maps to a filter. Each node also stores the possible value types inferred from the query. The value type of the first filter is unambiguous; it must be single-word string type (i.e., a variable) given the pattern is surrounded by '"'. The second filter, however, has ambiguous type; it can either be a variable, a log-text, an integer, or a floating point number.

Step 2: Key resolution further turns each key name into zero or more MPT leaf nodes by resolving ambiguities. Ambiguities come from two sources: (1) ambiguous key name, i.e. a key with wildcard can match more than one leaf of the MPT, and (2) ambiguous value type, when it is polymorphic. In both cases we replace the corresponding filter with an OR node where every child of the OR is the same filter with the key replaced by each of the matching MPT leaf nodes in turn. The "*.traceID<var>" in Figure 9 is an example of ambiguous key name. It is resolved into two MPT leaf nodes, node 4 and 10, which corresponds to "serviceA.traceID" and "serviceB.traceID" respectively. These two nodes are connected by OR in the refined AST after the key resolution.

The "error<var,int,float>:*404" node in the initial AST has potentially ambiguous value type. In our example, because the only possible type for the "error" key is a variable (i.e., single-word string), we replace it with a single node "5<var>:*404". However, if "error" has polymorphic type, say an integer, in the dataset, then we need to consider both possibilities and connect them by an OR.

When a key name matches no leaf nodes in the MPT, that AST node is eliminated by replacing it as false and propagating this false up the AST, a process known as *false propagation*. This can eliminate part or all of the query.

After key resolution each key in the search AST refers to a leaf node from the MPT. The one exception is if the searched key name is a single wildcard '*'. Expanding such keys would result in a bloated AST because it can match any key name, adding combinatorial overhead to the later steps (particularly if the query specifies multiple filters on '*' key). Wildcard keys are expanded dynamically only at the last step, before search on an ERT.

Step 3: Schema resolution looks up the *schema map* to find a set of schemas that match the record structure implied by the query. It first transforms the AST into OR of ANDs form (i.e. sum of products). The key insight is that for an AND to ever be true, all of its children must exist together in a schema. We implement this check by performing an intersection between the set of MPT node IDs of the children of an AND node with each schema. If the intersection is empty, the entire AND sub-tree is removed by treating it as false, and we propagate this false along the AST.

The last AST in Figure 9 shows the AST after schema resolution. The rightmost AND expression matches no schemas and can be removed since MST node 5 and 10 never appear in the same schema. In this case we are able to narrow down the ambiguous query to a single schema, schema 0, by only searching the schema metadata.

Step 4: Search on strings. Next μSlope searches the dictionaries on relevant string filters. Search needs to be performed over the log type dictionary, the variable dictionary, or the timestamp dictionary. Searches on log-text are handled the same way as CLP would. The ability of the dictionaries to reject string queries is critically important for performance. Consider the query *:<uuid>, which is commonly issued at Uber. In archives that do not contain this uuid, this query can be terminated early after searching the variable dictionary, avoiding any column scan. In general, an empty dictionary search would result in the AST node being eliminated, and the false value gets propagated to further simplify the AST.

Step 5: Column decompression and scan is guided by the remaining nodes in the AST. Specifically, the remaining AST tells us exactly which ERT(s), and which column(s), should be scanned. This minimizes the decompression and scan.

Note that we also add a simple timestamp range index at the archive level. This is used to avoid having to decompress and scan any data in the archive when there is no overlap with the time range specified by the query.

7 Implementation

The implementation of μSlope closely follows the design specified in the previous sections. However, some details not called out in the design are critical to the overall performance of the system, so we highlight them here.

We have written a custom JSON serializer in order to improve decompression and search speed. With each schema precisely defining the structure of a log record, μSlope is able to generate a bytecode that describes how to reconstruct records in terms of the columns they have been split into. Unlike JSON serializers designed for dynamic objects, our serializer doesn't require the creation or traversal of mutable in-memory data structures during serialization. Instead, it uses the bytecode generated at the table granularity to directly append the values to the serialization buffer. This approach has proven several times faster than conventional JSON serializers based on our experience.

Given that μSlope can sometimes produce archives containing many small ERTs, minimizing the overhead of storing and loading ERTs is crucial. In μSlope, ERTs are concatenated together into a single file, with a metadata file that describes the location of each ERT within the file and the number of log records within each ERT, which reduces I/O overhead. During search, μSlope scans the AST to determine which ERTs need loading, and then loads them following the storage order, thus eliminating random I/O. Additionally, it optimizes bytecode generation by only producing bytecode for serializing records from an ERT after finding at least one matching record.

8 Evaluation

We implement μSlope with about 18k lines of C++ code. We evaluate the performance of μSlope on both Uber logs and public logs. Specifically, we focus on the following aspects: (1) the compression ratio and speed; (2) the query performance; (3) worst case performance on synthetic logs; (4) the scalability of μSlope on large-scale logs.

8.1 Experiment Setup

Overall we conduct the experiments in two setups: (1) single-thread, single-process experiments on smaller datasets (referred as single-thread experiments), and (2) parallel setups on larger scale Uber's logs. For (1) we compare μSlope with a number of other SSDMSes. The logs are from the same services as described in §3, except that here we increased the data size. In addition, we include logs from five public software, which are generated by running HiBench [24] and YCSB [14] benchmarks. Table 1 shows the size and the number of records of each log dataset. These datasets are relatively small because (1) we had problems to ingest larger data to some of the tools we compare with (for example the ingestion throughput for Elasticsearch is 5MB/s), and (2) μSlope is embarrassingly parallel, therefore its single-threaded performance is the most critical. We also evaluate μSlope on larger Uber's datasets in §8.5.

Single-thread experiments were performed on a Linux server with Intel Xeon E5-2630v3 processor and 128GB of DDR4 memory. Both the uncompressed and compressed logs are stored in a distributed file system (MooseFS) running on multiple 7200RPM SATA HDDs.

We compare μSlope with SSDMSes including CLP 0.0.2, MongoDB 6.0.5, PostgreSQL 15.2, ClickHouse 23.3.1.2823, Elasticsearch 8.6.2, Zstandard 1.4.9 and XZ Utils (for LZMA compression) 5.2.2. (we were informed that Steed [30]'s artifact isn't yet available upon contacting the authors). MongoDB and PostgreSQL have native JSON support (i.e. BSON and `jsonb` data type respectively). For ClickHouse, we explore three setups to store JSON records: (1) in pair-wise arrays which was described in §2.2. Here we only use two arrays and do not differentiate types of the values. (2) in a single string field, which can be parsed by ClickHouse functions. Both setups are commonly used in practice for JSON management. (3) in a single JSON field, which is a new experimental data type introduced in v22.3. It can infer the schema of a JSON record and store every field in a separate file automatically.

	Name	Uncompressed Size	Number of Records
Uber Logs	LogA	30.0GB	22,996,492
	LogB	47.1GB	16,606,964
	LogC	60.4GB	15,306,125
	LogD	50.7GB	58,309,754
	LogE	91.8GB	22,345,071
	LogF	102.9GB	17,251,752
	LogG	30.9GB	3,046,845
	LogH	30.8GB	11,461,221
	LogI	39.7GB	27,209,375
	LogJ	36.0GB	13,605,274
	LogK	30.2GB	57,919,224
	LogL	37.1GB	45,827,554
	LogM	36.5GB	42,206,452
	LogN	38.0GB	22,307,407
	LogO	38.6GB	4,438,786
	LogP	38.3GB	34,840,347
Public Logs	Spark	2.0GB	1,011,651
	MongoDB	64.8GB	186,287,600
	CockroachDB	9.8GB	16,520,377
	elasticsearch	8.0GB	140,012,234
	PostgreSQL	392.8MB	1,000,000

Table 1: Log datasets used in our experiments.

For these systems we do not create any index for a fair comparison with μSlope, because μSlope is designed to be an archival SSDMS and does not have any external index. MongoDB automatically builds an index on the default key `_id` and we exclude the size of the index when calculating compression ratio.

We also compare μSlope with two general-purpose compressors Zstandard and LZMA. Zstandard is the underlying compression method for μSlope and LZMA is known for its high compression ratio.

We do not evaluate search on CLP because wildcard queries (which CLP supports) are incompatible with semi-structured data model. For example, a KQL query `error: "*404"` searches for the "error" field whose value ends with "404"; but CLP could return records like {"error": "0", "keyx": "404"}, because '*' could match an arbitrary amount of text. We do not evaluate search on Elasticsearch because we cannot ingest the three datasets where we designed query benchmarks on into Elasticsearch. Nevertheless, as we will show that Elasticsearch consumes too much storage space that cannot be used as an archival SSDMS.

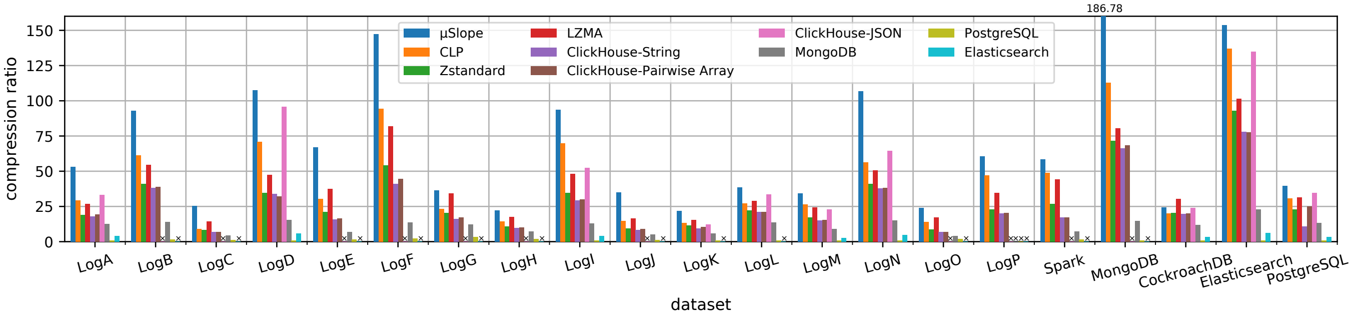

Figure 10: Compression ratio of μSlope and other tools on different JSON datasets. A "×" means the dataset cannot be ingested by the tool.

8.2 Compression Ratio and Speed

Figure 10 shows the compression ratio of μSlope and other tools on different datasets. The compression level of Zstandard is set to 3 (default) for μSlope. For a fair comparison, we use the same compression method and level for CLP, ClickHouse and MongoDB. PostgreSQL and Elasticsearch do not support Zstandard compression, so we use lz4 [32] instead. For LZMA, we use the default compression level 6.

Note that out of 21 datasets, ClickHouse-JSON can only ingest 10 and Elasticsearch can only ingest 9. The most common reason is that they cannot accept fields with the same key name but different types. Additionally, MongoDB and PostgreSQL cannot ingest one dataset because of the escape character. For the average compression ratio and speed comparison, we only include the datasets that are successfully ingested by these systems.

μSlope achieves the highest compression ratio on all JSON datasets. The average compression ratio of μSlope is 68.1:1, ranging from 21.9:1 (LogK) to 186.8:1 (MongoDB). On average, μSlope's compression ratio is 2.75x of ClickHouse-String's, 2.62x of ClickHouse-Pairwise Array's, 1.34x of ClickHouse-JSON's, 6.10x of MongoDB's, 16.50x of PosgreSQL's, and 15.71x of Elasticsearch's. It surpasses Zstandard's, LZMA's, and CLP's compression ratios by factors of 2.34x, 1.70x, and 1.50x respectively. but it is only 4.8% on average, which still makes μSlope's compression ratio the best among all.

We delve into the breakdown of compressed data size in μSlope, using LogP as an example. Out of the 710 MB total compressed data, the MPT and schema map only occupy 3.6KB and 1.9KB, respectively. Dictionaries account for 26.3% of the storage space, with the remaining 73.7% attributed to compressed columns of ERTs.

Figure 11 shows the average ingestion speed on all datasets. μSlope's ingestion speed is slower than ClickHouse-String and ClickHouse-Pairwise Array because ClickHouse-String directly store the raw JSON string and does not parse it, while ClickHouse-Pairwise Array only parses the top-level fields. In comparison, μSlope parses every field of the entire JSON record. μSlope's ingestion is slighter slower than CLP and faster than all other fully-parsed JSON tools, outperforming ClickHouse-JSON, MongoDB, PostgreSQL and Elasticsearch by 19.3%, 186.7%, 419.8%, 1127.3% respectively. Additionally, it exceeds LZMA's performance by 814.8%.

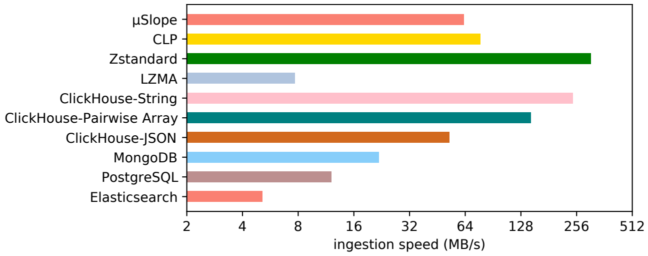

Figure 11: Average ingestion speed (log scale).

8.3 Search Performance

We use 15 queries to evaluate the search performance of μSlope and other tools on Uber LogF, LogO and MongoDB logs. For queries on LogF and LogO, they are the top queries performed in Uber (with repetitive patterns removed). For queries on MongoDB, we try to cover different possible patterns. Table 2 shows the queries in KQL [6]. For ClickHouse and PostgreSQL, we convert KQL queries to SQL queries with their built-in functions and operators. For MongoDB, we use their own query language.

Query B is a special case. It does not specify any search key, but searches for all fields for the matched UUID. Other tools does not natively support this kind of query so we have to convert it to a full-text search instead. It works for Query B, but may get incorrect results for other queries that span across keys and values. MongoDB is required to have a text index on that table to do a full-text search. However, after running for 196 seconds, it reports an error.

We clear the OS buffer cache before every run. This is to simulate search on archival storage. However, by default MongoDB uses about half of the memory (63.5G in our machine) to cache uncompressed data and the cache cannot be cleared, while others use only a minimum amount (or even no) or the cache can be cleared. For a fair comparison, we test MongoDB with the minimum cache size.

Figure 12 shows the query latency of those 15 queries on

Queries for LogF	
A	zone:... AND NOT @reserved.collector.filename:stdout AND runtime_env:staging
B	*: "d...-...-...-...-...9"

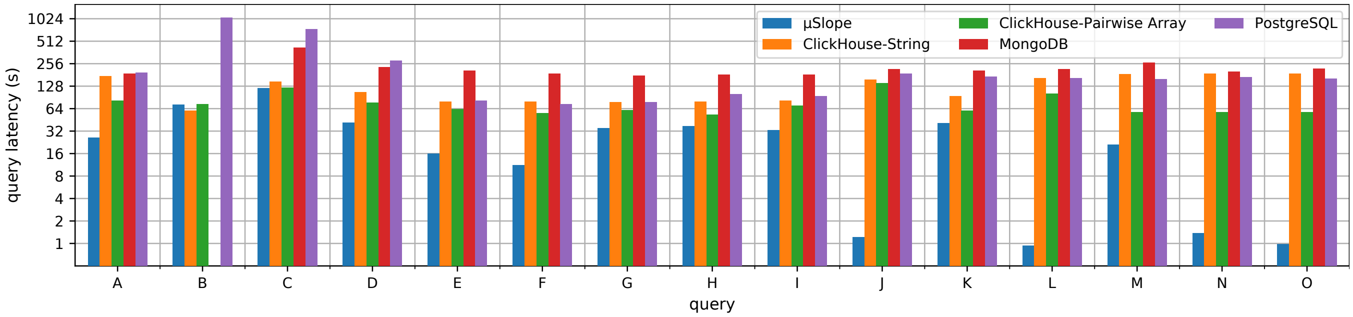

Figure 12: Query latency of μSlope and other tools (log scale).

different tools. It includes both the search time and the time to write results to the disk. On average, the speed of μSlope is 2.47x of the fastest setup of ClickHouse (ClickHouse-Pair Array), 8.09x of PostgreSQL’s, and 6.74x of MongoDB’s.

μSlope outperforms all other tools on 14 queries. The fast search performance comes from its use of metadata (MPT and schema map). For example, μSlope outperforms all other tools by at least 116x on Query J. This query checks the existence of a key and returns all the records containing that key. In this case, there are only a small number of schemas that contain this key, so after μSlope checks its MPT and schema map, it only needs to decompress a small number of ERTs. For other tools, they will have to scan nearly the entire dataset. Query L, N, O are also similar as there are only a small number of matching schemas and μSlope only needs to decompress small ERTs. Note that even for these queries, the schema metadata lookup is not the bottleneck. For Query J, for example, searching the MPT, schema map and ERTs only accounts for 5.5% of the total query time and loading dictionaries accounts for 73.0%. An even more extreme case is that μSlope can return no-match right after the MPT and schema map search, because, say, the query searches for a key that doesn’t exist. In fact, our query benchmark does not even contain such best-case scenario for μSlope.

For Query B, μSlope is slower than ClickHouse-String and ClickHouse-Pairwise Array because μSlope needs to scan all the ERTs and decode them. , while the two ClickHouse setups can perform a full-text search on the raw JSON string values, without the need to decode them.

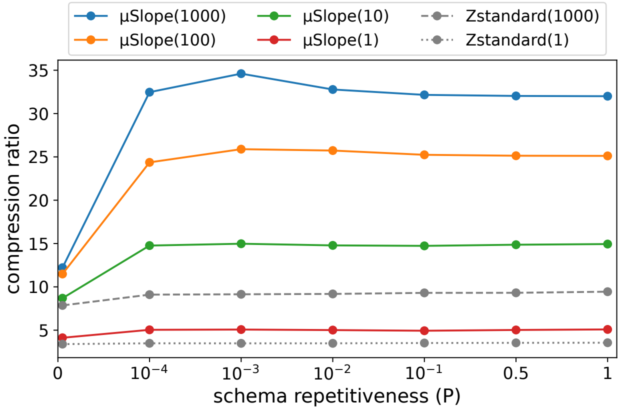

Figure 13: Compression ratio of μSlope against Zstandard on synthetic logs. The number enclosed in brackets within the legend represents the repetition ratio of variable values.

8.4 Synthetic Evaluation

The efficiency of μSlope relies on the repetitiveness of schemas and variable values. To demonstrate the boundaries of μSlope’s capabilities, we evaluate its compression and search performance on a corpus of synthetic log data, which

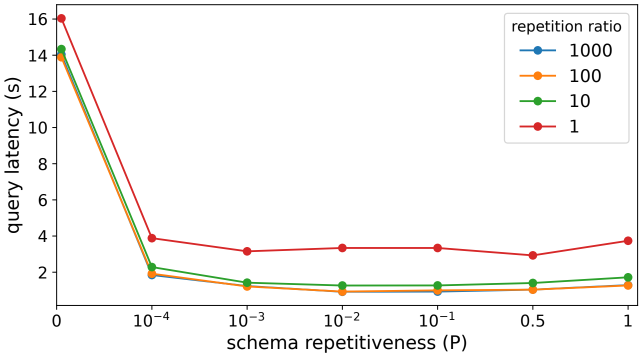

Figure 14: Query latency of μSlope for needle-in-haystack wildcard queries on synthetic logs.

varies in both repetitiveness of schemas and variable values.

Each synthetic dataset contains 1GB of data, consisting of 670K records. Each record has 20 fields. Every key and value is a UUID. We use UUIDs because they are one of the most common source of noises (i.e. non-repetitiveness) in the real logs. To vary the repetitiveness of variable values, the logs are generated with repetition ratios (§3) of variable values ranging from 1 to 1000, achieved by randomly drawing values from a uniform distribution. Specifically, we use four repetition ratios: 1, 10, 100, and 1000.

To vary the repetitiveness of schemas, we draw schemas from a power law distribution. Specifically, the n-th most frequent schema appears in $P \times (1-P)^n$ of the records (where n starts from 0). P is a value within the range of $(0,1]$, and it is a constant within one dataset. For example, the most frequent schema ($n=0$) appears in P of the records, the next most frequent schema ($n=1$) appears on $P \times (1-P)$ of the records, and so on. We use a total of 7 different P values as shown in Figure 13. The degree of schema repetitiveness increases with P. When P is the smallest every log record has a unique schema; when it increases to 1, all records have the same schema.

In total, we generate 28 (4 different repetition ratios combined with 7 different P values) synthetic datasets each with a different combination of schema repetitiveness and repetition ratio of the variable values. Figure 13 illustrates the interplay among compression ratio, schema repetitiveness, and repetition ratio of variable values. In all scenarios, μSlope outperforms Zstandard, with the compression ratio increasing as the repetition ratio of variable values increases. In the extreme case where P approaches 0, the compression ratio drops notably. This is attributed to each log record having a unique schema. The small tables and extra metadata overheads lead to a significant reduction in the compression ratio. However, the compression ratio quickly increases as P increases to the next smallest value (10^{-4}) and remains relatively stable.

We evaluate the search performance using a needle in the haystack query. One variable value is replaced with a fixed UUID value known as the "needle", so we can benchmark the query `*: "needle-value"`. The performance of this query is influenced by both the repetition ratio of variable values and schema repetitiveness. Lower repetition ratio leads to larger variable dictionaries, which are required to be loaded before decompression and scan, introducing a constant overhead before any results can be returned. This explains the consistent gap between each curve in Figure 14. As a result μSlope sometimes struggles to achieve low response time for datasets with a low repetition ratio, although this challenge can be partially addressed in practice by generating smaller archives.

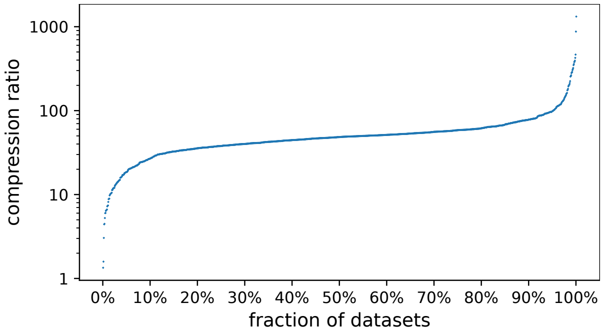

Figure 15: Compression ratio distribution of 1378 datasets in Uber's production logs.

Figure 14 shows a significant decline in query performance as P approaches 0. This is because in this extreme case where each record has a unique schema, we have a large number of small Encoded Record Tables where each has only one record. This significantly slows down the decompression and scan as we need to load a large number of small tables, and each table is decompressed using a different Zstandard stream.

8.5 Scalability Evaluation

We evaluate μSlope on 434TB of production logs from Uber representing 1,378 datasets, and select a 26.2TB subset from Uber's LogF to evaluate search scalability. This production dataset achieves an average compression ratio of 30.5:1, Figure 15 shows the compression ratio for each of the 1378 dataset in sorted order. The outliers with low compression ratio typically contain large amounts of random non-repeating binary data such as base64 encoded binary data and UUIDs. For example the index with the worst compression ratio has a column which appears to contain several megabytes of base64 encoded binary data in each log message.

To evaluate the scalability of search we run queries A-G from Table 2 on 26.2TB of Uber's LogF data with increasing amounts of parallelism. Values in the queries have been changed to match this dataset where appropriate. Results for query F have been omitted because its characteristics are identical to query E on this dataset.

Experiments are run across 8 containers, each has access to 96 cores, 2TB of network attached SSD, and 32GB of RAM.

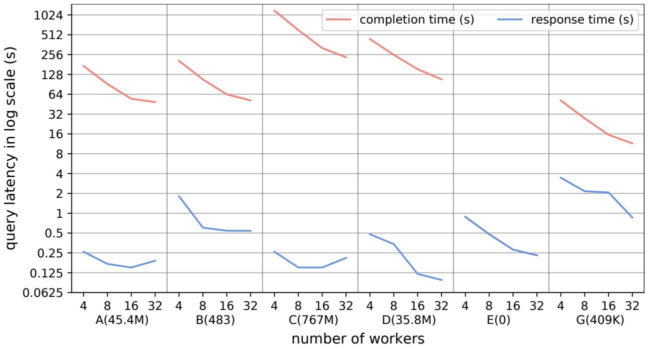

Figure 16: Query completion time and response time of μSlope (log scale) using 4, 8, 16 and 32 workers per container. The number of matching records for each query is indicated at the bottom.

There are a total of 2,155 archives after compression. These archives are evenly distributed across the 8 containers. The maximum skew between any two containers is 11% in both data size and in number of archives.

The searches are run using 4, 8, 16, and 32 workers per container. Each archive is processed by a single worker process. We show two results: (1) end-to-end completion time including marshalling all matching records, and (2) time to get the first matching record, i.e. response time. This experiment was conducted before we implemented our optimizations for JSON marshalling, so archives which contain many matching results can have an outsized impact on overall query performance. Figure 16 shows how the search performance scales with the increase of number of workers per container.

All of the queries scale well to 16 workers but have limited scalability to 32 workers. This limit is imposed by different kinds of skew in the dataset. For example in Query A a single archive becomes a bottleneck for completion time because it returns 5.9x more results than average, and in Query D all 19 archives with matching results happen to be allocated to the same container. Query E is extremely fast because it only needs to consult the MPT before terminating.

In practice, we manage this sort of skew within a dataset by producing smaller archives.

9 Limitations and Future Work

μSlope is a system designed for storing and searching archival semi-structured log data. It is not suitable for data that can be updated or deleted. Since μSlope leverages the repetitive nature of logs to achieve a high compression ratio, if the data has too many different schema structures or values are unique overall, μSlope may not be able to achieve a high compression.

As for search, μSlope provides support for basic queries, including term search, field search, wildcard search, and range search. However, currently it lacks support for more complex queries like joins. Besides, μSlope may struggle with queries that necessitate scanning the entire dataset and generating a large number of results.

The current implementation of μSlope compresses each table into its own Zstandard stream. We plan to implement optimizations to combine small tables into fewer streams (to improve compression ratio and amortize the cost of decompressing each small table), and split large tables into several streams by columns (to avoid decompressing columns in large tables not being searched on unless necessary). We also plan to improve scan performance and support more aggregation operators in the future.

10 Concluding Remarks

This paper presents μSlope, a resource efficient system for semi-structured log management that losslessly compresses the log data, and enables search without full decompression. Its design is guided by a careful analysis on the characteristics of real-world semi-structured logs and their query patterns. μSlope does not require any user annotation, and can automatically handle the dynamic schema structures. Our evaluation shows that μSlope achieves unprecedented compression ratio of up to 186.8:1, and its search speed is at least 2.47x of the fastest existing SSDMSes. μSlope is available at https://github.com/y-scope/clp.

Abstract

This paper presents ServiceLab, a large-scale performance testing platform developed at Meta. Currently, the diverse set of applications and ML models it tests consumes millions of machines in production, and each year it detects performance regressions that could otherwise lead to the wastage of millions of machines. A major challenge for ServiceLab is to detect small performance regressions, sometimes as tiny as 0.01%. These minor regressions matter due to our large fleet size and their potential to accumulate over time. For instance, the median regression detected by ServiceLab for our large serverless platform, running on more than half a million machines, is only 0.14%. Another challenge is running performance tests in our private cloud, which, like the public cloud, is a noisy environment that exhibits inherent performance variances even for machines of the same instance type. To address these challenges, we conduct a large-scale study with millions of performance experiments to identify machine factors, such as the kernel, CPU, and datacenter location, that introduce variance to test results. Moreover, we present statistical analysis methods to robustly identify small regressions. Finally, we share our seven years of operational experience in dealing with a diverse set of applications.

1 Introduction

In our hyperscale private cloud, tens of thousands of services run on millions of machines to serve billions of users, and engineers make thousands of code changes to these services daily. Performance or resource usage regressions caused by these changes may impact user experiences or even cause a site outage. Therefore, engineers critically rely on automated performance testing to catch regressions early.

Consider, for example, the frontend serverless platform called *FrontFaaS*. More than ten thousand engineers write code on this platform, with thousands of code changes committed daily and a new version released into production every three hours. If a code change causes even just a 0.01% regression in the platform's overall CPU usage, an alarm is raised. To our knowledge, strict thresholds of this level have not been studied before. We use this strict threshold because FrontFaaS consumes more than half a million machines and 0.01% would mean more than 50 machines. Moreover, if left undetected, many small regressions would accumulate over time. Each year, we catch regressions in FrontFaaS that amount to the capacity of more than one million machines.

This paper presents our performance testing platform called *ServiceLab*. It currently tests about one thousand diverse services and ML models, which, in aggregate, consume millions of machines in production. Although performance testing is widely used, there is no detailed report of its usage at hyperscale. Specifically, we have encountered several challenges that have not been studied before:

1. How to run tests on heterogeneous machines provided by the cloud while still ensuring comparable results?
2. How to detect regressions as small as 0.01%?
3. How to support hundreds of diverse services with one uniform testing platform?

We elaborate on each of these challenges below.

Use heterogeneous cloud machines. To detect small regressions, we must conduct numerous trials for an experiment and then apply statistical analysis. Since running these trials sequentially on one machine can take a long time (a trial takes over one hour on average), a natural solution is to run them in parallel on many machines. Ideally, these machines should be identical to reduce performance variance.

However, when a test workload is launched on a cloud, the cloud chooses machines to run the workload and even machines of the same instance type exhibit varying performance [47], due to differences in SSD wearing, memory chips from different vendors, and varying frequencies of CPU's uncore components like memory controller, etc. This phenomenon not only exists in public clouds but also in our private cloud that we use to run testing workloads. Note that

Contributions: Yang wrote the majority of the paper, followed by Mike and Chunqiang. Mike led the development of ServiceLab for multiple years, and other authors also made major contributions to its development.

our private cloud runs workloads on Linux containers instead of virtual machines (VMs) so there are no performance variances caused by VMs.

Although it is theoretically possible to reduce performance variance by maintaining our own dedicated pool of identical physical machines for testing, it is impractical for two main reasons: (1) testing workloads are spiky, and running them as on-demand workloads in the cloud is more cost-effective, and (2) maintaining a dedicated pool of tens of thousands of machines for testing requires an operations team that we cannot afford, which is exactly the problem that clouds aim to solve anyway.

Like in a public cloud, we can provision a batch of machines, keep a subset of "*nearly identical machines*" to run test workloads, and return the rest. The key question is how to select "*nearly identical machines*." Specifically, among the factors affecting a machine's performance, which are crucial for machine selection, and which can be ignored and addressed through statistical analysis?

To answer this question, we conducted a large-scale study with millions of performance experiments on various machines, using both microbenchmarks and real-world applications. We find that the performance variance on two machines is comparable to that on a single machine if the two machines share the same instance type, CPU architecture (e.g., Intel Cooper Lake), and kernel version, are located in the same datacenter region, and have CPU turbo disabled. An interesting observation is that the datacenter location matters, while other factors such as RAM vendor and RAM speed are less important. We will delve into this in §4.

Detect small regressions. For large services that consume tens of thousands of machines, we need to detect regressions as small as 0.01% while maintaining a low false positive rate. A high false positive rate not only wastes engineers' time in unnecessary debugging but also leads to engineers distrusting and ignoring the warnings even when they are correct. Our experience indicates that there is no one-size-fits-all statistical model that can accurately detect regressions for all services, due to the different outlier patterns of these services. To address this issue, we leverage multiple statistical models simultaneously and evaluate their false negatives and false positives on historical data to select the best model for each service. Although this ensemble approach may seem conceptually simple, we will discuss the intricacies of applying it at scale in highly noisy production environments.

Support diverse services. Our private cloud runs numerous services with intricate interdependencies, a complexity shared with other hyperscalers [30,38,48]. A single testing solution capable of covering all these services likely does not exist. Can we achieve the next best thing, i.e., having a single solution to cover the majority of code changes submitted by engineers? ServiceLab indeed accomplishes this. Currently, as a general-purpose testing platform, it covers more than half of the total code changes, surpassing the combined coverage of other specialized testing platforms.

ServiceLab takes the record-and-replay approach for testing, with three key distinctions. First, unlike past solutions that emphasize deterministic replay [8,20,24,62], ServiceLab replays requests captured from a production system (PS) to a system under test (SUT) without expecting the SUT to exhibit the same behavior as the PS. In fact, due to testing changed code, it is anticipated that the SUT may make outgoing calls to downstream services that differ from those made by the PS. Therefore, ServiceLab does not replay the responses from downstream services to the SUT.

Second, ServiceLab allows the SUT to call downstream services running in production, provided there are no adverse side effects. Although users can set up a group of interdependent services in ServiceLab to create a self-contained testing environment without relying on the production environment, this approach is not consistently implemented due to practical reasons. For instance, making a per-test replica of certain massive datasets accessed by the SUT, such as the social graph for billions of users, is economically impractical.

In ServiceLab, the SUT can call downstream production services, and most of those calls do not incur side effects, as they are read-only or idempotent. If a SUT's call to a downstream service does cause side effects, ServiceLab provides a mock framework to assist the SUT in mitigating it. For example, instead of writing to a production database, the writes can be redirected to a test database.

Third, due to the complexity of hyperscale services, ServiceLab does not attempt to provide a simple but inflexible solution that requires no involvement from service owners, because such a solution would only work for a small fraction of services. Instead, ServiceLab allows and encourages the service owner's participation. For example, when testing a sharded stateful service, it is the service owner's responsibility to populate the necessary states before the test starts.

With the three key distinctions above, while ServiceLab's record-and-replay approach may necessitate occasional involvement from the service owner and does not extend to certain complex services, it effectively covers the majority of code changes submitted by engineers.

Contributions. We make the following contributions:

- We address the performance variance issue arising from running tests in the cloud. Specifically, we conducted millions of experiments to identify the factors that contribute most significantly to performance variance across machines. Such a large-scale study has not been reported before.
- We develop statistical analysis methods to robustly identify performance regression as small as 0.01%, even when tests do not use identical machines. This represents a significant refinement of existing methods, as no prior research has achieved this level of a low threshold.
- This is the first holistic report of a hyperscale testing plat-

form, including its design and our seven years of operational experience in dealing with a diverse set of applications.

2 ServiceLab from a User's Perspective

Before presenting the internals of ServiceLab, we first describe its usage from a user's perspective. ServiceLab can be used in different testing modes. The *efficiency mode* tests a code or configuration change's impact on key metrics such as latency or CPU/memory usage. The *capacity mode* tests a code or configuration change's impact on the maximum throughput that can be achieved, which affects the amount of capacity needed to run the service. The *hardware mode* compares the performance of different hardware running the same code. Below, we focus on the efficiency mode.

2.1 ServiceLab in the Development Workflow

Figure 1 depicts our development workflow, where ServiceLab is involved in the review-time test, commit test, deployment test, and config test. We elaborate on them below.

Meta uses the monorepo approach [12] to store code for all projects in one repository. When developing a new feature for an application, the developer clones the repository and makes local changes without affecting others. Once the code is ready, they submit the change, referred to as a *diff*, for peer review. Both functional and performance tests are automatically executed for the diff. The peer reviewer examines the code and test results, requesting changes as needed before approving the diff. Upon approval, the developer commits the diff, triggering post-commit tests.

On a set schedule, the continuous-deployment tool compiles a new executable for the application and creates a release candidate (RC). It conducts tests to compare the RC with the executable running in production. The RC is abandoned if a regression is identified. Otherwise, it is deployed into production in stages, and the application's health metrics, including performance metrics, are monitored continuously. If any health issue is detected, the deployment is reverted.

A common practice is to use a configuration parameter known as a *gate* to control access to the new code path. Initially, the gate is disabled so that the application continues to execute the old code path even after the new release is deployed. Then, the developer makes a remote configuration change to toggle the gate, enabling the application to execute the new code path. If any issues arise, the gate can be instantly disabled to revert back to the old code path without requiring a new code release.

2.2 Setting Up Tests with ServiceLab

To register a system-under-test (SUT) with ServiceLab, the application owner provides the following information:

- The selection criteria for code or configuration changes to trigger a test (note that it may not be necessary to run tests on every change);
- A container manifest that specifies the executable to test and how to set up Linux containers to run the executable;
- The metrics to be aggregated at the end of a test run, and the condition to fail the test;
- A traffic-recording configuration that instructs the RPC system how to sample production traffic for later replay;
- The rate at which the recorded traffic will be replayed during a test run.

ServiceLab supports both synthetic and record-and-replay traffic for testing, but primarily relies on the latter because it more accurately represents the production system. This approach records live production traffic and then replays it on a separate application instance in the testing environment, which may run modified code. It is the application owner's responsibility to ensure that a replay in the testing environment does not cause undesirable side effects on the production system. Moreover, a stateful application needs to set up its state properly so that it can handle the replayed traffic.

Once a SUT is registered at ServiceLab, it undergoes tests in four phases. The *build* phase compiles all required code into a package. The *allocation* phase acquires necessary machines from the cloud. The *running* phase initiates the target application on the allocated machines and replays the recorded workload. The *analysis* phase conducts statistical analysis on the results to draw a conclusion.

3 Applications Tested by ServiceLab

Currently, ServiceLab tests about one thousand diverse services and ML models, and their collective capacity consumption in production amounts to millions of machines. We describe several representative and large workloads below.

3.1 FrontFaaS Serverless Platform

FrontFaaS is one of the most complex software ecosystems in our private cloud. It is a serverless function-as-a-service (FaaS) platform that runs on more than half a million machines and has tens of thousands of developers making changes to its code base, with thousands of code commits every workday. ServiceLab tests FrontFaaS to detect CPU usage regression as small as 0.01%. It holistically tests different aspects of FrontFaaS: its PHP runtime called HHVM [27], the FaaS code written by tens of thousands of developers, and that code's impact on downstream services like databases.

Testing the language runtime. HHVM performs just-in-time (JIT) compilation for efficient execution. The HHVM team relies on ServiceLab to collect performance signals on compiler optimizations, monitoring metrics such as instructions per cycle, execution time, and cache misses. In addition to the core code written by the HHVM team, HHVM links with many libraries developed by other teams, any of which may cause regressions. HHVM tests compare the code running in production with the code in the *trunk* (i.e., the latest code

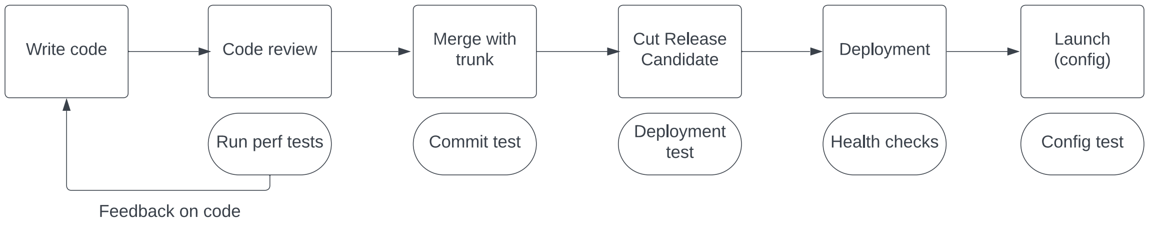

Figure 1: Code change workflow. In this figure, *tests* refer to both functional and performance tests, but this paper focuses on performance tests.

in the monorepo shared by all developers), enabling developers to catch regressions before a new release candidate is created. If a regression is detected, ServiceLab uses bisection to identify the root cause.

Selecting diffs to test. In addition to testing HHVM, ServiceLab also tests FrontFaaS' application-level FaaS code. FrontFaaS is the primary entry point for user-facing traffic for our products and runs thousands of unique application endpoints. With thousands of FaaS code changes (diffs) occurring every workday, it is not cost-effective to test every change. Moreover, since a change is unlikely to affect all thousands of application endpoints, it is unnecessary to replay the traffic for all those endpoints during a test.

A ServiceLab component called *DiffSuggester* selects which diffs to test based on a calculated *impact score* and also determines the traffic for which endpoints to replay during a test. DiffSuggester traverses the compiler's abstract syntax tree to identify functions modified by the diff. It calculates an impact score for each modified function by leveraging a profiling dataset of FrontFaaS' execution in production to estimate the global cost of the function, considering both its execution frequency and resource consumption per invocation. The diff's impact score is simply the sum of the impact scores for all impacted functions. If a diff's impact score is above a threshold, ServiceLab will run experiments for it. The threshold is statically chosen based on the number of machines available to run experiments and the distribution of diffs' impact scores. Moreover, DiffSuggester also uses the production profiling data to infer which application endpoints are impacted by the diff and selectively replay traffic for those endpoints with the right proportion.

Dealing with side effects. Because of the complexity of FrontFaaS, it is too costly to set up an entirely isolated testing environment for it. It invokes hundreds of downstream services, which recursively have their own dependencies. All these are hard to replicate in a testing environment and keep them faithful to the production environment. Moreover, given numerous concurrent tests, it is economically impractical to make a per-test copy of certain massive datasets accessed by FrontFaaS, such as the social graph for billions of users.

Therefore, ServiceLab allows a test instance of FrontFaaS to call downstream services running in production and carefully manages any adverse side effects. The non-functional side effects, such as test-induced load on downstream production systems, is not a concern because that test load is negligible compared to the production traffic from billions of users. The functional side effects, such as writing to a production database, is the main concern and is managed carefully.

By default, FrontFaaS' writes to databases, caches, and data warehouses are automatically dropped via a shim layer in the client libraries, while reads to these production systems are allowed. Unlike data stores where differences between read and write can be easily identified, for generic RPC calls, ServiceLab and the RPC system cannot easily infer whether an RPC method has undesirable side effects or not. Therefore, the RPC system drops calls to downstream production systems by default to ensure safety, while users can provide a list of specific RPC calls that are allowed to proceed. However, this method may prevent certain code paths from being executed and result in ServiceLab missing the opportunity to detect regressions on those code paths. If the owners of certain FrontFaaS endpoints really want to cover those code paths, it is their responsibility to modify the code's behavior so that it can run in ServiceLab to exercise those code paths without causing adverse side effects to production systems. We will delve into this in §5.3.

Testing performance impact on downstream services. A FrontFaaS diff may not cause regressions in the resource usage of FrontFaas itself but may regress in the load it imposes on downstream services. Specifically, the social graph database (*TAO* [11]) is one of the most important downstream services for FrontFaaS, and ServiceLab also detects increased reads to TAO. During a test, ServiceLab monitors the number of read requests that FrontFaaS issues to TAO when processing a replayed end-user request. Statistics are gathered at the granularity of each type of end-user request because the number of reads to TAO may vary widely depending on the type of the end-user request. Similar to reporting regressions on FrontFaaS' own metrics, ServiceLab also reports regressions in reads to TAO.

3.2 Sharded and Stateful Services

LASER is a low-latency key-value store that is frequently accessed by FrontFaaS on the critical path of serving user requests. LASER primarily serves as an indexing service for data in the data warehouse. Its index can be updated either by real-time stream processing that extracts data from data streams or by running daily MapReduce computation to build the index and then performing a bulk load into the key-value store. LASER is sharded and managed by a shared, central control plane similar to ShardManager [36] and Slicer [4], which dynamically assigns shards to different LASER servers.

Testing LASER faces several challenges. First, to bring up a LASER instance in the isolated test environment, we have to disconnect it from the central shard control plane and specifically instruct it to load certain shards, instead of relying on the control plane's dynamic shard assignment. Second, we allow LASER to perform read-only accesses to the data warehouse to set up its stateful index for testing. Finally, in production, requests routed to a specific LASER shard have an RPC header with the shard ID that matches with the shard; otherwise, the requests would be rejected. LASER uses record-and-replay for testing, which broadly samples requests for different shards. When requests are replayed, ServiceLab dynamically adds an RPC request header that matches with the shard ID of the LASER server under test.

LASER uses three major metrics for regression detection. These metrics and their regression thresholds are CPU usage (2%), anonymous memory usage (5%), and SSD storage usage (5%).

3.3 ML Prediction

MLPredictor is a shared ML deployment platform used by ML engineers to effortlessly deploy and manage thousands of ML models without the need for an understanding of the underlying infrastructure. This "serverless" approach conceals the operational complexities of large-scale distributed systems, which are often unfamiliar to ML engineers.

MLPredictor uses record-and-replay, along with ServiceLab's *capacity mode*, to test performance under varying load levels. ServiceLab incrementally increases the load level of the replayed traffic until MLPredictor breaches its service level objective (SLO), helping identify both the maximum throughput and potential capacity regressions. Initially, we recorded traffic for different models using uniform sampling, leading to an overwhelming number of samples from high-traffic models. Later, we switched to interval-based reservoir sampling [5,57], capping the number of samples for a popular model at a constant per time interval.

MLPredictor uses the maximum requests rate for regression detection, with a threshold of 5%.

3.4 Data Aggregation

DataAggregator is a CPU-intensive backend service that handles all news feed rankings. It is invoked by FrontFaaS upon a user request, and its role is to collect all relevant information about posts and analyze all the features (e.g., how many people have liked this post previously) to predict the posts' values to the user. New releases of DataAggregator are deployed to production multiple times throughout the day, and it primarily uses ServiceLab for release-time testing.

Instead of using record-and-replay, it uses a forker service to duplicate live production traffic and send it to the testing environment in ServiceLab. The forker sends the production system's responses back to users but drops the test instance's responses so that they will not affect users. DataAggregator prefers testing with shadow production traffic instead of recorded traffic because the setup is straightforward for them, and the existence of the forker even predates ServiceLab.

DataAggregator uses 68 key metrics for regression detection. Examples of the key metrics and their regression thresholds include container-level CPU usage (1.25%), process-level CPU usage (0.6%), and p99 memory usage (3%). Some metrics are related to the application logic, e.g., log error or warning counts (5%), no stories returned (2%), and latency to process all stories in the ranking service (30%).

3.5 XFinder

XFinder is a large service performing ads aggregation and ranking. Upon receiving a user request, it fans out requests to many leaf services, aggregates, and ranks the results before returning them to the user. XFinder uses record-and-replay, but to obtain accurate results, it requires near real-time traffic recorded from production within the past hour. Each week, it conducts over 3,000 and 1,000 experiments on code and configuration changes, respectively. To understand the impact of a change more precisely, instead of A/B tests, it runs 3-sided experiments: (1) the version currently running in production; (2) the latest version before this change; and (3) the new version with the change to be tested.

XFinder uses 65 key metrics for regression detection. These key metrics all use a regression threshold of 0.5%. The key metrics include total CPU time, log error or warning counts, count of ads returned, number of calls to downstream services, and failure rates of these calls.

3.6 Ranker

Ranker executes a graph of rules for ranking. A diverse set of application clients calls Ranker with different rules to provide ranking for their specific purposes, and these rules impact Ranker's performance. Ranker relies on record-and-replay to capture these rules. Requests from each application client are sampled on the client side and stored in the data warehouse. Each major client corresponds to a different shard of Ranker deployment, and these different shards run the same Ranker executable but serve different clients. Previously, Ranker created a mix of requests when replaying them for testing in ServiceLab. However, maintaining the correct ratio of requests in the mix became a burdensome process, and an incorrect ratio would lead to missed regressions. As a result, Ranker now runs separate experiments to replay traffic from different major clients.

Ranker uses 30 key metrics for regression detection. The key metrics and thresholds include container-level CPU usage (9%), container-level memory usage (7%), CPU MIPS busy (5%), and application metrics such as different types of candidates fetched (20%).

3.7 Applications not Using ServiceLab

ServiceLab tests now cover more than half of the total code changes at Meta. The remaining applications choose other testing methodologies for various reasons as described below. A common theme among them is that setting up a service for testing in ServiceLab requires effort, and sometimes a simpler alternative exists.

First, Meta's continuous deployment tool, Conveyor [22], and its in-production detection tool, FBDetect, can catch performance regressions either during the staged deployment process or during steady-state execution in production. Despite the higher risk of catching issues in production, these tools work sufficiently well for some services, leading those services to skip pre-production testing in ServiceLab.

Second, some services have complex interdependencies, and services like Meta's cluster manager ecosystem [42,54] even depend on the physical data center environment. These complex services have their own sophisticated ways of setting up their testing environments, which are often overly complicated to migrate to ServiceLab.

Third, some stateful services require a massive amount of data for effective testing. It is too slow to populate such data in newly allocated containers during each ServiceLab test run. Therefore, these services maintain their own dedicated and persistent test environments with prepopulated data, without relying on ServiceLab.

Fourth, some services do not consume significant capacity and do not have stringent performance requirements. As a result, thorough performance testing is not a priority for them. Their developers often prefer simpler ad-hoc testing methods, as opposed to the burden of setting up and maintaining their service setup in ServiceLab.

Finally, in a large organization with tens of thousands of developers, our experience indicates that achieving universal adoption of a technology is challenging unless it becomes a company priority, as demonstrated by the Push4Push program driving the universal adoption of the continuous deployment tool at Meta [22]. So far, ServiceLab has relied entirely on organic, bottom-up adoption without top-down push.

4 Taming Performance Variance

A key challenge in designing any testing platform is managing variance in testing data to separate signals from noises. To set the stage for the discussion, we first define some terminology. Assessing a code change's performance impact uses an *A/B test* to compare two *test runs*, one with the change and one without. A *trial* is a singular A/B test, and an *experiment* comprises multiple such trials. An *A/A* test compares two runs of the same code.

Performance differences may stem from (a) *accidental variance* caused by code's random factors such as the timing of lock contention; (b) *environment variance*, stemming from testing environment differences like CPU generation and kernel version; and (c) *true regression* in the code change. Our goal is to minimize the impact of accidental and environment variance to identify true regression.

To detect true regressions as small as 0.01%, we must aggressively reduce both accidental and environmental variance, as they could conceal small regressions. To reduce accidental variance, we collect a large amount of test data and then apply statistical analysis. To reduce environmental variance, we always acquire entire machines from our private cloud to run tests, avoiding the "noisy neighbor" problem. However, sequentially executing all test runs on one machine, while minimizing environmental variance, leads to prolonged test times and a slowdown in the iteration speed of software development.

One fundamental decision we have made is to run tests concurrently on different machines to expedite testing. Initially, the ServiceLab team operated its own dedicated machine pool and meticulously configured the machines to be nearly identical to reduce environment variance across machines. However, as the pool size expanded, maintaining it became uneconomical, leading us to switch to using our private cloud's shared machine pool. Moreover, the cloud allows ServiceLab to use temporarily reclaimed resources called "Elastic Servers", akin to Spot Instances in AWS, for testing. Since Elastic Servers can be revoked, our cloud employs predictive models to infer the availability of Elastic Servers and run tests correspondingly. When Elastic Servers are revoked unexpectedly, ServiceLab simply re-runs the interrupted tests.

When acquiring machines from the cloud, ServiceLab can specify a certain coarse-grained configuration such as CPU cores and memory, but cannot control other details, such as memory chip or kernel version. Note that the cloud automatically updates kernels at its own schedule to ensure security compliance. ServiceLab can provision a batch of machines, retain a subset of "*nearly identical machines*" to run test workloads, and return the rest. We do not require machines to be identical in every aspect as finding a sufficient number of such machines is difficult. Next, we discuss how to select "*nearly identical machines*" by using factors that impact a machine's performance most.

4.1 Machine Factors Impacting Performance

We analyze millions of test records to identify key factors impacting a machine's performance. Our analysis involves two large datasets. The Release to Production (RTP) dataset comprises 21.5 million records, each executing a CPU or memory benchmark. The ServiceLab dataset contains 186K records, each testing a real production application. Each record in both datasets specifies the test result alongside the used hardware and software configuration. Leveraging both datasets is crucial as they complement each other. The RTP dataset provides diverse hardware results, though its benchmarks are less complex. Conversely, the ServiceLab dataset contains real application results, but the machines used are less diverse.

We use the ANOVA method [52] to identify factors that best explain the variance in the data. ANOVA is similar to linear regression but operates on categorical data. Its output, the coefficient of determination (R^2), represents the proportion of the variance in the dependent variable (performance metrics in our case) that is predictable from the independent variables (e.g., CPU generation or kernel version). Our goal is to find a minimal subset of key machine factors (independent variables) that can explain as much variance as using many factors. This allows us to use these key factors for machine selection. Otherwise, a large number of factors would make it hard to find matching machines due to overly aggressive filtering. To achieve our goal, we first use many factors to establish an approximate upper bound for R^2, and then explore different subsets of factors to approach the upper limit.

To set the stage for discussion, we will first describe how physical machines are classified with three levels of granularity. At the most coarse level, machines are classified into tens of *ServerTypes*. Examples of ServerTypes include single-CPU general-purpose machine, two-CPU general-purpose machine, GPU training machine, GPU inference machine, etc. The median granularity, known as *ServerSubType*, takes into account more hardware information, such as RAM size and CPU architecture (e.g., Intel Skylake, Cooper Lake, etc.). The finest granularity, referred to as *ServerModel*, includes the model names of all major components, such as CPU, RAM, NIC, disk, etc. Typically, users specify ServerType when requesting machines from our private cloud. While specifying ServerSubType is allowed, it is discouraged because it limits flexibility for the cloud to choose machines. Users are not allowed to specify specific ServerModel. Concretely, our private cloud uses O(10) *ServerTypes*, O(100) *ServerSubTypes*, and more than 10,000 *ServerModels*. They are equipped with O(100) CPU models, O(100) RAM models, O(1000) disk models, and O(100) NIC models.

To approximate the upper bound of R^2, we use ServerModel as one factor since it includes almost all hardware information and add non-hardware factors like the kernel release version. We first report our results on the RTP dataset. These factors can achieve an R^2 of 0.89 for the CPU benchmark and an R^2 of 0.97 for the memory benchmark. In the remainder of this section, we will focus on the CPU benchmark as the memory benchmark exhibits much less variance.

We explore various factor subsets to determine if a small combination can achieve an R^2 close to the upper limit. Using three factors—ServerType, CPU architecture, and kernel release—we attain an R^2 of 0.87 on the CPU benchmark, closely approaching the upper bound. In practice, we observe that the cloud can generally provide matching machines based on these three factors. Note that this subset is not the only viable option. As hardware factors are correlated, some factors can be replaced by others. Additionally, we find that certain factors, such as RAM speed and RAM vendor, have minimal impact, even in memory benchmarks.

Analyzing the ServiceLab dataset reveals two additional important factors: CPU turbo and the datacenter region where the test was executed. Their impact varies across applications, and adding these factors can increase R^2 by up to 0.23. In comparison, in the RTP dataset, adding these factors only increases R^2 by 0.01 for the CPU benchmark. The influence of CPU turbo, previously reported in research [40], manifests only in the ServiceLab dataset, not in the RTP dataset. This difference arises due to constant CPU activity in the RTP benchmarks. The datacenter region is significant for real applications tested in the ServiceLab dataset because many of them have external dependencies. For example, if the test instance of an application reads from a production database in the region, the test result would be affected by the database's performance, which tends to vary across regions. In contrast, the RTP benchmarks have no external dependencies.

While the key factors account for 87% of the variance, the remaining 13% is attributed to other smaller factors. For example, in machines with CPUs of the same model, the frequency of their uncore components, such as cache and memory controller, can vary, resulting in approximately a 2% performance difference across tests. However, these factors cannot be used for selecting machines from the cloud as they are not exposed by the cloud.

Our analysis further reveals that certain CPU models and kernel versions contribute significantly more variance than others. Like prior works [40], we use Coefficient of Variance (CoV), defined as the ratio of the standard deviation to the mean, to compute the variance of a set of values. Specifically, regarding CPU models, Intel Xeon E5-2680 v4 @ 2.40GHz has the highest CoV at 42%, while AMD EPYC 7D13 36-Core Processor has the lowest CoV at 5.6%, with an overall P50 at 19%. Regarding the kernel, version 5.6.13-0 has the highest CoV at 52%, and 5.2.0-240 has the lowest CoV at 9.5%, with the overall P50 at 36%. While investigating the root cause of CoV is beyond the scope of this paper, ServiceLab avoids using CPUs or kernel versions with high variance.

In summary, the strategy we use is to select similar machines with matching kernel versions, ServerTypes, CPU architecture, and datacenter regions, while disabling CPU turbo. To assess whether performance variance within the similar machines selected by our criteria is comparable to that for a single machine, we compare their CoVs. The comparison is conducted using the RTP dataset with turbo disabled. The CoVs for same-machine tests are 5.9% at P50 (50 percentile) and 28% at P99, while for similar-machine tests, they are

5.7% at P50 and 38% at P99. The P50 values are nearly identical, with a higher difference at P99. Overall, the difference is deemed acceptable, considering the advantage of running tests in parallel.

Applicability to public cloud. To implement our machine selection method in a public cloud, we recommend using bare metal instances, which are offered by all major cloud providers, rather than the more commonly used virtual machine instances. Although it is reported that lightweight hypervisors like AWS Nitro System can match the performance of bare metal machines [34], they may still introduce greater performance variability than bare metal machines. We have not validated our method in virtualized environments.

4.2 Statistical Methods

Despite using matching machines, experiments still exhibit variance. We conduct experiments multiple times and employ statistical methods to determine the level of regression with a confidence interval. In general, we observe that there is no one-size-fits-all model due to the diverse requirements and varying performance-data distribution of different services. Therefore, ServiceLab incorporates multiple models with a mechanism to learn the best model for each service based on historical data.

Recall that a *trial* is a singular A/B test, and an *experiment* comprises multiple trials. An *A/A* test compares two runs of the same code. A test may generate multiple data points. For example, a test may measure CPU utilization for an hour and generate a CPU-utilization data point per minute.

A model used by ServiceLab is a combination of a statistical test method and a data preprocessing method. ServiceLab uses the following statistical test methods:

- **Student's t-test** [17]. If an experiment only contains a single trial, we use the student's t-test to determine whether there is a significant difference between the means of the A side and the B side.

- **Permutation test** [6]. If an experiment includes multiple trials, for each trial, we first compute the difference in means between the A side and the B side. This step results in a vector of m values called $\vec{M}$, where m is the number of trials. Then we posit the null hypothesis H_0: $\mu_\Delta = 0$, where μ_Δ is the mean of $\vec{M}$. We apply a permutation test for this hypothesis as follows. We generate a large number of permuted samples from $\vec{M}$ and calculate the mean for each. Then we derive the p-value from the proportion of permuted sample means that are as extreme as or more extreme than the observed mean of $\vec{M}$.

- **Confidence interval test**. The above tests infer the distribution of the data from the experimental data. Since we can only run a limited number of trials within an experiment and some tests may incur outliers, such inference may not be accurate. The confidence interval test builds the data distribution from historical data. Specifically, it leverages A/A tests from the past two weeks to build the distribution of $mean(A') - mean(A)$, and further computes the confidence interval given the p-value, i.e., the probability of the observed difference of means being smaller than the confidence interval is larger than $1 - p$. Then, for an experiment, it can test whether the B side follows the same distribution as the A side by determining whether $mean(B) - mean(A)$ is smaller than the confidence interval.

ServiceLab uses the following data preprocessing methods:

- **Square root transformations.** An important preprocessing step involves square root transformations. This is motivated by recognizing significant heterogeneity in the cost of requests, with certain requests disproportionately impacting mean metric values. Such disparities are exacerbated across multiple trials, leading to skewed aggregations. The square root transformation mitigates this, ensuring a more uniform contribution from each request to the trial's mean metric value. This adjustment has been empirically validated to enhance detection accuracy, especially for high-demand services.

- **Outlier detection.** We use conventional outlier mitigation methods, such as winsorization [18], which are particularly effective in moderating the elevated variance observed when services operate under strenuous conditions. Specifically, we either delete data points that are above a certain percentile (called outlier-elim) or cap those data points at the percentile value (called outlier-cap).

Out of all possible combinations of statistical test methods and data preprocessing methods, currently ServiceLab uses seven combinations: t-test-none, t-test-sqrt, t-test-outlier-elim, t-test-outlier-cap, permutation-test-none, permutation-test-sqrt, and confidence-interval-none, as well as some service-specific models.

ServiceLab uses an adaptive method to determine the best model for each <*service, metric*> combination. It conducts periodic A/A experiments and artificial A/B experiments (i.e., A/A experiments with injected regression on one side) to generate a "ground truth." Then, ServiceLab tests each model on the results of these experiments to obtain the model's false positive rate (from the A/A experiments), the false negative rate (from the artificial A/B experiments), and the detectability [10] (from the A/A experiments). ServiceLab then selects the model with the highest score, which is a linear combination of the false positive rate, false negative rate, and detectability, under the constraint that its false positive rate is below a threshold. ServiceLab runs this model selection algorithm periodically to adapt to changes in existing services and accommodate new services and metrics.

In our production, 51% of the services have adopted the confidence-interval-none model, 21% have adopted the t-test-sqrt model, 21% have adopted the adaptive method, 5% have adopted the t-test-none model, and 1% have adopted the permutation-test-none model. Not all services use the adaptive method, either because they find a fixed model always works well or because they have not tried the recently introduced adaptive method.

The breakdown of the models chosen by the adaptive method is as follows: confidence-interval-none (49%), t-test-none (19%), t-test-outlier-cap (10%), t-test-outlier-elim (9%), permutation-test-none model (5%), t-test-sqrt (4%), and permutation-test-sqrt (3%). Over a 90-day period, for services using the adaptive method, more than 50% of them have changed models at least once, and more than 10% of them have changed models at least four times. This indicates that the best model for a service can change as the service's code and characteristics evolve.

Next, we discuss our journey to arrive at the current set of models. Initially, ServiceLab only supported single-trial experiments and thus used the student t-test with outliers handled by winsorization. When working with services requiring multiple trials, we found that the t-test did not work well. Outliers in both trials and requests within a trial affected the experiment results, showing up as either false positives or missed regressions due to excluding outliers. Consequently, for multiple-trial experiments, we added the permutation-test-none and permutation-test-sqrt models. The confidence-interval test was added to handle noisy metrics or ones that are not continuous like CPU or memory. We found that for these metrics, looking at the historical data to find the regression threshold would work better than dealing with a t-distribution (as the t-test and other variants do). Finally, motivated by the observation that different metrics follow different distribution patterns and such patterns may change over time, we added the adaptive method to help users find the best model.

Finally, we describe two optimizations that improve the accuracy of the statistical methods.

Test warm up time. Identifying and excluding initial warm-up periods in service operations is crucial for isolating steady-state performance metrics. We employ an algorithm using exponential moving averages to determine the point at which a time series reaches approximate stationarity. Observations before this point are discarded. As the duration of the warm-up phase depends on the test environment, this determination is made on an individual trial basis, ensuring that only matured performance data undergoes further analysis.

Periodic A/A experiments. ServiceLab conducts periodic A/A tests, and aggregates the results into a user dashboard, enabling users to monitor the false positive rate and detectability. This dashboard aids users in modifying workload settings to enhance the statistical signal of their experiment. For instance, users can adjust parameters such as increasing the number of trials, extending experiment duration, removing noisy metrics, or changing the aggregation method.

5 ServiceLab Design

This section presents the design of ServiceLab, utilizing the architecture diagram shown in Figure 2 in our discussion.

5.1 Experiment Lifecycle

During an experiment's lifecycle, it transitions through several phases: *queued→build→allocation→running→analysis*. An experiment begins when a user or an automation tool submits a request via the Windtunnel API, which enqueues the request into a *DurableQ* (durable queue) and creates an entry in the Windtunnel DB to represent the experiment, setting its phase as *queued*. The phase transition of an experiment is managed by a *processor*, and multiple processors can work independently to manage different experiments. When a processor determines it can take on additional work, it polls the DurableQ to claim a queued experiment and locks the corresponding Windtunnel DB entry to prevent other processors from performing duplicate work.

After some input validation and preprocessing, the processor transitions the experiment to the *build* phase, where the experiment's executables are created. The processor does not compile the executables directly but instead sends a request to a separate build service, which acts as a caching layer to prevent duplicate builds.

Once all executables are built, the experiment enters the *allocation* phase. Each team is configured with a certain testing-machine quota that they are allowed to use. The processor tracks the already used portion of the quota and determines when to allocate machines for experiments, enforcing priority and fairness. An experiment may need to run multiple jobs, such as one for the A side of the A/B test and another for the B side. As all jobs of an experiment must be allocated from the same datacenter region to minimize variance (§4.1), the processor decides from which region to allocate the jobs based on the remaining quotas in different regions. Additionally, the processor filters machines based on ServerType, CPU architecture, and kernel version to minimize variance across the selected machines (§4.1).

In addition to allocating the system-under-test (SUT) jobs, the processor also allocates a traffic-replay job and a test-harness job. The test-harness job drives the experiment and monitors the test's status. Depending on the experiment's purpose, different test-harness jobs can be used. For example, to measure the maximum throughput that the SUT can sustain, the *capacity* test harness can gradually increase the test throughput until the SUT violates its SLOs, such as response time, error rate, or CPU utilization exceeding a threshold.

Once all the necessary jobs are allocated, the experiment enters the *running* phase. If the experiment is testing a configuration change, the corresponding configuration canary [13,15,53] is set up correctly on the test machines. Subsequently, the traffic-replay job loads the previously recorded requests that will be replayed during the experiment. Finally, the processor instructs the test harness to start the test. Through-

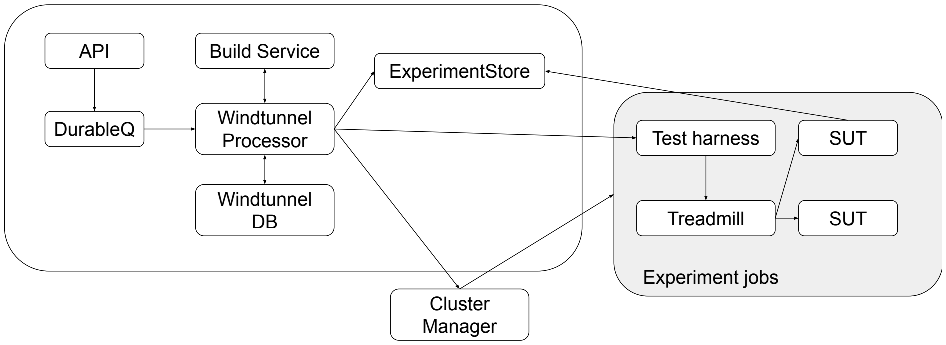

Figure 2: ServiceLab architecture. *Windtunnel* is the orchestration engine and *Treadmill* replays traffic and runs tests.

out the experiment, the test harness monitors the health checks of all jobs and fails the experiment if any job fails its health check. Meanwhile, the SUT exports performance metrics to monitoring databases during the experiment.

After the test finishes, the processor deallocates all jobs and transitions the experiment to the *analysis* phase. Aggregation and statistical analysis of performance metrics are performed by a service called *Experiment Store* (ES). The results are written to the Windtunnel DB, which users can view from a UI. These results can also trigger certain actions, such as blocking a service from being released into production.

5.2 Traffic Record-and-Replay

At Meta, all services use the Thrift [49] RPC protocol, which is leveraged by ServiceLab to record production traffic transparently. The user specifies the Linux containers where RPC traffic should be recorded. Upon receiving a request on these containers, the Thrift server's recording module flips a coin to decide whether to sample the request. To minimize the impact on RPC latency, the recorded data is written asynchronously. The user configures the request sampling rate, and by default, requests are sampled uniformly. For a service with a highly variable request rate, reservoir sampling [5, 57] ensures that sampled requests are evenly spread over time, with at most K samples during each T time interval. In practice, the median sampling rate is 0.03%, and above that, 22% of services set sampling rate to 1%.

By default, ServiceLab assumes that RPC requests are independent—meaning the execution of one request does not depend on the execution of the previous request. However, this assumption may not hold for some services. In these cases, the service can record all requests, and then during replay, all recorded requests are replayed in order. For some services, request dependencies are encoded at the RPC layer and can thus be recorded accurately and transparently.

For sharded services, since sharding is done at the application layer and is invisible to the RPC layer, ServiceLab relies on the service owner to specify the set of Linux containers to capture requests for all shards.

ServiceLab leverages the open-source load testing platform Treadmill [61] to replay requests. Treadmill employs an open-control loop to send requests at a fixed rate. We have implemented several modifications to Treadmill, extending it to load recorded requests from a datastore and replay Thrift RPC requests. In support of A/B experiments, we further enhanced Treadmill to ensure consistent pacing and request rates for both sides. A single Treadmill instance loads an identical set of requests to be dispatched to both SUTs, synchronizing the sending of requests to ensure simultaneous receipt on both sides. For the capacity mode, a control loop in the test harness monitors the SUT and instructs Treadmill to dynamically adjust the request rate.

Additionally, services may have a warm-up period during which performance measurements should not be taken until the service reaches a steady-state behavior. ServiceLab can be configured to enable a *warm-up phase*, allowing a lower request rate to be set during this phase to gradually increase the load on the service. The service exports a counter to indicate whether it has reached warm-up. Treadmill waits for both sides to be warmed up before synchronizing and sending requests once again for steady-state performance measurement. For example, HHVM employs a JIT compiler, and steady-state performance measurements should start after JIT compilation is sufficiently warmed up.

Finally, services with high variability in request processing time due to diverse request types are harder to handle. FrontFaaS is one such example. We can reduce variability by testing only with request types relevant to a specific code change, as opposed to all request types.

5.3 Handling Service Dependencies

Meta products are built out of tens of thousands of services with intricate interdependencies, akin to those documented in prior research [30, 38, 48]. For example, FrontFaaS invokes hundreds of downstream services. Consequently, testing a service in isolation is challenging due to these interdependencies. ServiceLab tackles this issue through various approaches.

First, users can set up a group of interdependent services together in ServiceLab, creating a self-contained testing environment. While theoretically possible, this approach is not consistently implemented in practice due to various reasons. For instance, replicating the massive datasets accessed by services, like the social graph for billions of users, is often economically impractical.

Second, ServiceLab allows a system under test (SUT) to invoke certain services in the production environment, provided there are no adverse side effects. In ServiceLab, most calls to downstream production services do not incur side effects because they are read-only or idempotent. Moreover, the testing load imposed on these downstream services is often negligible compared to their ample capacity to serve billions of users. However, as these downstream services often exhibit performance variance across datacenter regions, meaningful comparisons can only be drawn from tests conducted in the same region (§4.1).

Third, for a SUT that potentially can cause side effects on downstream production services, ServiceLab requires the service owner to modify the SUT's behavior to prevent those side effects. For example, the SUT may use a mock interface of a database so that it writes data to a test database instead of the production database. Moreover, to prevent a SUT from accidentally accessing a production service, the RPC layer can be instructed to block all traffic to production services except those on an allowed list. Mocking or blocking traffic can result in certain code paths not being executed, potentially causing false negatives in testing results. However, § 6.1 shows that the false negative rate of ServiceLab is acceptable.

Fourth, the business and performance metrics logged by the SUT are kept separately from those generated by its counterpart in production. This ensures that the analytics for these metrics do not interfere with each other.

In summary, ServiceLab provides tools to assist service owners in managing service dependencies during test environment setup but does not offer complete isolation out of the box. As a result, some complex services (e.g., MySQL) are not tested in ServiceLab. They either use a specialized test environment or conduct canary tests directly in production by deploying new code to some instances of the production service and comparing those instances with the rest. Despite its limitations, ServiceLab is successful as a general-purpose testing platform, covering more than half of the total code changes by all services and surpassing the combined coverage of all other specialized testing platforms.

6 Production Experience

During its steady state, ServiceLab constantly leverages tens of thousands of machines to test hundreds of services and hundreds of ML models. We use production data to answer the following questions:

1. What are the statistics for different use cases (e.g., regression thresholds, number of trials, etc.)?
2. What are the false positive and false negative rates of ServiceLab?
3. How much regression did actually ServiceLab prevent?

6.1 Testing FrontFaaS

As FrontFaaS is our largest programming platform and has more code changes than other services, we report its statistics separately. ServiceLab has been running for FrontFaaS for over 5 years in production. It has a regression threshold as low as 0.01%, and by default, it runs 25 trials in each experiment. On average, developers made over 100,000 FrontFaaS changes per month. ServiceLab ran at least one experiment on 23% of those changes during that period. Leaving out 77% showcases the importance of ServiceLab's DiffSuggester in reducing the machine capacity needed for testing. For the code changes tested by ServiceLab, ServiceLab signaled performance regressions on 0.3% (5,560) of those changes.

ServiceLab assigns regression tickets to developers, and we calculate ServiceLab's accuracy based on the developers' actions in these tickets. We classify a signaled regression as a true positive if the developer fixed the issue or marked the issue as "*expected*," perhaps due to a new product feature requiring more resources. We classify it as a false positive if the developer identified it as such. If the developer did not provide a clear answer, we classify the regression as unknown. Among all signaled regressions, 57% (3,173) are true positives, 15% (823) are false positives, and 28% (1,564) are unknown. Assuming the unknowns have the same false positive rate as others, the overall false positive rate is about 21%.

Although the false positive rate of 21% may seem high initially, it actually signifies a significant success of ServiceLab because FrontFaaS uses a very low regression threshold, 0.01%. Out of all FrontFaaS diffs submitted by developers, only 0.014% experience a false positive flagged by ServiceLab, calculated as $23\% \times 0.3\% \times 21\% = 0.014\%$. Assuming a developer writes one diff per day, they will experience a false positive about once every 20 years! While promoting the adoption of ServiceLab, we learned that the per-developer experience significantly affects whether developers ignore the regression tickets assigned by ServiceLab. If a developer frequently receives false-positive tickets, they are likely to ignore them after repeated futile investigations. Conversely, if they receive a false-positive ticket only once every 20 years, they will likely always take ServiceLab regression tickets seriously and investigate them. The good developer experience even at a very low regression threshold of 0.01% demonstrates the robustness of ServiceLab's statistical methods.

Figure 3 shows the distribution of the level of regression of those true positive cases. The median value (p50) is 0.14%, p90 is 1.7%, and p99 is 38.7%. Summing them together, they account for 12284% of regression over five years. Since very large regressions are often caused by experimental purposes, if we only sum those causing less than 1% regression, they account for 545% of regression, which translates to over 2 million machines (i.e., 545% × the number of machines used by FrontFaaS). This shows that ignoring small regressions is not acceptable, as they will accumulate to a large number over time. That is why FrontFaaS uses a strict threshold.

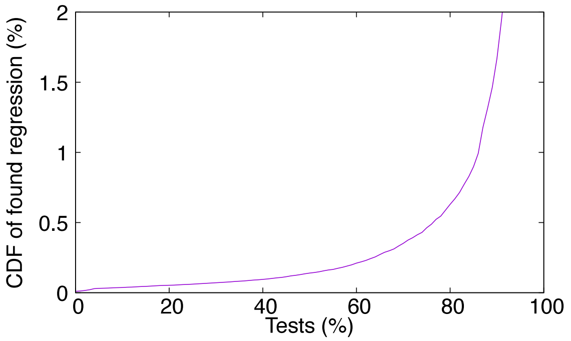

Figure 3: Cumulative distribution of regressions detected by ServiceLab for FrontFaaS.

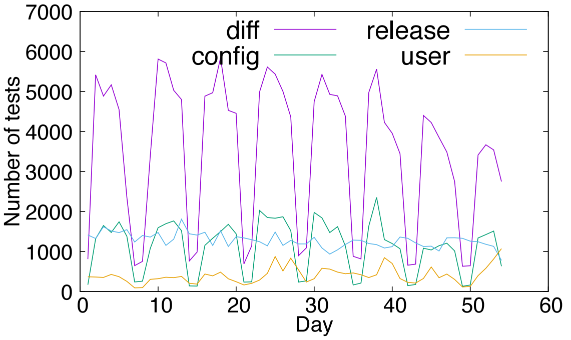

Figure 4: Number of experiments completed each day.

To approximate the false negative rate, we rely on reports from in-production monitoring of performance changes. FrontFaaS has a production monitoring system that examines the per-function CPU usage of functions and raises a signal if it detects a performance regression. It then attempts to triage the performance regression to a code change. Out of all changes, 0.02% (2038) of changes were found to cause regressions but have been missed by ServiceLab, leading to a false negative rate of 32%, calculated as $\frac{2038}{2038+5560\times(1-21\%)}$. However, this number should be viewed with caveats because 1) there are potential performance regressions that cannot be root-caused to their original changes, which are not included in this number, and 2) there is no guarantee that the production monitoring system is fully accurate.

In summary, despite FrontFaaS' low threshold of 0.01%, ServiceLab achieves a reasonable false positive rate and false negative rate, and helps us prevent a significant amount of regressions, which could accumulate over years.

6.2 Testing Other Services

While FrontFaaS is reported in its own category, in this section, we report the aggregate statistics for all non-FrontFaaS services in one category. Figure 4 shows the number of ServiceLab experiments completed each day for non-FrontFaaS services. The majority of completed experiments are run automatically as part of code changes, configuration configs, or service releases. ServiceLab supports a total of 483 distinct use cases, and their breakdown is shown below. Note that ServiceLab also tests hundreds of distinct ML models, which are counted as a single use case.

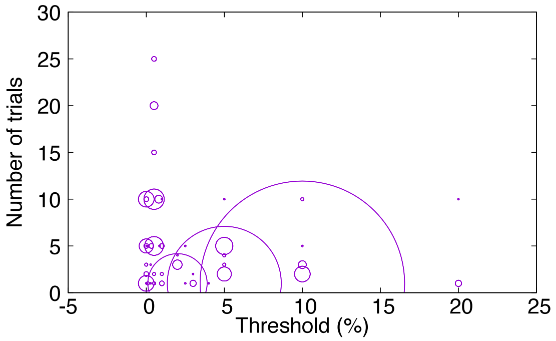

Figure 5: Thresholds and number of trials. The size of the circle represents the count of use cases with the same setting.

- 44% (N=211) of the use cases have experiments that automatically run on code diffs.
- 15% (N=74) run automatically on code commits.
- 21% (N=100) run automatically on configuration changes.
- 22% (N=107) run as part of their release process.

The distribution of the number of trials in experiments is as follows: p50=1, p90=10, p99=10, and p100=25. The distribution of the execution time of trials is as follows: p50= 2,820 seconds, p90= 4,200 seconds, p99=p100=259,200 seconds. Among the 483 use cases, 413 have defined a relative threshold on some metric; 5 have defined an absolute threshold on some metric; the remaining ones do not define any threshold. We focus on the 413 cases with a relative threshold in the following discussion.

Each use case may contain multiple metrics with different thresholds. Since the number of trials and trial duration are usually determined by the strictest threshold, we define the threshold of a use case as the smallest threshold among all its metrics. 23% of the use cases have a threshold smaller than 1%, while p50=5%, p90=10%, and p99=20%. This, once again, emphasizes the importance of using small thresholds.

Figure 5 plots the threshold and the number of trials used by different use cases. A circle in this figure represents the count of use cases using a specific setting. This figure shows that a large number of use cases use a relaxed threshold of 5% or 10% with only one trial, but a small number of use cases use a very small threshold with up to 25 trials. This small subset includes many of the largest services.

Services often run preliminary experiments with a large number of trials to determine how many trials are needed to achieve a certain confidence interval in regression detection. Specifically, they run multiple trials of A/A tests, compute the difference between each pair of A/A test (i.e., $\frac{A'-A}{A}$), and then determine the confidence interval (i.e., 95% within two standard deviations assuming normal distribution). Figure 6

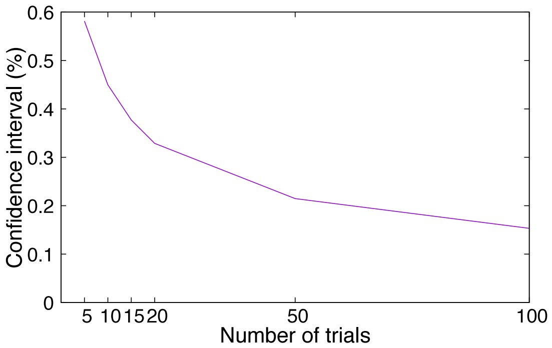

Figure 6: The number of trials required for detecting small regressions.

shows, for one service, how the confidence interval decreases with more trials. Users can then decide the number of trials according to their required confidence interval.

We examine how often ServiceLab signals a regression on code changes during the 54 day period shown in Figure 4. During this time, 15,058 code changes were tested and ServiceLab signaled on 2,742 (18.5%) of those code changes with at least one metric crossing its configured threshold. For non-FrontFaaS services, ServiceLab reports on a diverse set of metrics. Across these code changes, 2,714 different metrics were considered as significant. 80% of the signaled metrics had a threshold of less than 2%. Unlike the uniform FrontFaaS platform used by over ten thousand developers, for these 413 diverse use cases, there are no uniform tools and hence no clear marking about whether a reported regression is a true or false positive. In subsequent sections, we will present some examples with these use cases to understand their impact.

6.2.1 Example of True Positives

ServiceLab helps non-performance experts understand the performance implications of their code. For example, consider one case where ServiceLab successfully detected and prevented a CPU performance regression in XFinder (§3.5) before the change landed in production.

In the change, the developer inadvertently copied a large data structure when introducing a new function. The ServiceLab experiment that ran for this change detected a significant CPU regression of around 20%. ServiceLab flagged this change to both the developer and performance engineers working on XFinder. The developer was working on a product feature across multiple services, and was neither familiar with the XFinder codebase nor C++. After ServiceLab flagged the regression, the developer applied a fix by adding `const` when passing the parameter to the function, eliminating the memory copy of the data structure.

In another incident involving the Ranker service (§3.6), a change increased the service's memory usage by 50%. The change involved enabling a new ranking library that increased memory usage due to loading additional ranking configurations. The increase in memory was expected due to the additional functionality; however, the amount of increased memory was not. ServiceLab detected the memory regression before a release deployment. In this case, the developer who included the additional ranking library knew that there would be an added resource cost. However, ServiceLab helped the developer and service owners understand the resource cost of the regression before deployment. The developer reverted the change and found optimizations to minimize the use of the ranking library by excluding unused ranking configurations.

6.2.2 Example of False Positives

In another incident, a ranking service using ServiceLab occasionally experienced high rates of false positives due to a production issue with a downstream dependency. A production misconfiguration led to imbalanced load among the machines in the downstream service. During experiments, some of the SUTs would send requests to these overloaded instances of the downstream service. The queuing resulting from those overloaded downstream instances affected the performance measurement in ServiceLab, resulting in false positives. To remediate this issue, the production routing configuration that led to the imbalanced load was fixed. This remediated the load imbalance issue in production and also eliminated the false positives in ServiceLab.

6.2.3 Examples of False Negatives

False negatives are incidents where ServiceLab does not report a regression but a regression actually occurs. These cases are often reported by service owners. In one incident with XFinder (§3.5), a developer was implementing a new feature to read from an online classifier instead of an offline classifier. The change introduced a new function call making use of the new classifier to better classify the type of ads to return. The change resulted in an increase of 0.62% in the total capacity used by XFinder. ServiceLab failed to report a regression for this change since this regression only applied to a subset of request types, and those types were not represented in the set of requests replayed in the experiment. Those request types were newly added after the request trace was captured.

6.2.4 Summary

In our experience, the top reason for false positives is that another event, such as another test or deployment either in the SUT or in the downstream services, is happening concurrently with a ServiceLab test, which will disrupt the result of the ServiceLab test. The top reason for false negatives is that a newly introduced feature is not tested since the requests for replaying were recorded when this feature does not exist.

6.3 False Positive in A/A Experiments

As described in § 4.2, periodic A/A experiments provide an empirical measurement of whether a metric would be considered significant with the same experiment inputs. Periodic A/A experiments run every two hours and test for statistically significant differences without considering any signaling thresholds. Over a two-month period, we examined 6,783 metrics from A/A experiments where signaling was enabled. Among these 6,783 metrics, the p50, p90, and p99 metric had a false positive rate of 0.6%, 40%, and 64%, respectively. This signifies the inherent variance in the services and the test environment. It also emphasizes the importance of our method of using results from A/A experiments to help select the best statistical model for each service (§4.2).

6.4 Key Takeaways

We have learned several key lessons from our experience of operating ServiceLab over seven years. Initially, the ServiceLab team maintained a dedicated pool of identical physical machines for testing to reduce performance variance. However, as ServiceLab adoption increased, we had to switch to using heterogeneous cloud machines. This change was driven by the high maintenance burden of a dedicated machine pool and the lower cost of running some tests using the cloud's elastic capacity.

Testing a wide range of services is a key design goal for ServiceLab. To achieve this, unlike traditional systems that aim for completely isolated and reproducible environments, ServiceLab allows Systems Under Test to call external dependent services that handle live production traffic. This approach significantly broadens the scope of services that ServiceLab can test, accommodating those with complex interdependencies that are too intricate or costly to replicate fully in a test environment. Moreover, ServiceLab is extensible and allows for developer customizations, recognizing that a one-size-fits-all approach would fall short in supporting diverse services. For example, while traffic record-and-replay simplifies test setup, some services face strict time constraints for replay, and others choose to use synthetic traffic.

7 Related Work

Performance Variance. Performance variance is a well-known issue for performance experiments and reproducibility, especially when the performance of two versions to compare is close. There are multiple lines of work in this direction: 1) some works mitigate the problems by re-designing systems [9, 16, 21, 25, 45, 51, 60], tuning configuration parameters [37, 39, 59, 64], or changing hardware [40, 58, 63]. 2) Some works try to detect machines that are significantly slower than others [19, 23, 28, 29, 43], so as to exclude such outlier machines from performance experiments. We also run routine performance tests to filter those outlier machines. 3) Some works propose statistical methods for performance comparison [26, 31, 40].

The closest work is the study by Maricq et al. on performance variance in CloudLab [40]. ServiceLab differs from the CloudLab study in several ways. First, the CloudLab study assumes repeated experiments are run on the same or identical machines, whereas ServiceLab identifies heterogeneous machines with comparable performance to run experiments in parallel. Second, the CloudLab study focuses on the number of experiments needed to achieve a certain confidence interval, whereas ServiceLab addresses the problem more holistically, using an ensemble of statistical models, A/A tests, and artificial A/B tests. Finally, the CloudLab study only runs microbenchmarks in a single-machine environment, whereas ServiceLab must be robust enough to work in real-world scenarios with full services and complex interdependencies.

Performance Testing. Synthetic benchmark [14, 41, 46, 50, 55] and record-and-replay [1–3] are two primary methods for performance evaluation. ServiceLab supports both but primarily uses record-and-replay due to its high fidelity in testing real applications.

Treadmill [61] and TailBench [32] overcome several common pitfalls of performance testing frameworks with synthetic traffic, allowing them to precisely measure at microsecond-scale. Lancet [33] incorporates online statistical tests to ensure the obtained measurements are statistically sound. Primorac et. al. leverage kernel-bypass networking and advanced NIC features to further improve the precision of microsecond-scale tail latency measurements [44].

Performance data from Google's gmail [7] shows that workloads change constantly, both QPS and response size. Hence we need to do real production traffic record and replay. Recent studies including Kraken [56] and WSMeter [35] directly utilize production traffic to carry out the performance tests, to address the limitation of synthetic benchmarking in how accurately they can reproduce the complex production environment. Similarly, deterministic record and replay are commonly leveraged to reduce the non-determinism to simplify multiprocessor software development and testing, which can be done at multiple levels (e.g., virtual machine-level [20], OS-level [8], and library-level [24]).

8 Conclusion

We have presented ServiceLab, which tests a large, diverse set of applications to catch small performance regressions. It selects similar but non-identical machines for testing and learns the best statistical model for each service. During seven years of production, ServiceLab has helped us prevent a significant amount of regression, which could accumulate over time if not detected promptly.

Acknowledgments

This paper presents over seven years of work by past and current members of several teams at Meta, including ServiceLab, HHVM, Ads, Release Engineering, and Instagram. In particular, we would like to thank those who have contributed to ServiceLab and this paper: Matt Meyers, Elena Mironova, Yun Jin, Harish Dattatraya Dixit, and Gautham Vunnam. We also thank all reviewers, especially our shepherd, Atul Adya, for their insightful comments.

Abstract

In public clouds, users must manually select a datacenter region to upload their ML training data and launch ML training workloads in the same region to ensure data and computation colocation. Unfortunately, isolated decisions by individual users can lead to a mismatch between workload demand and hardware supply across regions, hurting the cloud provider's hardware utilization and profitability. To address this problem in Meta's hyperscale private cloud, we provide a global-scheduling abstraction to all ML training workloads. Users simply submit their training workloads to MAST, our global scheduler, and rely on it to intelligently place both data and training workloads to different regions. We describe three design principles that enable MAST to schedule complex ML training workloads at a global scale: temporal decoupling, scope decoupling, and exhaustive search. MAST successfully balances the load across global regions. Before MAST, the most overloaded region had a GPU demand-to-supply ratio of 2.63 for high-priority workloads. With MAST, this ratio has been reduced to 0.98, effectively eliminating the overload.

1 Introduction

The success of ML applications [8, 46] has resulted in ML training becoming the fastest-growing datacenter workload. Public cloud providers run ML training workloads in multiple geo-distributed datacenter regions [3,4,15] to ensure sufficient capacity. Accordingly, users need to manually select a region to upload their ML training data and then launch training workloads in the same region to ensure colocation of data and computation. Unfortunately, such manual selection can lead to a regional mismatch between workload demand and hardware supply. For instance, one region may exhaust its capacity, accumulating a long queue of pending jobs, while another region has surplus capacity remaining idle.

Meta's private cloud used to experience this load imbalance. It comprised tens of datacenter regions, millions of machines, and tens of thousands of GPUs. Similar to public clouds, users initially had to manually select regions to store training data and launch workloads. Users' suboptimal decisions previously led to an imbalance in the GPU demand-to-supply ratio, reaching as high as 2.63 in certain regions for high-priority workloads, which was later reduced to 0.98 through optimizations described in this paper.

While much research has been conducted on scheduling ML workloads in a single cluster [1, 2, 5–7, 9, 13, 17, 21, 23–25, 30, 31, 33–35, 39, 40, 45, 49, 51–54, 57, 59], there has been little effort to address the issue of regional mismatch between workload demand and hardware supply. To address this challenge, our private cloud has introduced the *global-scheduling* abstraction that shields users from the complexity of regions. With the global-scheduling abstraction, users simply submit their ML training workloads to our global scheduler called MAST (short for ML Application Scheduler on Twine [44]) and rely on it to intelligently place both training data and workloads into different regions.

To provide the global-scheduling abstraction, MAST faces two major challenges:

- *Data-GPU colocation*: Without careful coordination, there is a risk of location mismatch between GPUs and data. For instance, one region may have the necessary training data but run out of available GPUs, while another region may have available GPUs but lack the required training data. Due to the massive volume of training data and the limited cross-region network bandwidth, on-demand cross-region data migration can be both costly and time-consuming.
- *Scalability*: MAST allocates not only GPU machines for training but also CPU machines for data preprocessing [58]. As CPU machines may be dynamically reassigned across ML and non-ML workloads based on demand, conceptually, MAST needs to find machines to run ML workloads out of millions of machines spread across tens of regions. Global resource allocation at this scale has not been studied before.

Contributions: Chunqiang, Kutta, and Tuomas initiated the MAST project in 2020. In terms of paper writing, Yang wrote the majority of the paper, followed by Chunqiang. In terms of coding, Arnab, Kutta, and Tuomas led the project's development at different times. All other authors also made major contributions to the project's development.

We leverage three principles to address these challenges: *temporal decoupling*, *scope decoupling*, and *exhaustive search*. We elaborate on these principles below.

Temporal decoupling. We divide the scheduling responsibilities into two paths: a fast path for real-time job scheduling and a slow path that continually optimizes data and machine assignment in the background. The slow path intelligently replicates ML training data across regions, enabling the fast path to more easily colocate computation with data. Despite the relaxed timing, cross-region data placement remains very challenging. It requires continuous optimization of the placement of billions of data partitions across tens of geo-distributed regions, considering per-region capacity constraints and the data access pattern of millions of daily ML training jobs and analytics jobs from Spark [55] and Presto [42].

We model data placement as a mixed integer programming (MIP) problem, and the scarcity of GPUs drives novel decisions in our solution. Due to the high cost and demand of GPUs, we target maximizing GPU utilization. Imposing a hard constraint in the MIP problem that GPU demand must be lower than GPU supply in every region, as in prior work [20] for CPU and storage, often renders the problem unsolvable. Instead, MAST allows GPU oversubscription and preempts low-priority jobs as needed. This approach mandates a reassessment of the objective function and constraints in the MIP problem, not only for GPU-related terms but also for other resources that GPUs depend on. We share insights gained from multiple iterations refining the MIP problem through production experience (§3).

To tackle the scalability challenge, as illustrated in Figure 1, MAST adopts a three-level scheduling hierarchy: Global ML Scheduler (GMS)→Regional ML Scheduler (RMS)→Cluster Manager (CM). In addition to managing data placement, the slow path also helps scale RMS by constraining its search for available machines. It dynamically pre-assigns machines to *dynamic clusters*, allowing RMS to only search through machines within the ML dynamic clusters and disregard non-ML dynamic clusters.

Scope decoupling. A job scheduling system has three main responsibilities. First, it manages the job queue, which entails queuing and prioritizing jobs when there are insufficient resources to run all jobs. Second, it handles resource allocation, which involves computing bin-packing-like solutions by modeling machines as bins and tasks as objects. Third, it manages container orchestration, which executes the bin-packing plan, runs containers, and monitors their health. Traditional systems [19, 47, 48, 56] handle all these responsibilities within the same scope, i.e., within a cluster.

Our key insight is that sharing the same scope for all three responsibilities unnecessarily limits scalability, reducing the potentially larger scopes of job queue management and resource allocation to the minimal scope of container orchestration. Note that container orchestration is the least scalable due to its heavy duties and, consequently, has the smallest scope.

In contrast, as shown in Figure 1, our *scope-decoupling* principle allows the three responsibilities to operate at different scopes: (1) the job queue is managed by GMS at the global scope, covering all pending jobs for all regions; (2) resource allocation is managed by RMS at the regional scope, taking into account all machines in a region's ML dynamic clusters; and (3) container orchestration is managed by the CM at the smallest dynamic-cluster scope. This approach allows job queue management and resource allocation to operate at bigger scopes to minimize stranded resources and optimize job placement. A key challenge is to make GMS and RMS sufficiently scalable to operate at their bigger scopes, which is further discussed in §4.2.1 and §4.3.1.

Exhaustive search. Existing systems [10, 20, 28] often adopt the federation approach to scale out. When a new job arrives, the Federation Manager employs simple heuristics to assign the job to the least loaded cluster, and then its cluster manager manages all subsequent operations, including job queuing, resource allocation, and container orchestration. However, as ML training clusters are almost always fully utilized, scheduling a new job often requires a complex decision to preempting existing lower-priority jobs. This complexity makes the simplistic federation approach less effective.

Our key insight is that, unlike short-lived analytics jobs [10, 38, 41, 50], ML training jobs often run for extended periods on expensive GPUs. Therefore, instead of searching just one cluster to allocate resources hastily, it is beneficial to conduct an *exhaustive search* across all relevant clusters for higher quality placement. As depicted in Figure 1, MAST's multiple RMSs can concurrently compute resource allocation plans for one job in different regions, with the optimal plan determined through a final auction process. A key hurdle is ensuring the scalability of RMS, which is discussed in §4.3.1.

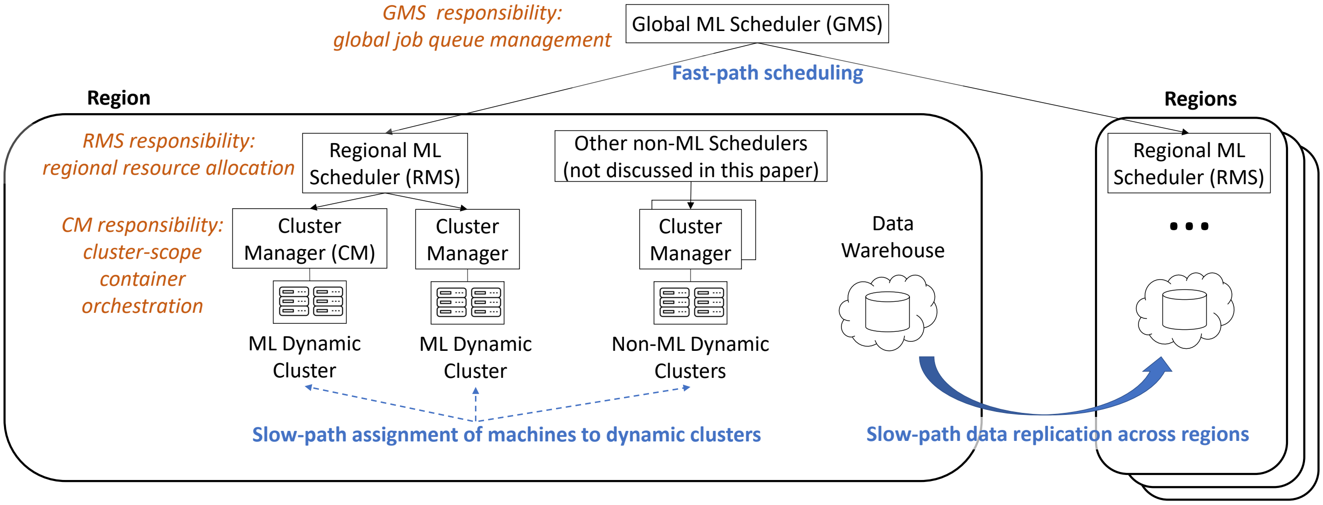
Contributions. We make the following contributions.

- We propose the *global-scheduling* abstraction to shield users from the complexity of geo-distributed datacenters and improve hardware utilization through joint placement of data and training workloads across regions.
- We propose three principles–*temporal decoupling*, *scope decoupling*, and *exhaustive search*–to achieve high-quality data and computation placement in a scalable manner.
- We demonstrate the effectiveness of global ML scheduling through our hyperscale deployment of MAST and validate its design using production data.

2 Background of ML Training at Meta

In this section, we provide the necessary background to set the stage for future discussions.

Datacenter and hardware. Our private cloud comprises tens of regions and millions of machines. A region comprises



GMS responsibility:
global job queue management
Global ML Scheduler (GMS)
Fast-path scheduling
Region
Regions
RMS responsibility:
regional resource allocation
Regional ML Scheduler (RMS)
Other non-ML Schedulers (not discussed in this paper)
Regional ML Scheduler (RMS)
CM responsibility:
cluster-scope container orchestration
Cluster Manager (CM)
Cluster Manager
Cluster Manager
Data Warehouse
ML Dynamic Cluster
ML Dynamic Cluster
Non-ML Dynamic Clusters
Slow-path assignment of machines to dynamic clusters
Slow-path data replication across regions

Figure 1: Conceptual architecture of MAST. Global ML Scheduler (GMS), Regional ML Schedule (RMS), and Cluster Manager (CM) handle different scheduling responsibilities at different scopes: global, regional, and cluster, respectively.

multiple datacenters that are close to one aother. The cross-region network bandwidth is about 10 times lower than the bisection bandwidth between datacenters within a region. Parts of a datacenter are occupied by ML training clusters, with machines equipped with multiple GPUs and connected by both 8x200Gbps RoCE network and 4x100Gbps Ethernet.

ML training is data intensive and prefers colocating the compute and data of a training workload. For tasks that belong to an ML training workload, we prefer to place them in the same rack, cluster, datacenter, and region, in that order. Separating the compute and data across regions or placing tasks in different regions would result in unacceptable performance.

Historically, datacenter hardware has been procured incrementally depending on the specific needs at different times, resulting in uneven distribution of hardware types across regions. This is discussed in Flux [11] and also shown in Figure 2. This disparity makes colocation of data and compute difficult, requiring global optimization. For example, since *Region6* is short of GPUs, it is better to place data used by CPU-based analytics jobs in *Region6*. If a few GPU-based ML training workloads share the same data as those analytics jobs, we should schedule them in *Region6* as well. However, if there are too many such ML workloads, we will have to replicate their data to other regions and execute them there.

Dynamic clusters. As shown in Figure 1, a slow-path component called RAS pre-assigns machines to *dynamic clusters*, which are known as "*reservations*" in the RAS paper [36]. This enables the Regional ML Scheduler (RMS) to scale by searching only through machines that are within the ML dynamic clusters. Typically, an ML dynamic cluster comprises both GPU and CPU machines. To update dynamic clusters, RAS takes as inputs all machines in a region and the new or updated specification for each dynamic cluster's intended size and preference for certain hardware types. RAS formulates a MIP problem to allocate machines to dynamic clusters. MAST consumes the outputs of RAS (i.e., the dynamic clusters created by RAS), and MAST's scheduling decisions do not influence or feed back into RAS.

We provide a brief summary of RAS and refer readers to the RAS paper [36] for details. RAS ensures that the total machine capacity allocated to a dynamic cluster meets the requirements specified by administrators and includes sufficient buffers to handle both random and correlated machine failures. Correlated failures, such as power outages in large fault domains within a datacenter, can render tens of thousands of machines unavailable. RAS distributes a dynamic cluster's machines across different fault domains to ensure that sufficient healthy machines remain available when a large fault domain fails. Additionally, RAS reduces unnecessary cross-datacenter communication by ensuring a proper ratio of compute machines to storage machines in each datacenter. Finally, RAS reruns its optimization periodically (e.g., every 30 minutes) to adapt to changes. For example, when new datacenters are brought online, RAS can reduce the buffer size needed for handling correlated failures by further spreading out a dynamic cluster's machines into these new datacenters.

ML training workload. A training workload comprises multiple heterogeneous jobs, each job comprises multiple homogeneous tasks, and a task is mapped to a Linux container. Therefore, the hierarchy is workload→job→task. For example, a training workload may comprise (1) a training job that executes back-propagation training; (2) a data-preprocessing job [58]; (3) a parameter-server job; and (4) an evaluator job that evaluates the generated model. A workload's all tasks need gang scheduling, i.e., they must be allocated together. If a training job uses less than a full GPU, in theory, the GPU can be shared by multiple jobs using Multi-Instance GPU (MIG) [37] or other software approaches. In practice,

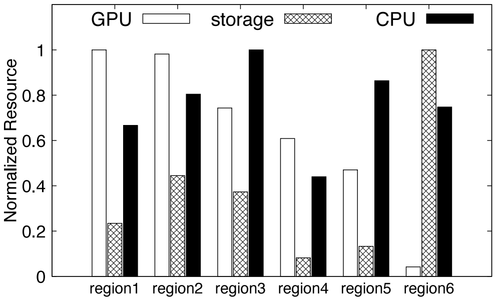


Figure 2: Uneven distribution of hardware across regions. Storage is normalized by capacity, and GPU and CPU are normalized by server count.

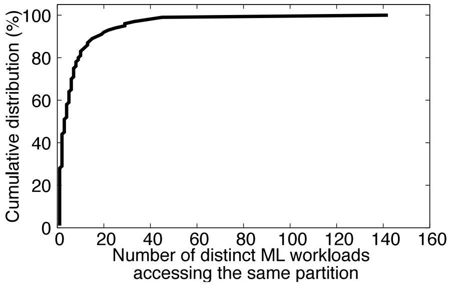

Figure 3: Hotness of data partitions, measured by the number of distinct ML workloads accessing each partition.

however, all our training jobs use at least one full GPU due to the large amount of training data.

Data warehouse. Our data warehouse stores exabytes of data in a three-level hierarchy: hundreds of namespaces→millions of tables→ billions of data partitions. A partition is immutable once created, but new partitions can be added to an existing table. For example, every day, the "*user_activity*" table can add a new partition to record user activities in the past 24 hours. Some data partitions are simultaneously used by ML training and data analytics, such as Spark [55] and Presto [42]. We have developed a system called Tetris, which optimizes data placement across regions, taking into account the data-access patterns of Spark, Presto, and ML training jobs.

Sharing of data partitions by workloads. Figure 3 shows that data partitions are often shared by multiple ML workloads. At the P50, P90, and P99 percentiles, a data partition is shared by 3, 17, and 45 distinct workloads, respectively. Data sharing complicates the problem of data placement, as migrating one data partition across regions may require the migration of multiple workloads dependent on the partition. Furthermore, it is necessary to replicate the hottest partitions across multiple regions to prevent load imbalance, as a large number of workloads dependent on those partitions will otherwise be forced to run in a small number of regions.

Long execution time of ML training jobs. ML training is resource intensive and can take a long time to finish. At Meta, ML training workloads often take 10 times longer to finish than Spark [55] analytics jobs. Therefore, a suboptimal placement decision has a bigger negative impact on ML training. This motivates the *exhaustive search principle* described in §1. Moreover, when workloads run longer on a larger number of machines, the workload scheduling throughput decreases. Therefore, as shown in Figure 1, it is feasible to manage the job queue and resource allocation at the global and regional scope, respectively, rather than at the smaller cluster scope that leads to more fragmentation.

Quota and job preemption. Training workloads with different priorities are assigned capacity quotas per priority level. If a team's capacity usage is within their quota, MAST guarantees starting their training workloads within a certain latency. Once a team exceeds their quota, they can still submit workloads to run opportunistically at the lowest priority, subject to preemption when a higher-priority workload arrives. Consequently, training clusters are always fully utilized due to low-priority workloads for experimental purposes. Scheduling a new workload often involves a complex decision to preempt lower-priority jobs. This complexity renders a simple Federation Manager less effective.

Checkpoint for recovery. A training workload periodically checkpoints its state. When a machine fails, the cluster manager restarts its workload on a replacement machine, allowing it to recover its state from the checkpoint and resume execution. Before preempting a low-priority workload for a high-priority one, it also saves a checkpoint for later restoration. As we continuously reduce the time needed to save a checkpoint, we are moving towards more frequent checkpoints to minimize the amount of lost work between two checkpoints during recovery. This has become increasingly important as the size of training workloads for large-language models keeps growing, and recovery becomes more costly.

Separate application-level schedulers for ML and non-ML workloads. As depicted in Figure 1, ML and non-ML workloads are managed by distinct schedulers. The extensible architecture of Twine [44] allows all workloads to share a common cluster manager for machine and container management, while employing different application-level schedulers for specific workloads. For instance, MAST is used for ML training workloads, Shard Manager [29] for stateful databases, Turbine [32] for stream processing, and Chronos for analytics jobs. Each of these application-level schedulers is optimized for a specific purpose. Shard Manager, for example, is optimized for high database availability, Chronos for high scheduling throughput of short-lived analytics jobs, and MAST for high-quality decisions and data-GPU colocation.

3 Slow-path Data Placement

To enable global ML scheduling, it is crucial to have both the necessary hardware and training data for an ML workload available in certain datacenter regions simultaneously. Following the *temporal-decoupling* principle, MAST optimizes cross-region data placement on a daily basis using a slow-path component called Tetris, which determines data placement and replication for the underlying storage system. Given that data analytics (e.g., Spark [55] and Presto [42]) and ML training can concurrently access the same data, Tetris jointly optimizes data placement for them. The entities accessing the data, such as Presto queries, Spark jobs, and ML workloads, are collectively referred to as "*jobs*" for simplicity.

3.1 Context of Data Placement

Recall that our data warehouse uses a three-level hierarchy: hundreds of namespaces→millions of tables→billions of data partitions. The large number of data partitions presents a significant scalability challenge for data placement. To improve scalability, Tetris determines data placement in two steps: first by placing tables to regions, which means that all partitions of a table must reside in the same region; and then by placing partitions to data centers within each region. Since the algorithms for both steps are similar, we mainly present the table-to-region placement algorithm.

Each table has a home datacenter region, which is where its new data is generated. Subsequently, the table may be replicated to other regions for various purposes. If an ML job takes a table as input, then at least one of the table's regions should have the types of GPUs required by the job. We refer to this property as "*data-GPU collocation*." Due to the large size of our data warehouse (exabytes) and limited cross-region network bandwidth, replicating data takes time. Consequently, a table's replicas in other regions are more stale compared to those in the home region. Therefore, high-priority jobs requiring fresh data must run in the home regions of their input tables, and these home regions must have the types of GPUs required by those jobs. We call this property "*training-at-home-region*." For low-priority jobs, *training-at-home-region* is preferred but not required.

Tetris first determines the home region of each table and then determines replica regions. We are still evaluating the feasibility of determining both simultaneously. While it may result in improved placement, currently we find its computational cost to be too high.

To plan data placement, Tetris requires the usage information of each job's input tables, hardware needs, and estimated runtime. High-priority training jobs, with trained models deployed for immediate production use, are typically retrained daily or more frequently with updated data. The usage information of such recurring jobs rarely changes, so Tetris can derive this information from their historical data. Tetris does not predict usage information for new training jobs that show up for the first time. Instead, MAST's fast-path online scheduling manages first-time jobs upon submission. If no region has both the necessary data and hardware to run a first-time job, MAST will initiate data movement and wait for its completion before scheduling the job. However, many first-time jobs benefit directly from data placement plans for recurring jobs and will not be blocked on data replication, as jobs from the same team frequently share input tables and require the same types of hardware. For instance, multiple one-time experimental jobs are often submitted to fine-tune a parameter of a production recurring job. Our production data in §5 shows that although about 70% of the jobs are first-time jobs, only a small fraction of them trigger on-demand data movement. Note that on-demand data movement may also be triggered due to failures or in rare cases where a recurring job changes its input tables or hardware needs.

3.2 Problem Formulation Overview

We formulate home-region placement as the mixed-integer programming (MIP) problem shown in Figure 4. While MIP has been applied in resource allocation [11, 20], the key insights often lie in the details of a specific problem formulation. In Tetris, we need to carefully evaluate various approaches for resource allocations:

- The *hard-quota* approach mandates that resource demand must stay below supply in every region.
- The *hard-balance* approach does not enforce *hard-quota* but mandates that the overload situation (i.e., demand above supply) must not deteriorate for any region due to a new placement.
- The *soft-balance* approach does not enforce *hard-quota* or *hard-balance* but instead aims to balance the demand-to-supply ratio across all regions as much as possible.

After iteratively improving Tetris based on production experiences, we have learned that different resource types require different approaches. For GPUs, imposing hard constraints in the MIP problem, as in previous work for CPU and storage [20], often renders the problem unsolvable due to the scarcity of GPUs. Hence, we adopt the *soft-balance* approach and preempt low-priority jobs to accommodate high-priority jobs as needed. Specifically, we introduce a penalty if a region's GPU demand deviates from the ideal case where all regions' GPU demand-to-supply ratios are the same. In our initial implementation, the situations of overload and underload were penalized equally. However, in practice, overload is more problematic as it causes longer wait times for the impacted jobs. Therefore, our current implementation more severely penalizes overload.

For storage space, the *hard-quota* approach is necessary because we cannot delete data when demand exceeds supply. However, *hard-quota* alone is insufficient, as an imbalanced data distribution across regions may occur, leading to GPUs in some regions being bottlenecked on I/O bandwidth to access the data. Therefore, we also apply *soft-balance* to storage. In the past, we also experimented with using *hard-balance*, but it proved ineffective as it completely prevents moving data from a region to another region with a higher demand-to-supply rate, which is sometimes necessary for other goals.

Concretely, our MIP problem formulation aims to achieve the following soft goals:

1. Minimize cross-region traffic for reading data during training (Expression 1).
2. Balances the demand and supply of GPUs across regions (Expression 2).
3. Balances the demand and supply of storage space across regions (Expression 3).

In addition, it aims to meet the following hard constraints:

4. Each region has sufficient storage space for the tables it stores (Expression 4).
5. Each application's CPU usage does not exceed its quota (Expression 5). Here, applications refer to those generating data for or sharing data with ML training, such as analytics jobs. An application may comprise multiple jobs.
6. The demand of jobs satisfying the training-at-home-region property remains above a certain threshold (Expression 6).

3.3 Problem Formulation Details

This section can be safely skipped during the initial reading, as it mainly details the problem formulation.

Minimize:

$$w_1 \sum_{\text{job}_j} \sum_{\text{table}_i \in \text{job}_j} \text{size}(\text{table}_i)\ \left[1 - I(R(\text{job}_j), R(\text{table}_i))\right] \tag{1}$$

$$+ w_2 \sum_{\text{region}_i} \sum_{\text{GPU}_j} \sum_{P_k} w_{p_k} \sigma_1(\text{Demand}^{\text{region}_i}_{\text{GPU}_j, P_k}, \text{Supply}^{\text{region}_i}_{\text{GPU}_j}) \tag{2}$$

$$+ w_3 \sum_{\text{region}_i} \sigma_2(\text{Demand}^{\text{region}_i}_{\text{storage}}, \text{Supply}^{\text{region}_i}_{\text{storage}}) \tag{3}$$

Subject to:

$\forall \text{region}\ \ r$

$$\sum_{\text{table}_i} \text{size}(\text{table}_i)\ \ I(R(\text{table}_i), \text{region}_r) < \text{storage\_capacity}(r) \tag{4}$$

$$\forall \text{app} \sum_{\text{job}_j \in \text{app}} \text{CPU}(\text{job}_j)\ \ I(R(\text{job}_j), \text{region}_r) < \text{CPU\_capacity}(\text{app}, r) \tag{5}$$

$$\sum_{\text{high-priority job}_j} \text{GPU}(\text{job}_j) I(\text{GPU-Type}_{\text{job}_j}, R(\text{job}_j)) \geq \text{threshold} \tag{6}$$

Where:

$$\sigma_1(\text{Demand}^{\text{region}_i}_{\text{GPU}_j, P_k}, \text{Supply}^{\text{region}_i}_{\text{GPU}_j}) =$$

$$\left(\frac{\text{Demand}^{\text{region}_i}_{\text{GPU}_j, P_k}}{\sum_{\text{region}_i} \text{Demand}^{\text{region}_i}_{\text{GPU}_j, P_k}} - \frac{\text{Supply}^{\text{region}_i}_{\text{GPU}_j}}{\sum_{\text{region}_i} \text{Supply}^{\text{region}_i}_{\text{GPU}_j}} \right)^2 \tag{7}$$

$$\times \text{ sigmoid}(\max(0, \text{Demand}^{\text{region}_i}_{\text{GPU}_j} - \text{Supply}^{\text{region}_i}_{\text{GPU}_j}) \tag{8}$$

$$\sigma_2(\text{Demand}^{\text{region}_i}_{\text{storage}}, \text{Supply}^{\text{region}_i}_{\text{storage}}) =$$

$$\left(\frac{\text{Demand}^{\text{region}_i}_{\text{storage}}}{\sum_{\text{region}_i} \text{Demand}^{\text{region}_i}_{\text{storage}}} - \frac{\text{Supply}^{\text{region}_i}_{\text{storage}}}{\sum_{\text{region}_i} \text{Supply}^{\text{region}_i}_{\text{storage}}} \right)^2 \tag{9}$$

Figure 4: Formulation of the data placement problem.

Among the expressions in Figure 4, $R(\text{table}_i)$ is the only decision variable, which determines the home region of table_i. The region in which job_j is placed is represented by $R(\text{job}_j)$, which is not a decision variable and is inferred from the placement of tables. A job may access multiple tables. For Spark or Presto jobs, the home region of the majority of the tables accessed by the job determines $R(\text{job}_j)$. For an ML training job_j, if the home regions of all tables accessed by the job are the same, then their home region determines $R(\text{job}_j)$. Otherwise, Tetris sets $R(\text{job}_j)$ to NULL temporarily, and will fix it at a later stage by replicating tables to ensure that at least one region has all these tables (§3.5). Note that while a Presto or Spark job can read some of its input tables across regions, an ML job must read all its input tables from the local region. This difference is due to the fact that GPUs used by ML jobs are much more costly and should not be stalled on reading data during execution. Further note that $R(\text{job}_j)$ is an auxiliary variable used when determining $R(\text{table}_i)$. After the completion of table placement on the slow path, MAST's real-time job scheduling on the fast path (§4) has the freedom to place the job in a region different from $R(\text{job}_j)$, depending on the available resources and table replicas at the scheduling time. Similarly, all the *Demand* variables are also auxiliary variables, inferred from $R(\text{table}_i)$ and $R(\text{job}_j)$.

Other symbols are defined as follows: $\text{size}(\text{table}_i)$ (size of a table), $\text{CPU}(\text{job}_j)$ (CPU hours required by a job), $\text{GPU}(\text{job}_j)$ (GPU hours required by a job), and $\text{GPU-Type}_{\text{job}_j}$ (types of GPUs required by a job) are estimated from the past history of the tables and jobs. $\text{storage\_capacity}(r)$, $\text{CPU\_capacity}(\text{app}, r)$, and *Supply*, are set by the administrator. The weights, w_1, w_2, w_3, w_{p_k}, and w_{job_j}, can be tuned by the administrator to prioritize certain terms or jobs.

$I(a,b)$ is a binary operator that evaluates to 1 if its two operands meet certain conditions and 0 otherwise. Specifically, $I(R(\text{job}_j), R(\text{table}_i))$ checks if the job and the table are in the same region. $I(R(\text{job}_j), \text{region}_r)$ checks if the job is placed in region r. $I(R(\text{table}_i), \text{region}_r)$ checks if the table is placed in region r. $I(\text{GPU-Type}_{\text{job}_j}, R(\text{job}_j))$ checks if job_j's region has the needed type of GPUs to run the job.

Expression 1 aims to minimize the total size of tables that are read across regions, i.e., when job_j needs to access table_i but they are not in the same region. The notation $\text{table}_i \in \text{job}_j$ denotes the tables accessed by job_j. For an ML training job_j, if its home region $R(\text{job}_j)$ is NULL (i.e., the home regions of the tables accessed by the job are not the same), Expression 1 will assume that all of these tables are accessed across regions.

Expression 2 *soft-balances* the supply and demand of GPUs across regions. GPU_j is a specific type of GPU and P_k is a job priority level. $\text{Demand}^{\text{region}_i}_{\text{GPU}_j, P_k}$ is the demand for GPU_j at region_i at priority level P_k. $\text{Supply}^{\text{region}_i}_{\text{GPU}_j}$ is the supply for GPU_j at region_i. Demands and supplies are measured in GPU hours. Expression 7 minimizes the imbalance of supply and demand across regions. If the load is perfectly balanced, Expression 7 is zero. Expression 8 minimizes region oveload. Without overload, Expression 8 is a constant, $\text{sigmoid}(0) = 0.5$. As the region becomes more severely overloaded (i.e., demand above supply), Expression 8 approaches 1, and the attempt to minimize Expression 8 would lead to reducing overload.

Expressions 3 and 9 *soft-balance* the supply and demand of storage space across regions. However, there is no term similar to Expression 8 to minimize storage space overload, as it is disallowed to allocate more space than available, enforced by Expression 4. Similarly, Equation 5 ensures that every region's CPU demand is below supply. Note that there is no such hard constraint for GPUs, as it would often lead to an unsolvable problem due to GPU scarcity.

Expression 6 only applies to time-sensitive high-priority jobs, ensuring that most of these jobs are trained in their home regions, i.e., satisfying the *training-at-home-region* property. Moreover, we empirically validate but do not mandate that the number of jobs satisfying this property does not decrease over time.

3.4 Efficient Approximate Solution

The MIP problem in Figure 4 is NP-hard. Tetris uses a hill-climbing algorithm [26] to compute an efficient approximate solution. Starting from the current placement, Tetris goes over each table and finds the best region for it out of different home region choices. The best region should have the lowest cost (Expressions 1-3) and can satisfy all constraints (Expressions 4-6). If the best region differs from the current home region of the table, the table is added to a move queue. The queue is ordered by the gain of table moves, i.e., the initial cost before the move minus the new cost after the move.

After determining the new home region for all tables, Tetris iterates over the queue to move tables, starting from the table with the highest move gain. Before moving a table, it recalculates its best region because moving tables in prior iterations may have changed the cost of moving this table. The moves continue until either the queue becomes empty or a daily move quota is reached due to limited cross-region network bandwidth. Tetris runs this algorithm daily which takes about five hours to complete, although the actual data replication may take much longer to finish.

To move a table, Tetris replicates the table to the new home region before deleting its data in the old home region. A data-migration service schedules and executes cross-region data replication. Tetris can set a soft deadline for a migration operation, and the migration service allocates the necessary bandwidth accordingly. Our network's cross-region traffic receives differentiated quality of service to ensure that background bulk data replication does not affect latency-sensitive services. As for the data-replication size, the P50 (50th percentile) is 565MB, the P90 is 103GB, and the P99 is 7.5TB. In terms of data transfer time, the P50 is 2.1 hours, the P90 is 3.7 hours, and the P99 percentile is 4.9 hours.

It is possible that the new home region becomes suboptimal during the move due to various reasons. Typically, the next day's rerun of Tetris will correct the problem. However, if MAST needs to schedule the corresponding job before the rerun, it can use heuristics to determine whether on-demand data movement is needed to temporarily fix the issue.

In addition to the hill-climbing algorithm, we have evaluated other solutions such as commercial MIP solvers [12, 18], but a comprehensive comparison with local-search alternatives is yet to be conducted. We chose hill-climbing for several reasons. Firstly, it offers greater scalability than other solutions we have explored. Secondly, hill-climbing simplifies the definition of the MIP problem formulation. As mentioned in §3.3, $R(\text{table}_i)$ is the sole decision variable, with $R(\text{job}_j)$ inferred from $R(\text{table}_i)$, and GPU and storage demands per region further inferred from $R(\text{job}_j)$. In traditional MIP formulas, $R(\text{job}_j)$ must also be declared as a decision variable constrained by $R(\text{table}_i)$, and the same must be done for all demand requirements. This would lead to mathematical formulas much more complex than those shown in §3.3. In contrast, with hill-climbing, we can compute $R(\text{job}_j)$ and demand requirements from $R(\text{table}_i)$ using code, which offers more flexibility. Lastly, the outputs of hill-climbing are interpretable and easy to debug, as we understand the exact reasons to migrate tables in each iteration. Given that hyperscale ML training is still relatively new and the problem formulation continues to evolve, the interpretability and debuggability of hill-climbing present significant advantages.

3.5 Creating Extra Table Replicas

In addition to a table's home region, it may have replicas in other regions for various reasons. For disaster recovery (DR) purposes, each table has a replica outside of its home region. The region that stores the DR replica is selected based on a DR policy, which takes into account factors such as the probability of correlated regional failures and the availability of hardware to handle increased load after a disaster.

After the hill-climbing algorithm finishes, some ML jobs may not be able to run in any region, because their home region $R(\text{job}_j)$ is NULL or does not have the type of GPUs needed by the job. The DR copy may fix some of these jobs, and for the remaining ones, Tetris creates additional replicas of the tables accessed by them in other regions, allowing them to be scheduled there. For example, suppose table_i is accessed by job_1 and job_2, which require GPU_1 and GPU_2, respectively. However, GPU_1 and GPU_2 are not available together in any region. Thus, Tetris may set $R(\text{table}_i)$ to be a region that has GPU_1 to run job_1 and then create a replica of the table in a region that has GPU_2 to run job_2. If multiple regions have GPU_2, Tetris selects the region with the highest supply.

A small fraction of tables, known as hot tables, are accessed by a large number of jobs (Figure 3). If these tables are replicated to only a few regions, it may create a significant load imbalance, as a large number of jobs dependent on these tables will be forced to run in a few regions. To address this problem, Tetris widely replicates hot tables per GPU type.

		Scope of job queue management		
		Cluster	Regional	Global
Scope of resource allocation	Cluster	(1) Borg, Hydra, Yugong	(2)	(3)
	Regional	(4) ✗	(5)	(6) MAST
	Global	(7) ✗	(8) ✗	(9) “Ideal”

Table 1: Design space partitioned by the scheduling scope. The symbol ✗ indicates invalid solutions.

For each region and each GPU$_j$, Tetris computes the region’s storage quota for GPU$_j$ based on the supply of GPU$_j$. Tetris sorts tables accessed by jobs using GPU$_j$ based on the tables’ hotness, and replicates as many hot tables as possible until it reaches the storage quota for GPU$_j$.

Extra table replicas provide MAST’s fast path with greater flexibility to choose the region for hosting a job at runtime. However, replicating a massive amount of data across regions could take hours, delaying the start of some time-sensitive jobs. To address this problem, Tetris takes a combination of measures. First, Expression 6 enforces that sufficient jobs are trained in their home regions. Second, instead of replicating the whole table, Tetris can be configured to only replicate the partitions needed by the training job. Finally, Tetris prioritizes first replicating data needed by high-priority jobs to meet their deadlines.

Overall, the additional table replicas created by Tetris increase storage consumption by approximately 75% to 125%. However, given the high cost of GPUs, we deem this a justifiable trade-off.

4 Fast-path Job Scheduling

While the slow path asynchronously prepares data for ML training, the fast path schedules ML workloads in real-time. Before presenting MAST’s scheduling solution, we explore the design space to understand its rationale.

4.1 Exploring the Scheduling Design Space

Traditionally, the federation approach [10, 20, 28] employs *early binding*, dispatching a new job to a cluster based on the current estimated cluster load, even if the cluster has no available resources to run the job immediately. In contrast, MAST adopts *late binding*, dispatching a job to a cluster only when certain that the cluster has available resources to run the job immediately.

Moreover, traditional scheduling systems handle all scheduling functions at the cluster scope: job queue management, resource allocation, and container orchestration. Below, we explore solutions that manage job queues and resource allocation at the regional or global scope.

Comparing solutions. Table 1 shows the solution space. Solution (1) is the traditional approach, with Borg [48] as an example, where job queue, resource allocation, and container orchestration are all managed at the cluster scope. Solution (6) is our approach, where the job queue is managed at the global scope and resource allocation is managed at the regional scope. Solution (9) is the “ideal” approach, where both the job queue and resource allocation are managed at the global scope. With a global view of all jobs and machines, theoretically, it can achieve optimal job placement, but the limited scalability of this approach is a main shortcoming.

For ML training workloads, it can be proven that among algorithms that schedule one job at a time, MAST achieves the same optimal job placement as (9) due to several reasons. First, all tasks of a training workload must be allocated to the same region for locality, simplifying resource allocation calculations to within regions. Moreover, following the *exhaustive-search* principle, MAST computes a resource allocation plan for the workload in *every* region with training data, and then chooses the best plan for execution. As a result, it can achieve optimal placement for individual workloads. However, solution (9) has an advantage over MAST in jointly optimizing the placement of a set of workloads. For instance, after MAST places *workload 1* in region X, it may discover that no region can accommodate *workload 2*. In contrast, solution (9) may intentionally place *workload 1* in region Y and leave region X to handle *workload 2*.

Solutions (2), (3), and (5) improve upon solution (1) as they can either better balance the load or manage allocation at a larger scope, but they still cannot provide the same level of scheduling quality as (6). Solutions (4), (7), and (8) are invalid as their scope of resource allocation is bigger than their scope of job queue management. Among the solutions in Table 1, assuming (9) is not scalable, our preference is (6) > (3) > (5) > (2) > (1).

Federated systems. Hydra [10] and Yugong [20] use the federated approach. Both fall under solution (1) as they employ early binding of a job to a cluster, and then manage the job queue and resource allocation with the cluster. This approach aligns well with the nature of lightweight analytics jobs, the focus of Hydra and Yugong. Such jobs demand high scheduling throughput but typically do not involve complex decisions like job preemption.

4.2 Global ML Scheduler (GMS)

Adhering to the *scope-decoupling principle* and as illustrated in Figure 1, MAST splits the scheduling responsibilities among different components: the Global ML Scheduler (GMS) manages the global job queue, the Regional ML Scheduler (RMS) allocates regional resources, and the Cluster Manager (CM) is responsible for container orchestration.

The main responsibility of GMS is to select the next workload to schedule among all pending workloads in the global job queue. For each pending workload, GMS calculates a $<$*priority*, *credit*$>$ tuple. It schedules the workload with the highest *priority* and, in case of a tie, selects the one with the highest *credit* for scheduling.

The *priority* is affected by quota usage. Each workload belongs to a tenant, i.e., a team. Tenants are assigned a priority level and a quota for running their workloads. The quota specifies the maximum number of GPUs and CPUs that a tenant can use simultaneously. Workloads from a tenant that has not exhausted its quota are assigned the tenant's priority, categorized as *within-quota workloads*. Conversely, when a tenant has used up its quota, its workloads are assigned the lowest priority and categorized as *over-quota workloads*. These workloads run opportunistically and can be preempted when a higher priority workload arrives. Tenant priorities are manually assigned based on business priorities. The strict adherence to these priorities does result in preemption, which is the intended effect. Currently, MAST uses seven priority levels. The distribution of workloads across these priorities (from highest to lowest) is as follows: 3%, 20%, 16%, 54%, 0.2%, 0.5%, and 0.02%. The remaining 6% of workloads do not specify a priority and are consequently treated as the lowest priority.

The *credit* of a workload is calculated as follows. Intuitively, a workload W has a higher *credit* if it has been waiting longer (Expression 10) or belongs to a tenant that has used fewer resources than others (Expression 11).

$$\text{credit(L)} = w_{\text{workload\_age}} \times \min(\text{L.age}, C_{\text{age\_cap}}) \tag{10}$$

$$+ w_{\text{fair\_share}} \times (1 - \frac{\text{window\_avg(L.tenant.resources\_used)}}{\text{window\_avg(all\_tenants.resource\_used)}} \tag{11}$$

Here, L represents a workload, $C_{\text{age\_cap}}$ is a constant, and $w_{\text{workload\_age}}$ and $w_{\text{fair\_share}}$ are tunable weights.

To determine the $<$*priority*, *credit*$>$ tuple for a workload, GMS calculates each workload's *credit* and sorts pending workloads based on it. It scans them to assess if they can be scheduled within their tenant's quota. GMS maintains a *resource_used* variable for each tenant, initialized to include resources used by the tenant's running workloads. When scanning a pending workload W, GMS checks if adding W's resource requirement to *resource_used* would exceed the tenant's quota. If so, W is assigned the lowest priority level; otherwise, W inherits its tenant's priority level, and GMS updates the tenant's *resource_used* to include W's resources.

Periodically, GMS executes a *GMS-scan pass* to update $<$*priority*, *credit*$>$ tuples for all pending workloads. This approach is chosen because the state change of one workload may impact others' $<$*priority*, *credit*$>$. Specifically, a workload's *credit* is influenced by other tenants' resource usage (Equation 11). Additionally, a workload's *priority* is tied to its tenant's other workloads' resource usage. This updating-all-workloads strategy enables MAST to implement sophisticated quota and priority management policies. The scalability of GMS with this approach depends on the frequency and duration of the GMS-scan pass.

4.2.1 Scalability of GMS

In practice, GMS scales well for ML workloads due to several factors. First, ML training workloads, running for extended periods on many machines, necessitate higher-quality scheduling decisions but lower scheduling throughput compared to short-lived batch jobs [10, 38, 41, 50]. Second, GMS has minimal responsibilities, calculating <priority,credit> for each pending workload and storing it in the job-queue database. Placement plans are computed by RMS, not GMS. Third, our evaluation in §5.4 indicates that the current GMS implementation can support workload growth by a factor of 8.8. Finally, currently implemented in Python for simplicity, if it becomes a bottleneck, we plan to scale it further by a factor of 10-100 by switching to C++ and parallelizing computation for different tenants.

4.3 Regional ML Scheduler (RMS)

RMSs perform auctions in a distributed manner to schedule ML workloads. Each RMS constantly checks the job-queue database maintained by GMS, and attempts to schedule the ML workload with the highest $<$*priority*, *credit*$>$.

To schedule a workload, an RMS consults a real-time component of Tetris to check whether its local region has the required data and necessary hardware types. If not, the RMS abandons the auction. If all RMSs abandon the auction, potentially occurring with the first-time execution of a new workload, MAST will start data replication, waiting for its completion to ensure some regions have both the necessary data and hardware.

Typically, due to Tetris, multiple regions have the required data and hardware types for the workload. Following the *exhaustive-search* principle, in each such region, RMS calculates a placement plan for the workload along with a corresponding placement-quality score (P_{score}). RMSs engage in an *auction* to identify the RMS with the highest P_{score}, which will execute the workload. If no region can generate an immediate placement plan for the workload, it enters the *waiting* state.

A region may have multiple ML dynamic clusters, and the workload can comprise multiple jobs, each assignable to a different cluster. Adhering to the *exhaustive-search* principle, for each job in the workload, RMS calculates a placement plan and P_{score} for every ML dynamic cluster in the region. It chooses the cluster with the highest P_{score} to host the job. The overall P_{score} for the workload is determined by summing up the P_{score} for each job in the workload.

When comparing two placement plans for a job, the one with a higher P_{score} wins. A plan has a higher score if it uses available resources to run the new job without preempting any running jobs. If preemption is necessary, a higher score is achieved by preempting jobs with lower priority, fewer jobs, or those running for a longer duration. The last condition implies refraining from preempting newly started jobs.

To generate a placement plan for a job in an ML dynamic cluster, RMS checks if it can allocate the job using available resources without preempting running jobs. For enhanced task locality within the same job, RMS sorts available machines based on rack IDs, allocating machines in the same or nearby racks in batches. While scanning, RMS aims to use the minimum number of machines by prioritizing those with the highest available CPU/GPU resources.

If preemption is necessary, RMS prioritizes preempting lower-priority jobs. It sorts all running jobs based on priority and running time, initiating the scan with the job having the lowest priority and longest running time. The scanning process continues until sufficient resources are found to execute the new job, combining available resources with those to be released through preemption.

RMS minimizes preempted jobs. For example, if a new job needs 10 GPUs and the scan reveals options of 4, 5, and 12 GPUs by preempting job_1, job_2, and job_3 respectively, the optimal choice is preempting job_3 without affecting job_1 or job_2. To achieve this, RMS re-sorts preempted jobs by size, prioritizing larger jobs first.

Multiple optimizations improve RMS performance, with the most effective being the use of a *negative cache*. When RMS cannot allocate resources for a job, it saves the decision in the cache. If it later attempts to allocate a job of the same or larger size, the cache signals that the allocation will fail. Specifically, the negative cache is initialized at the start of every GMS-scan pass that examines all pending jobs, and is cleared after the GMS-scan pass finishes. It is implemented as a hashtable that stores the scheduling properties of the jobs that could not be scheduled during the GMS-scan pass. These scheduling properties encompass the number of GPUs and CPU cores requested by the job, memory, hardware type, and so on. Such information consumes little memory, and there is no need for cache eviction during a GMS-scan pass. Overall, the negative cache is highly effective as unsuccessful placement attempts far outnumber successful ones due to nearly constant full resource allocation. It filters out the majority of these unsuccessful attempts early on, thanks to a cache hit rate of about 80% in practice.

4.3.1 Scalability of RMS

RMS demonstrates sufficient scalability, as evidenced by the analysis below. Scalability is examined concerning the number of regions (r) and the amount of ML hardware per region (h). Adding more regions does not increase the computation load of RMS, as it schedules workloads only for data stored in the respective region. When h remains constant, the number of such workloads also remains unchanged. However, linear growth in h results in quadratic growth in RMS's computation load. The complexity of RMS's exhaustive search is $E(h) = O(D(h) \times J(h))$, where D is the number of ML dynamic clusters and J is the number of jobs scheduled on these clusters. As both D and J are proportional to h, $E(h)$ experiences quadratic growth.

Our evaluation in §5.4 demonstrates that RMS can handle a 12x increase in h compared to our current production load. This scalability is likely sufficient even for the long run, given that the growth of h is constrained by the fixed electricity supply of a datacenter region. Currently, the largest RMS manages around 20 dynamic clusters, comprising a total of 64,000 CPU machines and 20,000 GPUs. In the improbable scenario of RMS becoming a bottleneck, we plan to parallelize scheduling for non-conflicting workloads with training data in non-overlapping regions. Additionally, if needed, RMS can be sharded to scale out, with each shard handling a subset of ML dynamic clusters.

4.4 Cluster Manager

Our cluster manager (CM), Twine [44], has the distinguishing feature of managing a dynamic cluster whose machine membership may be continuously updated by RAS [36]. The CM instances managing ML and non-ML clusters are separate and do not interfere with each other, while RAS can dynamically move machines between them to avoid stranded capacity.

We choose not to use a single, generic cluster to handle mixed ML and non-ML workloads, as it is suboptimal for our large-scale operations. Our large fleet size necessitates partitioning machines into independent clusters for effective management. Combining ML and non-ML workloads in a cluster compromises optimization for either type, whereas our scale benefits significantly from workload-specific optimization. For instance, online services prefer spreading across fault domains, whereas ML training workloads prefer not to be spread widely for better network performance. Furthermore, as gang jobs, ML training workloads prefer, for example, 10 out of 100 jobs to fail entirely while the remaining 90 jobs continue, as opposed to each job experiencing a 10% task termination. Optimizing for spread would lead to the latter undesirable situation. Previously, CM handled these complex differences between ML and non-ML workloads on the fast path of real-time job scheduling, often resulting in suboptimal choices due to limited computation time. Consequently, we adopted the strategy of RAS running on the slow path to pre-built separate ML and non-ML dynamic clusters that are deeply optimized for respective workloads, while simplifying the responsibilities of CM on the fast path.

CM and RMS collaborate in managing workloads. For example, when new machines are added to an ML dynamic cluster, the corresponding CM notifies RMS of this change. With complete information cached in its memory, RMS can efficiently compute placement plans. When a region's placement plan is selected as the best plan for execution, its RMS directs the corresponding clusters' CMs to execute the plan and run the relevant jobs. This may require preempting running jobs and checkpointing their current status, initializing containers for the new jobs, and restoring their job states if they were previously preempted.

4.5 Fault Tolerance

GMS, RMS, and CM are fault-tolerant and highly available, operating in a leader-follower mode. Specifically, two instances of GMS run in different regions, two instances of RMS operate in the same region, and three instances of CM serve the same cluster. They all follow a stateless design, storing their persistent state in a shared and replicated database. In the event of a leader failure, the follower can reconstruct its state from the database and the lower-level component (i.e., GMS from RMS and RMS from CM).

4.6 Limitations

In our hyperscale production environment, we prioritize implementation simplicity and robustness, leading to some implementation limitations rather than inherent design flaws. One such limitation is the inability to distribute a job's tasks across different clusters, despite the capability to allocate workload jobs to various dynamic clusters. RMS can compute a placement plan for distributing a job's tasks across different clusters by leveraging its comprehensive view of all resources in the ML clusters within the region. However, the integration with our cluster manager [44]'s "virtual job" feature, crucial for effectively managing scattered tasks as one virtual job, is not yet implemented.

Another implementation limitation is that currently, RMS schedules only one ML workload at a time. While it parallelizes the computation of placing multiple jobs from one workload into different clusters, it does not commence scheduling the next workload until a decision has been made for the current one. This simple approach is used because it is adequate and still has headroom to support further growth, as discussed in §5.4. However, if a bottleneck arises in the future, we are prepared to transition to scheduling multiple workloads in parallel. Moreover, scheduling multiple workloads simultaneously presents opportunities for enhancing scheduling quality. Note that although the current implementation schedules one ML workload at a time, different workloads can still run in parallel. Once a workload X is dispatched to run, without waiting for X to finish execution, the scheduler immediately schedules the next workload Y.

5 Evaluation

Our evaluation attempts to answer the following questions:

1. What are the important ML workload statistics?
2. Can MAST achieve a high resource allocation rate?
3. Is Tetris effective in ensuring colocation of data and compute resources?
4. Are GMS and RMS sufficiently scalable?
5. How long does it take to schedule a workload?
6. How does MAST compare with alternative solutions?

5.1 ML Training Workload Statistics

Currently, MAST is scheduling tens of thousands of ML training workloads daily across tens of regions, consuming $O(100,000)$ GPUs and $O(100,000)$ CPU machines. About 70% of the workloads use GPUs for training, while the remaining use CPUs for training. About 30% of the workloads are recurring, while the remaining are first-time workloads. On average, each workload gets preempted once, which leads to about 100,000 scheduling attempts daily. High-priority workloads may never get preempted and low-priority workloads may get preempted multiple times.

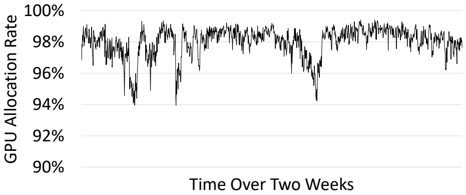

Figure 5: GPU allocation rate.

In terms of the number of machines utilized by a workload, the values for the 50th, 90th, and 99th percentiles are 72, 180, and 205, respectively. As for the number of GPUs used by GPU-consuming workloads, the 50th, 90th, and 99th percentiles are 16, 64, and 128, respectively, and the largest workload today, LLM pre-training, uses tens of thousands of GPUs. We measure the duration of workloads in terms of their execution time until the subsequent preemption, as it is more pertinent for a scheduling system. For GPU workloads, the 50th, 90th, and 99th percentiles of the duration are 20 minutes, 6.7 hours, and 66 hours, respectively. As for CPU workloads, the corresponding percentiles are 38 minutes, 7.9 hours, and 38 hours. Overall, training workloads run on many machines for an extended period. Therefore, it is worthwhile to spend time computing high-quality scheduling decisions.

5.2 Effectiveness of Global ML Scheduling

Thanks to the flexibility of placing both data and workloads globally, MAST has achieved a high average *allocation rate* of 98% for its GPU machines, as shown in Figure 5. The 2% loss is due to factors such as the overhead of preemption, inherent latency of scheduling, and imbalanced data and GPU distribution across regions. The allocation rate is determined by dividing the total hardware hours allocated to workloads by the total available hardware hours. Note that the GPU allocation rate differs from GPU utilization because even if some GPUs are allocated to a workload, they may be underutilized due to various factors, such as the workload's internal communication bottlenecks. We use the allocation rate as the metric because it is more relevant for a scheduling system, which is the primary focus of this paper, while GPU utilization is more pertinent for the ML training framework.

In comparison, the allocation rate for CPU machines is lower. Dedicated CPU machines for ML workloads have an allocation rate of 87%, while elastic CPU machines, which are borrowed temporarily from non-ML workloads, have an allocation rate of 72%. The lower allocation rate for CPU machines is largely due to slight overprovisioning to guarantee that costly GPU machines are never left idle due to a lack of available CPU machines to work with.

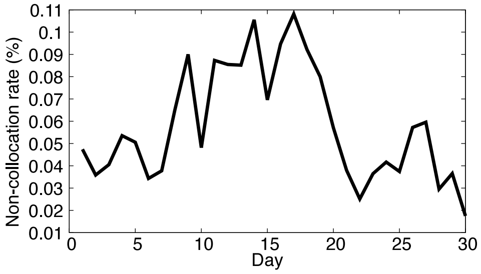

Figure 6: Percentage of workloads that have to wait for data.

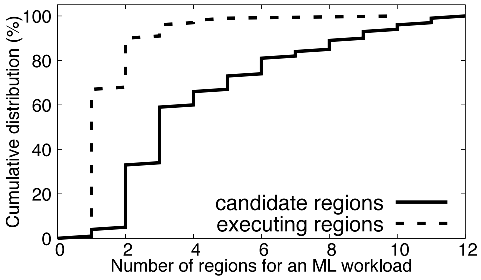

Figure 7: Cumulative distribution of candidate and executing regions per workload over 30 days.

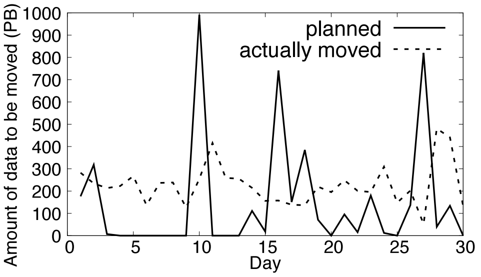

Figure 8: Daily data movement by Tetris.

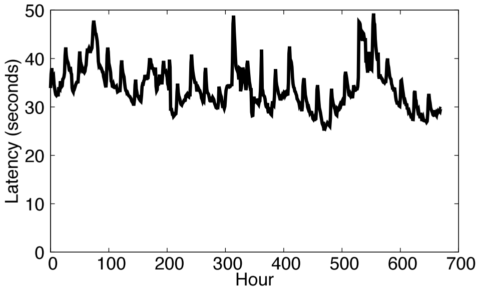

Figure 9: The latency of a GMS-scan pass in GMS (each data point is the average latency within one hour).

5.3 Effectiveness of Data Placement

Figure 6 shows the percentage of workloads that cannot satisfy the data-GPU-collocation property (§3.1) and thus have to wait for on-demand data movement to complete. The non-collocation rate is usually below 0.1%, demonstrating the effectiveness of Tetris. Although Tetris creates extra table replicas to increase the collocation rate (§3.5), non-collocation may still occur due to a workload appearing for the first time or due to machine maintenance rendering certain data or hardware unavailable. Considering 70% of our workloads are first-time ones, this figure shows most of them can still benefit from the data placement planned for recurring workloads.

Thanks to Tetris, often multiple regions can host the same workload, which gives MAST the flexibility to migrate the workload across regions on different days. In Figure 7, the "*candidate regions*" have the required training data and hardware types to host a workload, while the "*executing regions*" have actually hosted the workload on different days. As shown in the figure, the majority of workloads have two or more candidate regions, and approximately 40% of them have four or more. The number of executing regions per workload is smaller; roughly 30% of the workloads have more than one executing region, indicating they are relocated across regions during this period. This demonstrates that global ML scheduling indeed works as intended to dynamically optimize workload placement across regions.

Figure 8 shows the amount of data that Tetris move daily. The spikes in the planned movement are due to onboarding a new workload, which caused a large amount of data to be moved across regions. However, the data migration service has a limit on the maximum amount of data moved per day. Therefore, the actual amount of data moved per day is flatter. This figure shows that Tetris proactively moves hundreds of petabytes of data across regions daily. This enables the fast path to more easily colocate computation with data, and achieve the high GPU allocation rate of 98%.

Tetris's hill climbing algorithm runs daily on a single machine and it typically takes about five hours to finish. Although its CPU utilization is not very high, it spends a significant amount of time on I/Os to fetch various metadata necessary for computing the data placement plan. Currently, the performance of Tetris is not a major bottleneck, and can be further optimized as needed.

5.4 Scalability of GMS and RMS

Scalability of GMS. GMS periodically computes the $<priority, credit>$ tuples for all workloads (§4.2). We refer to one round of such computation as a *GMS-scan pass*. The scalability of GMS depends on the frequency and latency of the GMS-scan pass. Although its theoretical complexity is $O(N \log N)$ due to sorting, where N is the number of workloads, its actual execution time is approximately $O(N)$, dominated by the sequential computation of $<priority, credit>$ for each workload. Figure 9 shows the average latency of the GMS-scan pass. On average, it takes approximately 34 seconds for GMS to rank 6,000-10,000 workloads. Our evaluation shows that running the GMS-scan pass once every 5 minutes still produces high-quality scheduling. This implies that GMS can support $\frac{5\text{ minutes}}{34\text{ seconds}} = 8.8$ times more workloads. As described in §4.2.1, if needed, we can scale the GMS by another factor of 10-100 by switching from Python to C++ and parallelizing its computation for different tenants.

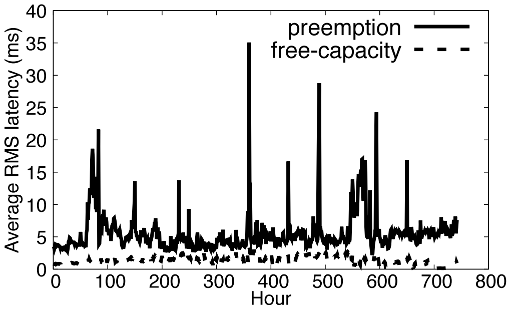

Figure 10: Average latency of scheduling a workload at the slowest RMS. It is computed by taking the maximum of the average latencies computed at each RMS every minute.

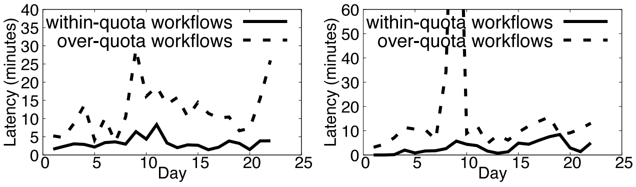
Scalability of RMS. Since our current RMS implementation does not initiate scheduling of the next workload until a decision has been made for the current one (§4.6), the maximum throughput of RMS can be estimated from its latency to schedule a single workload. As shown in Figure 10, the slowest RMS takes approximately 1.3ms and 5.5ms to schedule a workload without and with preemption, respectively. Even assuming that all scheduling requires preemption, the RMS can schedule 24*3600*1000/5.5=15 million workloads per day. Considering the current throughput of about 100K scheduling attempts per day and the quadratic growth of the computation load caused by exhaustive search (§4.3.1), the RMS can support approximately $\sqrt{\frac{15M}{100K}}$=12x more workloads and 12x more ML hardware. See §4.3.1 for a discussion on how to further scale RMS.

5.5 Scheduling Latency

Figures 11(a) and (b) show the average and P95 latency, respectively, for pending workloads to enter the running state, including queuing delay, scheduling-algorithm run time, and preemption time but not workload execution time. The preemption time is a major factor in the total delay. If workload A preempts B, rescheduling B counts as a new scheduling event in these figures, starting from the time B is preempted to the time B runs again. The preemption time of B counts towards A's latency as A needs to wait for the preemption to finish. One primary service level objective for MAST is P95 latency. These figures show that MAST has maintained consistently low latency for within-quota workloads. However, for over-quota workloads, the latency can occasionally be erratic, depending on the workload mix. This emphasizes the importance of distinguishing between within-quota and over-quota workloads.

To start a workload, MAST needs to acquire containers from the cluster manager and set up all containers. The P50 latency of this step is 150 seconds, while the P90 is 278 seconds, and the P99 is 449 seconds. For massive LLM jobs, the whole process could take 10 minutes or longer.



(a) Average

(b) P95

Figure 11: Latency for a pending workload to start running.

5.6 Comparison with Alternative Solutions

Tetris. The closest work to Tetris is Alibaba's Yugong [20], which uses MIP to place data for analytics jobs based on CPU (but not GPU), storage, and network constraints. It enforces hard quotas and would not produce a solution when resources are insufficient. However, as GPUs are scarce in our environment with consistently higher demand than supply (§3.2), Yugong would never provide a solution.

Since Yugong is not comparable to Tetris, we evaluate Tetris's different versions to demonstrate the importance of its key features. In the initial stage (V0) of MAST, users manually selected regions for table placement, and tables could not migrate across regions. In 2022, V1 was developed, which automated data placement, aligning with the approach in Section 3, albeit with key distinctions. V1 was a major improvement over V0, reducing the GPU demand-over-supply ratio for high-priority jobs in the most overloaded region from 2.63 to 0.98, with the standard deviation dropping from 0.76 to 0.30. Moreover, it boosts the training-at-home-region rate from 90.82% to 93.02%.

Despite V1's success, various limitations prompted the development of V2. As described in § 3.3, key differences include V2 penalizing GPU overload more than penalizing underload, and incorporating *soft-balance* alongside *hard-quota* for storage. Additionally, V1 defined the collocation rate uniformly for all workloads, treating small and large, high-priority and low-priority workloads alike. Recognizing the practical importance of large high-priority workloads, V2 has revised this definition to be the demand (i.e., GPU hours) of high-priority workloads that can satisfy colocation. With these enhancements, V2 significantly increased the collocation rate under the new definition from 78% to 96% compared to V1.

Fast-path Scheduler. We built a simulator to evaluate different scheduling algorithms of the fast path. The simulator takes a trace of past workloads as input, and follows the same logic of MAST's fast-path scheduler, excepts that it does not actually execute a workload, but instead assumes its running time is the same as recorded in the trace. For comparison, we modified the simulator to implement a federated approach, which dispatches a workload to the region with the lowest demand over supply rate of the required GPU type. When playing an 8-hour trace to the simulator, we find that for MAST, the rate of workloads violating SLOs stays below 1.3% all the time. For the federated approach, however, the SLO violating rate is much higher, especially when load is high. High-priority workloads suffer more, reaching a 50% SLO violating rate during busy hours. This is because high-priority workloads often need to preempt low-priority ones to guarantee SLOs, but with a simple heuristic, the federated approach may not be able to dispatch a high-priority workload to the right region where it can preempt others.

6 Discussions

Solutions suitable for smaller organizations. While MAST is designed for hyperscalers, some of its principles can be applied to smaller organizations. If a small organization only needs to run training workloads in a single cluster, implying one region, then it does not need any of MAST's advanced capabilities. However, in the event of a power or network outage affecting the region, it would be unable to run any ML training jobs due to the lack of disaster-recovery capability.

If an organization's infrastructure operates in at least two regions to be disaster ready, then it can leverage the key ideas in MAST. Without MAST, they would default to solution (1) in Table 1, leading to suboptimal resource allocation due to the isolated operation of the two regions. With insights from MAST, if the scale of their infrastructure is small enough to be handled by a single resource allocator, they could adopt solution (9), yielding optimal placement results. If they do not want to significantly modify their cluster manager like Kubernetes [27], they could at least adopt solution (3), which involves a relatively minor change to use a global job queue but still offers significant benefits in balancing the load across regions. Furthermore, if they cannot afford to replicate every table across every region, they would need a component similar to Tetris to intelligently determine data placement.

Future work. Currently, Tetris considers storage quota and network bandwidth as hard constraints. It is valuable to understand the impact of adding storage and cross-region network bandwidth to better utilize expensive GPUs.

For scalability, Tetris currently determines home regions (§3.2 to §3.4) and creates additional table replicas (§3.5) in separate steps. We plan to explore whether there exists an efficient MIP problem formulation that can simultaneously determine the optimal number of replicas and the home region for each table. It is important that such a problem formulation can be solved in a scalable manner.

Finally, we plan to leverage the fact that the slow path (Tetris) not only determines data placement but also, as a byproduct, calculates the placement of recurring jobs. The latter is currently overlooked by the fast path when placing jobs. Because unexpected one-time jobs may make some of the slow path's job placement decisions unfeasible or suboptimal, future research is needed to better connect the fast and slow paths. This would allow us to benefit from the job-placement decisions that the slow path has more time to compute.

7 Related Work

Scheduling within a cluster. There are many prior works about scheduling within a single cluster, including general-purpose schedulers [14,16,19,22,38,47,56] and those specific to ML training [1,2,5–7,9,13,17,21,23–25,30,31,33–35,39,40,45,49,51–54,57,59]. The latter often considers specific characteristics of ML training, such as model accuracy, gang scheduling, sensitivity to network topology, heterogeneity of compute resources, elasticity, etc. Cluster-level scheduling is largely orthogonal to the design principles of MAST, though some of their ideas may be applicable in the cluster-level placement algorithm of MAST.

Scheduling across clusters. Among existing systems, Yugong [20] and Hydra [10] are the closest to MAST as they can schedule jobs across cluster or datacenters, but they still differ from MAST since 1) they perform early-binding at cluster scope (§4.1), 2) they don't take GPU into consideration (§1 and §3), and 3) they rely on simple heuristics to dispatch jobs to clusters. Finally, in the data warehouse hierarchy (hundreds of namespaces→millions of tables→ billions of data partitions), Yugong places data at the namespace level (called "projects" in the paper), whereas Tetris places data at the partition level, which provides more opportunities for fine-grained optimization. However, Tetris' fine-grained placement makes the optimization problem about 10^6 times larger.

Singularity [43] is the only ML-specific global-scale scheduler we are aware of. However, the article does not disclose details about the scheduling part, but focuses more on how to provide elasticity to ML training jobs, and thus it's impossible for us to provide a concrete comparison.

8 Conclusion

This paper demonstrates that by utilizing the three design principles of *temporal decoupling*, *scope decoupling*, and *exhaustive search*, we can build a global ML training scheduler that can 1) scale to tens of regions and hundreds of thousands of machines and 2) provide high-quality data and job placement to achieve almost 100% allocation of GPUs.

Acknowledgments

This paper presents years of work by past and current members of several teams at Meta, including MAST, Tetris, and Twine [44]. In particular, we would like to call out some current team members not on the author list: Mike Begic, Rick Chang, Cheng Cheng, Fuat Geleri, Ankit Gureja, Christian Guirguis, Hamid Jahanjou, Johan Jatko, Jonathan Kaldor, Norbert Koscielniak, Alexander Kramarov, Mengda Liu, Running Lu, Duy Nguyen, Ivan Obraztsov, Colin Ovens, Marcin Pawlowski, Nader Riad, Derek Shao, Ahmed Sharif, Mihails Smolins, Bhushan Sonawane, Peeyush Taneja, Yingjie Tang, Hai Dang Tran, Tom Wan, Anthony Wang, Runmin Wang, Wenbang Wang, and Lukasz Wesolowski. We thank all reviewers, and especially our shepherd, Ryan Huang, for their insightful comments.

Automatically Reasoning About How Systems Code Uses the CPU Cache

Rishabh Iyer, Katerina Argyraki, George Candea
EPFL, Switzerland

Abstract

We present a technique, called CFAR, that developers can use to reason precisely about how their code, as well as third-party code, uses the CPU cache. Given a piece of systems code *P*, CFAR employs program analysis and binary instrumentation to automatically "distill" how *P* accesses memory, and uses "projectors" on top of the extracted distillates to answer specific questions about *P*'s cache usage. CFAR comes with three example projectors that report (1) how *P*'s cache footprint scales across unseen inputs; (2) the cache hits and misses incurred by *P* for each class of inputs; and (3) potential vulnerabilities in cryptographic code caused by secret-dependent cache-access patterns.

We implemented CFAR in an eponymous tool with which we analyze a performance-critical subset of four TCP stacks—two versions of the Linux stack, a stack used by the IX kernel-bypass OS, and the lwIP TCP stack for embedded systems—as well as 7 algorithm implementations from the OpenSSL cryptographic library, all 51 system calls of the Hyperkernel, and 2 hash-table implementations. We show how CFAR enables developers to not only identify performance bugs and security vulnerabilities in their own code but also understand the performance impact of incorporating third-party code into their systems without doing elaborate benchmarking.

CFAR is open-source and freely available at [58].

1 Introduction

System performance is important yet often poorly understood. Hence the recently proposed notion of a *performance interface* [30, 31, 47], defined by analogy to semantic interfaces (e.g., abstract classes, specifications, documentation) that have been used for many decades to succinctly describe a program's functionality. A performance interface describes a system's performance behavior in a manner that is simultaneously succinct, precise, and human-readable. The goal of performance interfaces is to help developers efficiently reason about the performance behavior of both their own and third-party code without having to delve into the code's implementation details—just like semantic interfaces help developers reason about functionality today.

Low-level systems code (e.g., operating system kernels, device drivers, network stacks, hypervisors) is special, because performance often critically depends on how the code interacts with the underlying micro-architecture. As a result, system developers spend a lot of time trying to understand this interaction, e.g., trying to understand whether the code's memory-access patterns are cache-friendly [2, 12–14, 50, 70] or whether the code's working set fits in cache [19, 23, 45, 67, 68, 77]. *Not* understanding this interaction can lead to performance bugs that are hard to diagnose, and can also result in unexpected performance behavior when using third-party code. For instance, a recent patch showed how the fast path of the Linux TCP stack had been experiencing a bloated cache footprint for over a decade, incurring slowdowns of up to 45% [42]; prior work has shown that applications may run up to 4× slower after calling into third-party code (e.g., a syscall) due to the callee's micro-architectural footprint [66, 74].

The goal of this work is to help system developers answer key questions about how their code and third-party code interacts with the underlying micro-architecture. We focus on interactions with the CPU caches (both data and instruction caches), since these often play a critical role in the performance of systems code [12–14, 19, 23, 38, 45, 57, 67, 68, 70, 77, 78]. We seek to answer frequently-asked questions about cache usage such as: "How does the code's cache usage scale as a function of the workload?" [6, 19, 23, 67, 68] and "Which workloads make the code's working set exceed the cache size?" [38, 57] without requiring developers to delve into the code's details or run elaborate, time-consuming benchmarks.

Answering the above questions requires visibility into how the code processes an *abstract* workload, so we look for abstractions that capture (in a succinct, precise, and human-readable manner) how the code interacts with the caches as a function of the workload. Our approach is in contrast to existing performance-analysis tools like profilers [10, 43, 59, 69] and cycle-accurate simulators [7, 9]: such tools can only provide insights into cache usage for the *concrete* workloads with which the code is profiled or simulated; they cannot provide visibility into how the code would behave for arbitrary, previously unseen workloads. As a result, when using these tools, developers are forced to manually reverse-engineer the answer to their questions. This process is both time-consuming and error-prone [29], particularly for code that the developers did not write themselves.

We present Cache Footprint AnalyzeR (CFAR), a technique for processing a piece of systems code into answers to developers' questions about how that code uses the cache. This processing consists of two phases: In the first phase, CFAR takes as input the target code and extracts from it an abstract representation (a "distillate") of how the code accesses memory. In the second phase, CFAR uses simple programs ("projectors") to transform the distillate into answers to specific questions about the code's cache usage. Since the distillate is a precise abstraction of the code's memory usage (i.e., it contains all the information relevant to how the code accesses memory), developers can use projectors to answer diverse questions about the code's cache usage. The eponymous tool that implements the CFAR technique relies on a combination of static analysis, symbolic execution, and binary instrumentation to automatically extract distillates. We chose these particular program-analysis techniques because, despite their scalability limitations (discussed in §4.3), they enable precisely the level of visibility a developer seeks, enabling her to reason about how the code processes an abstract workload.

The current CFAR prototype comes with three projectors that answer frequently-asked questions about cache usage: (1) $\mathcal{P}_{\text{scale}}$ computes how the amount of data the code brings into the cache (in bytes) varies as a function of the workload; (2) $\mathcal{P}_{\text{h/m}}$ computes, as a function of workload, whether memory accesses will hit or miss in the cache; and (3) $\mathcal{P}_{\text{crypt}}$ flags cryptographic code that branches on, or accesses memory in a way that depends on secret inputs, thereby flagging potential security vulnerabilities or proving their absence. $\mathcal{P}_{\text{crypt}}$ is an example that demonstrates the flexibility of CFAR's two-phased process: since the distillate contains all information relevant to how the code accesses memory, developers can write projectors to analyze more than just standard performance properties. We envision developers contributing more such projectors to the CFAR tool, making it more useful over time. In stable state, developers will likely just use whatever ships with CFAR, extending it only when they cannot get the answers they seek.

We use CFAR to analyze a performance-critical subset of the transport layer of 4 TCP stacks—2 versions of Linux's stack (i.e., before and after the recent reorganization for cache efficiency [42]), a TCP stack used by the IX kernel-bypass OS [6], and the lwIP TCP stack for embedded systems [20]—as well as 2 hash-table implementations [60, 73], all 51 of the Hyperkernel's system calls [51], and 7 algorithm implementations from the OpenSSL cryptographic library [54]. We use the results to demonstrate how distillates and projectors enable developers to understand the cache usage of both their own and others' code, for unseen workloads, without running elaborate benchmark suites. As part of the evaluation, we also uncover a cache-inefficient data layout in the kernel-bypass TCP stack, an error path in the Hyperkernel `mmap()` system call (which, despite looking innocuous, inadvertently pollutes 40% of the L1 d-cache), and a constant-time violation in OpenSSL 3.0's implementation of AES. For all the above code, CFAR's analysis completes in minutes, which means that extraction and analysis of distillates can be feasibly integrated into a real-world software-development cycle.

The rest of this paper is organized as follows: We first motivate CFAR using examples of cache-usage questions that existing tools cannot answer (§2), then provide an overview of the CFAR approach (§3) and detail its design (§4). We then evaluate the CFAR prototype experimentally (§5), discuss related work (§6), and conclude (§7).

2 Motivation

In this section, we give an example of the kind of questions that system developers ask about their code's cache usage (§2.1), and then describe why existing tools cannot answer such questions (§2.2).

2.1 Example

Consider a developer, Alice, who is building an in-memory key-value store that has to be fast. The key-value store uses a hash table to store the key-value pairs and runs atop a user-space, kernel-bypass transport stack. Alice has modified an existing hash-table implementation to suit her needs, and thus understands that part of the code well. However, she is using an off-the-shelf transport stack [20, 34, 75], of which she understands little beyond the semantic interface it exposes.

In such a system, throughput is often bottlenecked by the number of last-level cache (LLC) misses per request [41, 67, 79]; hence, to optimize throughput, Alice needs to know how the different parts of her code use the cache and how they affect the LLC misses as a function of the workload. For example, if her system fails to reach the expected throughput due to persistent LLC misses, what is the predominant cause? Is it that the hash table code touches too many cache lines per `put()` or `get()` request? Or is it that the transport stack's buffer-management code touches too many cache lines per connection [6]? In the former case, Alice should spend her time optimizing the memory layout of the hash table [12–14], whereas, in the latter, she should port her code to alternative stacks with smaller memory footprints [20, 67]. Finally, if both codebases were already highly optimized, she should avoid wasting time on code optimizations and replicate her key-value store across multiple machines [4].

2.2 Existing Tools Are Insufficient

Existing tools like profilers [10, 43, 59, 69] and cycle-accurate simulators [7, 9] are fundamentally ill-suited to answering Alice's questions. This is because profilers and simulators are designed to reason about what the code does to the micro-architecture *for a given* workload, whereas answering Alice's questions requires reasoning about what the code does to the micro-architecture *as a function of* workload. So, while profilers and simulators can provide visibility into the code's cache usage for a given workload, they do not have *predictive power*, and thus cannot provide Alice with visibility into cache usage for workloads beyond the ones that she herself provided to the tools.

As a result, developers like Alice are forced to guess the answers to their questions based on (incomplete) information derived from profiling. Between cycle-accurate simulators and profilers, performance engineers typically prefer profilers because they are orders of magnitude faster, even if less precise. So, Alice would typically profile her system with many workloads to measure micro-architectural events and then guess the predominant cause of LLC misses. In particular, she would try to identify the properties of workloads that led to low throughput: were they those that led to a large number of `put()` or `get()` accesses per request? Or those that led to a large number of concurrent connections? This is similar to what developers in industry do to answer such questions: they run their code for multiple workloads, use profilers to count the total number of unique cache lines touched, and then manually extrapolate how workload affects their code's cache footprint [5, 42].

Reasoning about cache usage in such a manner is not only time consuming but also error prone, particularly for third-party code. For instance, Alice (who knows little about the implementation of the transport stack) may not even think about running workloads that lead to different numbers of concurrent connections. In general, performance profiling suffers from the "large input problem" [48, 53]: unexpected performance behavior often manifests only when input size (e.g., the number of concurrent connections) exceeds some threshold that may seem arbitrary to those who are not intimately familiar with the code. So, designing a test suite that completely "covers" a system's performance behaviors is hard, and developers do not even have metrics for performance coverage. While line coverage is used as a proxy for what fraction of the code's semantic behaviors is covered by tests, performance profiling does not have even such an imperfect metric.

As a result, developers like Alice often fail to identify workload properties that significantly impact cache usage, causing performance cliffs to manifest in production. For instance, developers from Google recently showed that the fast path of the Linux TCP stack had been accessing 50% more cache lines than it needed to, for over a decade, which was leading to performance degradation of up to 45% [42]. Similarly, initial work on predicting the working set of network functions ignored the impact of different packet sizes [19], and a study of Linux's system-call performance showed how a newly introduced configuration parameter can destroy spatial locality and lead to increased LLC misses [62]. In practice, developers like Alice often use incomplete performance profiling to guesstimate their system's cache usage, and then they overprovision resources for their system, to mitigate unexpected performance degradation [24]. This leads to lower system efficiency and inflated costs, and is not always effective.

Summary. Existing tools like profilers and cycle-accurate simulators are ill-suited to answering frequently-asked questions about cache usage, because they do not have *predictive power* across the space of possible workloads. As a result, developers are forced to estimate the answers to their questions using incomplete information obtained via profiling. This process is not only time consuming but also error prone, particularly when applied to third-party code.

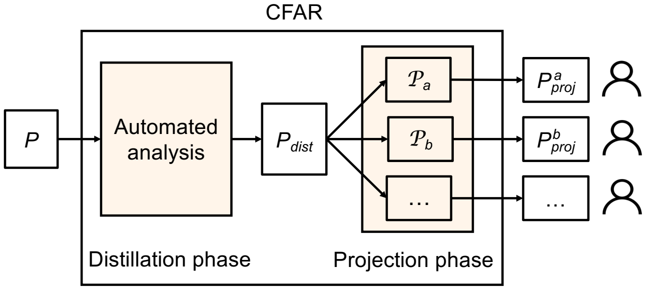

Figure 1: The CFAR workflow. P denotes a unit of systems code, P_{dist} denotes the corresponding distillate, $\mathcal{P}_i$ denotes the different projectors, and P^i_{proj} denotes the corresponding projections that provide answers to developers' questions about P's cache usage.

3 CFAR Overview

Answering questions about cache usage requires reasoning about the code. We therefore look for abstractions that precisely capture what the code does to memory (and thus the cache) as a function of its input (workload).

With this in mind, we propose two abstractions: *distillates* and *projections*. Let P be any well-defined part of a system that can be invoked individually, such as a system call in an OS kernel or a function in a library, or even a standalone program. A *distillate* P_{dist} is a program that specifies precisely and completely how P accesses memory. A *projection* P^{π}_{proj} is a much simpler program that answers a specific question π about P's cache usage. For any given P, there exists a unique distillate P_{dist}, but there can be as many projections as there are questions about P's cache usage.

We represent distillates and projections as programs—as opposed to denser, more mathematical representations (e.g., [22])—for two reasons. First, programs provide developers with a representation that they are familiar with, allowing them to quickly read and understand the answers to questions about cache usage. Second, programs can be executed, which makes it possible for tools to leverage distillates and projections for automated performance analysis; in §4 we show how CFAR executes a distillate against a cache model to reason about cache hits and misses.

Fig. 1 illustrates CFAR's workflow, which consists of two phases: The first phase takes as input a module P of a system's code and automatically extracts P's distillate. The second phase relies on simple programs ("projectors") that transform the distillate into projections that answer specific questions about P's cache usage, such as "How many unique cache lines does P touch as a function of the workload?" and "How does P's cache hit/miss profile vary as a function of the workload?" CFAR currently provides three such projectors, and we envision developers contributing more over time.

The two-phased workflow provides CFAR with the flexibility needed to answer diverse questions about cache usage. Since the distillate captures *all* information relevant to how the code accesses memory, it can always be transformed—

```
1  int sys_create(int fd, fn_t fn, uint64
       ftype, uint64 value, uint64 omode) {
2
3      if (ftype == FD_NONE)
4          return -EINVAL;
5      if (!is_fd_valid(fd))
6          return -EBADF;
7      if (&proc_tbl[pid]->ofile[fd] != 0)
8          return -EINVAL;
9      if (!is_fn_valid(fn))
10         return -EINVAL;
11
12     struct file = get_file(fn);
13     if (file->refcnt != 0)
14         return -EINVAL;
15     file->type = ftype;
16     file->value = value;
17     file->omode = omode;
18     file->refcnt = file->offset = 0;
19     set_fd(pid, fd, fn);
20     return 0;
21 }
```

```
1  def sys_create_dcache(fd, fn, ftype, value, omode):
2      # State: pid, proc_tbl, file_tbl
3
4      if ftype == FD_NONE: #6 accesses
5        return [(w,rsp-8),(w,rsp-16),..,(r,rsp-8)]
6
7      if not(fd >=0 and fd < NOFILE): #6 accesses
8          return [(w,rsp-8),(w,rsp-16),..,(r,rsp-8)]
9
10     if [proc_tbl+256*pid+64+8*fd]: #7 accesses
11         return [(w,rsp-8),(w,rsp-16),..,(r,proc_tbl+256*pid+64+8*fd),..,(r,rsp-8)]
12
13     if not(fn >=0 and fn < NOFILE): #7 accesses
14         return [(w,rsp-8),(w,rsp-16),..,(r,proc_tbl+256*pid+64+8*fd),..,(r,rsp-8)]
15
16     if [file_tbl+40*fn+8]: #9 accesses
17         return [(w,rsp-8),(w,rsp-16),..,(r,proc_tbl+256*pid+64+8*fd)..,(r,file_tbl+40*
       fn+8),..,(r,rsp-8)]
18
19     # Succesful create. 17 accesses
20     return [(w,rsp-8),(w,rsp-16),..,(r,proc_tbl+256*pid+64+8*fd),..,(r,file_tbl+40*fn
       +8),(w,file_tbl+40*fn),(w,file_tbl+40*fn+16),..,(w,proc_tbl+256*pid+64+8*fd)
       ,..,(r,rsp-8)]
```

Figure 2: Example program on left (Hyperkernel `sys_create` system call that creates a new file) and the corresponding data-accesses distillate.

```
def sys_create_icache(fd, fn, ftype, value, omode):
    # State: pid, proc_tbl, file_tbl
    # sys_create abbreviated as s

    if ftype == FD_NONE: # 10 instructions
      return [(r,s),..,(r,s+168),..,(r,s+176)]

    # Error paths elided for presentation clarity
    ......

    # Succesful create. 45 instructions
    return [(r,s),(r,s+8),..,(r,s+160),(r,s+168),(r,s+176)]
```

Figure 3: Instruction-accesses distillate for `sys_create`.

using a suitable projector—into a projection that answers a specific question about the code's cache usage. We demonstrate this flexibility by building a projector ($\mathcal{P}_{\text{crypt}}$) that goes beyond standard performance analysis and uses the distillate to identify potential cache-based security vulnerabilities.

CFAR does not make any assumptions about the kind of code that it takes as input. That said, in this work, we focus on systems code (e.g., operating systems, device drivers, network stacks, hypervisors), since it is code for which cache usage has a significant impact on performance.

We now define the three key components of CFAR, namely distillates (§3.1), projectors (§3.2), and projections (§3.3). Table 1 summarizes these definitions.

Notation	Description
P	A unit of code that can be invoked individually (e.g., system call, library function, standalone program). It takes as input I and has initial state S_0.
Ω	An ordered sequence of memory accesses (to symbolic addresses).
$\mathcal{P}_\pi$	A *projector*. It is a program that defines a function/property $\pi(\Omega)$ related to cache usage.
P_{dist}	The unique *distillate* of P. It is a program that takes as input I and computes Ω as a function of I and S_0, where Ω is P's memory-access sequence.
P^{π}_{proj}	A *projection* of P. It is a program that takes as input I and computes $\pi(\Omega)$ as a function of I and S_0, where Ω is P's memory-access sequence and $\pi(\Omega)$ is defined by a projector $\mathcal{P}_\pi$.

Table 1: Glossary.

3.1 Distillates

Consider a program (or function, or method) P, with input(s) I, and state S_0 at the time of invocation. S_0 consists of the values of P's objects in the heap and the stack up to `%rsp`.

P's *distillate* P_{dist} is another (typically simpler) program that takes the same input(s) I, and computes P's sequence of memory accesses Ω as a function of I and S_0. Since accessing data vs. instructions exhibits distinct patterns, we distinguish between a data-accesses distillate P^{data}_{dist} and an instruction-accesses distillate P^{instr}_{dist}. The former computes the sequence of data-memory accesses that would be observed if executing P with input I starting from state S_0, while P^{instr}_{dist} computes the corresponding instruction-memory accesses.

We illustrate what a distillate looks like with the example of the `sys_create` system call (Fig. 2, left) in the Hyperkernel [51]. First, each memory access in Ω is a tuple $<type, addr>$, where *type* can be read (`r`), write (`w`) or read-modify-write (`rmw`), and *addr* is a memory address. In a data-accesses distillate (Fig. 2, right), each memory address is a function of standard state components (e.g., the stack pointer `%rsp`), as well as components that are specific to P. For example, line 11 in the distillate describes accesses that are a function of `proc_tbl`, `pid`, and `fd`, which arise from executing line 7 in `sys_create`. If a memory address is independent of I and S_0 (e.g., the address of a `struct` allocated by P in the heap and then freed before returning), it is represented as a named constant (e.g., `mallocRetVal@file.c:342`). In an instruction-accesses distillate (Fig. 3), each memory address is represented as an aligned offset relative to the address of the first instruction in P. In our particular example, the compiler inlines all helper functions, hence there is only one base address `s`.

The distillate P_{dist} is a precise and complete representation of P's memory usage. It is *precise* because it provides the exact sequence of memory accesses for any execution of P. The symbolic expressions for data- and instruction-memory accesses as a function of I and S_0 are precise by construction, and therefore correct for any concrete instantiation of I and S_0. The distillate is *complete* in that it contains all information on P's memory accesses that can be found in P. No matter what the concrete values of I and S_0, how the address space is randomized [1], or where in memory the code is loaded, P_{dist} will always be able to produce the exact sequence of memory accesses that P makes when executing from S_0 with input I.

3.2 Projectors

A *projector* $\mathcal{P}_\pi$ is a program that defines a function $\pi(\Omega,\ldots)$ related to cache usage. For example, a projector may define $\pi(\Omega) = |\Omega|$, i.e., the number of memory accesses in Ω, while another projector may define $\pi(\Omega) = |\{\lambda(r) = \lfloor r/64 \rfloor : r \in \Omega\}|$, i.e., the number of unique 64-byte cache lines accessed by Ω.

We think of a function π as a question about cache usage (e.g., "How many memory accesses does this piece of code perform?" or "How many unique cache lines does the code access?"). CFAR enables developers to write their own projectors, such that they can formulate their own questions.

A key property of projectors is that they are *code-agnostic*: A function $\pi(\Omega, \ldots)$ defined by projector $\mathcal{P}_\pi$ is independent of the semantics of the code that produced Ω (or any of the other arguments). This code-agnostic nature makes projectors easy to express; for example, a developer can write the simple projector that defines $\pi(\Omega) = |\Omega|$ (mentioned above) to query the number of memory accesses performed by *any* P, without having to understand P's details.

The function π may take inputs beyond just Ω. For example, it may take as additional input a cache model, and compute the number of hits and misses incurred by Ω in the L1 data cache given that particular cache model. Since Ω is independent of where and how the code that produced it was executed, such a generalized function π can precisely characterize the impact of running a piece of code on different micro-architectures and/or with different OS configurations (e.g., for different memory-page sizes that P may use).

3.3 Projections

A *projection* P^{π}_{proj} of P is another (typically simpler) program that takes the same input(s) I as P, and computes the value of function π for P, as a function of I and S_0. Said differently, if we think of π as a specific question about cache usage, then P^{π}_{proj} is a program that provides the answer to that question for P. Fig. 4 shows a projection of `sys_create` that computes the number of data memory accesses performed by the system call as a function of its input and the OS state. CFAR produces P^{π}_{proj} by applying the projector $\mathcal{P}_\pi$ to P's distillate P_{dist}.

```
def sys_create_dcache_num_accesses(fd, fn, ftype, value, omode):
    # State: pid, proc_tbl, file_tbl

    if ftype == FD_NONE:
      return 6

    if not(fd >=0 and fd < NOFILE):
        return 6

    if [proc_tbl+256*pid+64+8*fd]:
        return 7

    if not(fn >=0 and fn < NOFILE):
        return 7

    if [file_tbl+40*fn+8]:
        return 9

    # Succesful create.
    return 17
```

Figure 4: Projection of `sys_create` that describes the number of data memory accesses.

Summary. CFAR provides abstractions to reason about what a program does to the memory hierarchy. If a program is a function P: $<I, S_o> \rightarrow$ semantic outputs, we say that the distillate is a function P_{dist}: $<I, S_o> \rightarrow \Omega$ that abstracts away everything that has to do with program semantics and preserves information about memory accesses. The projection is a function P^{π}_{proj}: $<I, S_o> \rightarrow \pi(\Omega)$ that computes an answer and abstracts away all unrelated information. This is a progression of abstraction steps, starting from the original program and arriving at the final projection. Each step takes the same arguments $<I, S_o>$, but returns a result that is increasingly more focused on the cache-usage question at hand.

4 CFAR Design

We now provide more details on the two phases of CFAR: distillation (§4.1) and projection (§4.2).

4.1 Phase #1: Distillation

CFAR automatically distills an input program P into its corresponding distillate P_{dist} using a four-step process, shown in Fig. 5: it ① enumerates all feasible executions paths in P using automated program analysis; then ② obtains a binary execution trace for each such path; then ③ based on the results of these two steps, prepares an execution tree for the distillate; and lastly ④ optimizes this tree and produces P_{dist}.

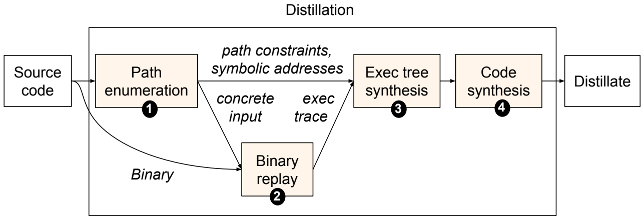

Figure 5: The four steps in CFAR's distillation process.

Our use of context-sensitive program analysis and binary replay ensures that CFAR can extract a precise distillate without requiring any effort on the part of the developer, but this also imposes limitations. Most notably, CFAR is subject to the scalability limitations of such program analysis and is thus not ideal for reasoning about multi-threaded code or about code with loops whose bounds cannot be statically computed. Additionally, CFAR is also limited by the proprietary nature of modern hardware. For instance, since the exact algorithms used to schedule instructions in an out-of-order processor are not publicly available, CFAR cannot reason about speculative memory accesses. We describe CFAR's limitations in detail in §4.3, but we note here that, despite these limitations, CFAR is able to provide valuable information about cache usage that is otherwise unavailable, and do so for a wide variety of systems code (§5).

4.1.1 Step ①: Path enumeration

To enumerate all the paths in P, CFAR uses *exhaustive* symbolic execution [11, 26, 36, 65]. This is a context-sensitive program-analysis technique that automatically traverses the feasible execution paths of a body of code, enabling a comprehensive analysis of its control flow. The technique is powerful but also faces challenges related to loops and pointers, which we discuss in §4.3. We use an exhaustive form of this technique, which yields *all* feasible paths in P.

For each enumerated path α, CFAR saves four key pieces of information: (1) the precise path constraint C_α that uniquely defines this path, i.e., the conjunction of the predicates of each conditional along α; (2) a concrete input I_α that exercises this path, obtained by asking an SMT constraint solver [18] for a satisfying assignment to the free variables in C_α; (3) the symbolic expression corresponding to the address of each data/instruction memory location accessed along the path, expressed as a function of P's inputs and/or state; and (4) a corresponding `file:linenum` identifier for each memory operation, to be used later. The sequence of these symbolic expressions is ω_α.

Our CFAR prototype uses KLEE [11] to perform the symbolic execution. KLEE, like many other symbolic-execution engines, analyzes the code at the IR level, which in KLEE's case is LLVM [16]. CFAR can therefore handle any code that is compiled to LLVM and can be handled by KLEE. Our KLEE modifications and additions total ~1,500 lines of C++.

4.1.2 Step ②: Binary replay

What actually executes on the hardware is not the source code or the IR. Compiler optimizations, such as link-time optimization, cause the executing machine code to not directly correspond to what is in the IR. Furthermore, many IRs are Static Single Assignment (SSA), in which each variable is assigned exactly once. This makes the data flow and dependencies among variables more explicit and easier for the compiler to analyze, but also implies an infinite register file. Processors do not have infinite register files so, during an actual execution, register values often need to be spilled to the stack. Since these pushes and pops to/from the stack are not present in an SSA IR, and thus not captured when analyzing P in its IR form, the corresponding memory accesses will not appear in ω_α.

Therefore, CFAR replays an *instrumented* version of the *P binary* for each I_α, to obtain a corresponding execution trace X_α for each path α in P. For each machine instruction executed in X_α, CFAR saves the program counter, the instruction opcode (e.g., `mov`, `push`, `pop`), the concrete memory addresses accessed, and the corresponding `file:linenum` debug information inserted into the binary by the instrumentation.

We deliberately split the CFAR analysis into a source-based and a binary-based step. On the one hand, it is easier to extract symbolic expressions for memory operations by analyzing the source code or the IR. On the other hand, analyzing the binary enables CFAR to be fully precise with respect to compiler optimizations and which instructions lead to memory accesses and do not merely manipulate CPU registers. In theory, these two steps could be combined into a single one by directly executing the binary symbolically (e.g., with S2E [15]). To answer with certainty whether this is possible, one would need to assess how CFAR is affected by the loss of type information when going from source code to binaries.

The CFAR prototype uses Intel PIN [46] to instrument binaries. Our Pintool consists of ~350 lines of C++.

4.1.3 Step ③: Execution tree synthesis for P_{dist}

In this step, CFAR combines the information extracted in the previous two steps. For each path α in P, it combines the symbolic memory trace ω_α with the corresponding binary execution trace X_α. To produce a *data*-access trace, CFAR takes the sequence of concrete addresses from X_α and replaces (using debug information) all input- and state-dependent accesses with the corresponding symbolic expressions from ω_α, resulting in Ω_α^{data}. To produce an *instruction*-access trace, CFAR uses the program-counter values and the call stack in X_α to compute the symbolic offset of each instruction from the start of P (e.g., from its entry point, if P is a function or a system call) to produce Ω_α^{instr}. The call stack gives CFAR information on which function the instruction belongs to, so that it can compute the function-specific offset.

Next, CFAR assembles an execution tree using the path constraints C_α. It arranges all the paths into a tree based on their common prefixes; for every path α there exists a path from root to leaf in the tree, and vice-versa. Each internal node of the tree contains the predicate corresponding to the original branch in P. The conjunction of the predicates for all internal nodes along a root-to-leaf path forms the corresponding path constraint C_α.

4.1.4 Step ④: Synthesis of the P_{dist} distillate

The final step in CFAR's distillation process consists of summarizing loop-related memory access patterns, along with other improvements for human readability of P_{dist}. Symbolic execution, by default, unrolls loops and thus produces a separate execution path for each loop iteration. This leads to bloated distillates that are hard to read and contain redundant information, particularly if the code's memory-access pattern does not change meaningfully across loop iterations.

Summarizing a loop entails representing the effects of that loop without representing all its iterations explicitly. Conceptually, the goal of this step is to eliminate from the execution tree the subtrees induced by loop unrolling. This step does not elide or lose any information contained in the distillate—it only optimizes the distillate's control flow for human readability. By definition, any projection derived from P_{dist} will retain P's control flow, as reflected in the distillate.

While automatically summarizing loops in general is undecidable [25], studies have shown that there exist four common categories of loops that relate to data locality issues in systems code [35]. Therefore, CFAR contains loop-summary templates for these four categories of loops—two that traverse array-like data structures, and two that traverse pointer-chasing data structures (e.g., linked lists, trees). All four categories require the loop body to not branch on the specific value of the iteration counter, and require the loop to have a maximum of two termination predicates, one in the loop definition and at most one `break` in the body. Each loop template has a corresponding loop summary.

For loops that do not match a template, the distillate presents them in unrolled form—still correct, just less human-readable. We thus call this "best-effort" loop summarization.

After loop summarization and a few other optimizations for readability, CFAR transforms the tree into a program that represents P_{dist}. This program takes the same input as P. Every internal tree node generates an `if` statement in the program, branching on the predicate contained in that node. Each path through the program ends with a `return` of the corresponding Ω_α. Depending on the memory-type of the distillate, the returned symbolic memory-access trace is either Ω_α^{instr} or Ω_α^{data}.

Fig. 6 shows a snippet for the P_{dist}^{data} distillate of the `memcmp` function in the C standard library. Our CFAR prototype uses Python to represent distillates, because it is one of the most widely used languages [52] and has an easy-to-understand syntax. The example illustrates CFAR's loop summarization for a loop that belongs to the first category of loops mentioned above. CFAR uses first-order logic to summarize loops with primitives from Z3's Python API [72]. The predicate that starts on line 3 identifies the smallest index `i` (bounded by `len`) at which the two strings differ. The distillate shows that the memory accessed by `memcmp` corresponds to every element of the two arrays up to `i`.

```
1 def memcmp_dcache(s1,s2,len):
2
3     if Exists(i,And(0<=i<len,[s1+i]!=[s2+i],
4                     ForAll(j, Implies(0<=j<i),[s1+j]==[s2+j]))):
5
6       return ForAll(k, Implies(0<=k<=i),[(r,s1+k),(r,s2+k)])
7     return ForAll(k, Implies(0<=k<=len),[(r,s1+k),(r,s2+k)])
```

Figure 6: P_{dist}^{data} for `memcmp` showing CFAR's loop summarization.

4.2 Phase #2: Projection

The distillate produced by the previous phase contains *all* the information on P's memory-access behavior. The answer to a developers' cache-usage question can therefore be found in the distillate, but it is buried among details that may not be relevant to that question. The projection phase turns distillates into focused, actionable answers that are not clouded by details irrelevant to the question being asked.

4.2.1 General overview

Developers write projectors in the form of programs that take as input a tuple $<\Omega, C>$, along with possibly other projector-specific parameters, such as the cache model mentioned in §3.2. Ω is a symbolic memory-access trace, and C is a constraint on the variables that appear in the symbolic addresses of Ω, in the form of a first-order logic expression.

We expect most projectors to ignore C and implement a function of just Ω, like $\pi(\Omega) = |\{\lambda(r) = \lfloor r/64 \rfloor : r \in \Omega\}|$. We therefore did not mention the C parameter in §3.2, for clarity of presentation, but, to answer all cache-usage questions, the more general function $\pi(\Omega, C)$ is sometimes needed. For example, determining if all memory accesses are cache-line-aligned requires, in the general case, both Ω and C. The origin of this constraint C is the path constraint that causes the original program to execute the memory accesses in Ω. The branch predicates in distillates are such constraints. The constraint can be simple, like `0≤idx<128`, or more sophisticated, stating for example that the value stored at a particular memory location is non-zero: `[file_tbl+40*fn+8]`$\neq 0$. In our prototype, Ω and C are Python lists of Z3 expressions [72].

To produce a projection, CFAR takes a projector program $\mathcal{P}_\pi$ and a distillate P_{dist}, and synthesizes a new program P_{proj}^{π}. For each branch in P_{dist}, the P_{proj}^{π} program has the same branch as P_{dist} but, instead of returning Ω (as the distillate does), it returns the value of invoking $\mathcal{P}_\pi\ (\Omega, C, \ldots)$. In other words, the projection P_{proj}^{π} has the same control flow as the distillate but, instead of calculating a memory-access trace, it calculates a specific cache-usage property of that trace.

4.2.2 Example projectors: $\mathcal{P}_{\text{scale}}$, $\mathcal{P}_{\text{h/m}}$, and $\mathcal{P}_{\text{crypt}}$

Our CFAR prototype comes with three example projectors: (1) $\mathcal{P}_{\text{scale}}$ computes how the cache footprint (in bytes) varies across an entire range of previously unseen inputs (e.g., how it scales with the number of active network connections); (2) $\mathcal{P}_{\text{h/m}}$ computes the cache hit and miss profiles per class of inputs, as opposed to per specific, concrete input; and (3) $\mathcal{P}_{\text{crypt}}$ flags cryptographic code that accesses the cache in a way that depends on secret inputs. This projector can be used to find potential security vulnerabilities or prove their absence.

While the questions answered by these projectors are non-trivial, the projectors themselves are straightforward to write. For example, we express the functionality of both $\mathcal{P}_{\text{scale}}$ and $\mathcal{P}_{\text{crypt}}$ in less than 100 lines of Python. While $\mathcal{P}_{\text{h/m}}$ requires ~800 lines, almost 600 of those are a Python translation of the cache model from the `gem5` cycle-accurate simulator [7]. In §5.2, we show how a simple 5-line projector helped us identify a performance bug in a TCP stack used by IX [6].

$\mathcal{P}_{\text{scale}}$ computes cache footprint based on the symbolic Ω for a given input class. $\mathcal{P}_{\text{scale}}$ first determines which addresses in Ω change if the value of the input changes. It then uses an SMT solver to check the alignment of these addresses and determine the number of unique bytes touched by the accesses to those addresses, and produces the result as a human-readable formula. For instance, applying $\mathcal{P}_{\text{scale}}$ to the `sys_create` distillate in Fig. 2, for the input class that corresponds to successful creation (line 20), yields the formula `8*fd + 32*fn`. This formula says that, in a sequence of successful `sys_create` calls, the cache footprint will increase by 8 bytes for each distinct `fd` argument value and by 32 bytes per distinct `fn` argument value. This is how `fd` and `fn` influence the cache footprint, and this is exactly the information that Alice wanted to know for keys and network connections in §2. $\mathcal{P}_{\text{scale}}$ can be used, for instance, to quickly determine when the code's working set will overflow the cache.

$\mathcal{P}_{\text{h/m}}$ is more sophisticated and takes four projector-specific parameters: a workload size W, an input set cardinality N, a probability mass function PMF, and a cache model. Its goal is to compute the number of hits and misses experienced by a workload of W inputs that can take on any of N distinct types, distributed within the workload according to the PMF, when using a cache that works according to the model. In the scenario we will explore in §5 for a TCP network stack, W would be the number of packets in a trace, and N the number of unique connections—what distinguishes packet types is which connection they belong to. The PMF would be the relative distribution of packets among the N connections.

$\mathcal{P}_{\text{h/m}}$ first produces a workload of W symbolic inputs satisfying the PMF. For example, if W=5 and N=2 and the PMF is $< 0.4, 0.6 >$, the workload would be $< \lambda_1, \lambda_2, \lambda_1, \lambda_2, \lambda_2 >$ or some other variant that satisfies the PMF. Then, for each symbolic input in the workload, $\mathcal{P}_{\text{h/m}}$ iterates through Ω and sends each memory access to the cache model; the access may be a function of the λ_i symbolic input, or independent of it. $\mathcal{P}_{\text{h/m}}$ records, for each access, whether it is a hit or a miss.

Since there are multiple workload variants that satisfy the PMF, the process above repeats, with alternate variants, until the resulting hits/misses counts are statistically significant.

$\mathcal{P}_{\text{h/m}}$ can be thought of as a symbolic, trace-based cache simulator. A major challenge is, when dealing with symbolic addresses, $\mathcal{P}_{\text{h/m}}$ cannot compute set-associativity conflicts precisely. Instead, $\mathcal{P}_{\text{h/m}}$ *approximates* them by allocating an unconstrained, symbolic memory address (typically the base of a data structure) randomly to a set in the cache, and then mapping all relative addresses as offsets from that base. For example, if the address γ is randomly mapped to set μ, then the address $\gamma + 64$ would be deterministically mapped to set $(\mu + 1)$ `mod` # of sets in the cache. In §5 we will see that this approximation works well when compared to real hardware.

By default, $\mathcal{P}_{\text{h/m}}$ provides a 3-level inclusive cache with a next-line prefetcher whose size and set associativity at each level is configurable. The default PMF is uniform, and W=100N. $\mathcal{P}_{\text{h/m}}$ assumes that the memory trace Ω does not update initial program state S_0 that influences addresses in Ω.

$\mathcal{P}_{\text{crypt}}$ is an example of a projector that also takes the path constraint C into account. Its goal is to answer the question of whether there are any data accesses to secret-dependent memory addresses or secret-dependent branches, both of which are known sources of side channels [3]. $\mathcal{P}_{\text{crypt}}$ takes, as a projector-specific input, a list of program inputs that constitute secrets. It then uses an SMT solver to determine which (if any) of the memory addresses in Ω are influenced by secrets. It then checks whether any of the secrets appear in the path constraint C. If it finds any, then $\mathcal{P}_{\text{crypt}}$ returns `file:linenum` debug information for the corresponding branch or memory access, as well as the path constraint that leads to it. If none found, then $\mathcal{P}_{\text{crypt}}$ states that the code does not have secret-dependent branch instructions or data accesses.

$\mathcal{P}_{\text{crypt}}$ cannot check for all types of cache-based leakage. For example, leakages due to speculatively executed instructions [44] are out of scope for $\mathcal{P}_{\text{crypt}}$.

4.3 Limitations and Assumptions

Scalability limitations of symbolic execution: CFAR's reliance on symbolic execution (SE) makes it subject to SE's own limitations. Depending on which SE engine is used, certain kinds of loops, or symbolic pointers, or multi-threading could prevent CFAR from obtaining all execution paths [8]. However, there is active research on this topic, and recent SE engines have brought various enhancements that overcome these challenges, such as state merging [39], loop-extended symbolic execution [64], loop summaries [27, 71], loop invariants [33], and symbolic abstract transformers [37].

Any CFAR prototype will ultimately inherit the power of its underlying SE engine. Since our prototype relies on KLEE [11], code whose loops do not have statically computable bounds, or that is multi-threaded, or that has arbitrary symbolic pointers is not an ideal match, because path exploration may take too long. This makes our current prototype a poor fit for analyzing entire systems, like the Memcached or Redis key-value stores. Nevertheless, we show in §5 that CFAR extracts useful distillates for key components of complex systems code (e.g., for data structures whose cache footprint is a common source of performance problems).

Using CFAR for code that is not amenable to exhaustive symbolic execution: CFAR's reliance on exhaustive symbolic execution means that automatically extracting complete distillates is not always feasible. We now discuss how developers can obtain useful results with CFAR even in such cases.

A simple approach is to *constrain the input space*, e.g., constrain CFAR to inputs that trigger the "fast path" through the code, since that is a common target of performance analysis. For instance, if the code of interest is an IP-packet forwarding function, it is reasonable to constrain the distillate to packets without IP options. This dramatically reduces both the size of the distillate and the time required to obtain it (since it eliminates the part of the code that loops through the variable-length IP options), while still yielding practically useful results (since performance-sensitive traffic typically does not carry IP options). Focusing on the cache usage of the fast path is common practice today; for instance, the recent reorganization of the Linux TCP stack was based entirely on the requirements of the TCP fast path [42].

For constraining the input space, CFAR provides an interface similar to KLEE's [11], with which developers can provide constraints on arbitrary program variables. In our evaluation, we use this approach to analyze code that is not amenable to exhaustive symbolic execution (e.g., the Linux TCP stack), and the results are compelling despite the constrained input space. Constraining the input space requires the developer to have some knowledge of, for instance, what typical/fast-path inputs look like. However, it does not require knowledge of the code's internal details, because these are explored automatically by CFAR.

An alternate approach is to run CFAR with a specified time budget. When the time limit is reached, CFAR outputs a partial distillate that returns the exact sequence of symbolic memory accesses performed by the code along the explored execution paths. While this approach does not require developer knowledge, the downside is that CFAR may not explore all meaningful execution paths in the given time budget. The CFAR prototype offers this time-budget feature, but we did not use it in any of the experiments in our evaluation.

Prototype cannot aggregate across input classes: In the current projection model (§4.2), a projector instance gets to see only the Ω corresponding to one input class. Our CFAR prototype does not yet support sharing state across different instances of projectors, and thus does not support aggregating measures across multiple input classes. This support is simple to add, we just have not encountered the need for it yet.

Cannot account for inter-process interactions: Projectors cannot answer questions that span multiple processes. Also, we assume that P is small enough to not have its execution interrupted by preemption. The distillate P_{dist} is always correct with respect to P, but the predictions made based on this distillate alone will miss cache accesses performed by code other than P during a preemption. In other words, if the period of interest includes a preemption, when a projector looks at Ω, it does not get the full picture, because P is not the only code that interacts with the micro-architecture.

Limitations due to proprietary hardware details: CFAR employs binary instrumentation to obtain an execution trace. Such instrumentation can only reveal instructions that the processor retires (i.e., finishes executing); it does not reveal instructions that were executed as a result of incorrect speculation, such as a mispredicted branch. Speculated instructions nevertheless could impact the cache, even if their semantic effects are undone. Since CFAR does not see those accesses, the answers computed by projectors may not be fully accurate. We are not aware of any tool that can precisely report such mis-speculated instructions during an execution, since the scheduling algorithms used in the out-of-order pipelines of commercial processors are proprietary.

5 Evaluation

In this section, we evaluate the CFAR prototype by answering two main questions:

- **Does CFAR work?** We show that CFAR extracts 100%-accurate data- and instruction-accesses distillates, and that this extraction completes in minutes for various kinds of systems code (§5.1).
- **Is CFAR useful** to system developers? We describe four use cases that demonstrate how CFAR provides developers with visibility into cache usage in a way that profilers and simulators cannot (§5.2).

Evaluation targets. We used CFAR to analyze the fast path of the transport layer of 4 TCP stacks: 2 versions of Linux's stack (before and after the recent reorganization for cache efficiency [42]), a TCP stack used by the IX kernel-bypass OS [6], and the lwIP TCP stack for embedded systems [20]. We also analyzed 2 hash-table implementations [60, 73], all 51 system calls in the Hyperkernel [51], and 7 algorithm implementations in OpenSSL 3.0.0 [54]. For the Linux TCP stack, we analyzed the stable versions before and after the reorganization (`v6.5` and `v6.8`). For all other code, we analyzed the latest stable version. IX uses the lwIP stack as a starting point, but heavily modifies the internal data structures and timer management [6].

We demonstrate that CFAR provides actionable cache-usage information for a broad spectrum of systems code. At one end of the spectrum are the Hyperkernel and OpenSSL, both of which are amenable to automated program analysis. The hash-table implementations occupy the middle, since they are both amenable to manual (but not automated) program analysis. At the other end of the spectrum are the four transport-layer implementations, which were not written to be amenable to any form of program analysis.

Setup. All experiments ran on an Intel Xeon E5-2690 v2 CPU at 3.30GHz with 25.6MB of LLC and 252GB of DRAM, with Ubuntu 22.04 and Linux kernel v5.4. The CFAR prototype incorporates a modified version of KLEE 2.1.

5.1 Does CFAR Work?

There are two key aspects to this question: does CFAR obtain an accurate abstract representation of performance from the code (§5.1.1), and does it do so in reasonable time (§5.1.2).

5.1.1 Accuracy of distillates

To measure the accuracy of our prototype's distillates, we randomly picked half the execution paths of each target, constructed inputs that exercised each path, counted the number of instructions and memory accesses executed while running with each concrete input, and then compared this number to the one predicted by the target's distillates.

The error was always **zero**, across all programs and inputs. That is, the number of instructions counted during real execution always equaled the number of memory accesses predicted by the instruction-accesses distillate for the given input, and the number of memory accesses counted during real execution always equaled the number of memory accesses predicted by the data-accesses distillate for that input. Additionally, CFAR's distillates correctly predicted every instruction-memory and data-memory address accessed by the code.

5.1.2 Time to extract distillates

Table 2 shows how long CFAR takes to extract distillates: for all programs, the analysis completes in less than 30 min. The longest times are for the Vigor hash table and the `echde` key-generation algorithm in OpenSSL; they are the only ones that take more than 15 min. This is because, for these programs, symbolic execution needs to unroll long loops that iterate over the hash map and that compute co-prime numbers, respectively. For all programs, the binary replay, execution-tree synthesis, and code synthesis take approximately 2-3 min in total. The dominant component of CFAR's analysis time—and the one that varies across programs—is symbolic execution.

Program	P_{dist} extraction time
Linux TCP ingress	11 min
Linux TCP egress	14 min
IX TCP ingress	5 min
IX TCP egress	7 min
lwIP TCP ingress	4 min
lwIP TCP egress	5 min
Hyperkernel syscalls (51 total)	Avg: 4 min / Max: 7 min
OpenSSL primitives (7 total)	Avg: 9 min / Max: 22 min
Vigor hash table	28 min
Klint hash table	12 min

Table 2: Time taken by CFAR to extract distillates.

5.2 Is CFAR Useful for System Developers?

We demonstrate CFAR's usefulness by presenting four cases of CFAR answering important questions that developer Alice cannot readily answer with the state of the art: How does my code's working set vary with the workload (§5.2.1)? I want to use a third-party data-structure library, but how does it interact with my cache (§5.2.2)? Does my code lead to inefficient memory-access patterns (§5.2.3)? Can I prove/disprove the absence of secret-dependent memory accesses (§5.2.4)?

5.2.1 How does the working set vary with workload?

We used the $\mathcal{P}_{\text{scale}}$ and $\mathcal{P}_{\text{h/m}}$ projectors to analyze the cache usage of the fast path of the transport layer of the four TCP stacks. Recall that this is the question that Alice wanted to answer in §2, but could not.

We constrain the input space as discussed in §4.3: focus the analysis solely on packets processed in the TCP fast path, i.e., packets that belong to an established TCP connection, are received in order, and do not suffer hash collisions with packets from other connections. We pick this particular class of packets because it represents a large fraction of packets processed by the TCP stack, on the path for which performance matters the most. The recent re-organization of the Linux TCP stack was focused entirely on this fast path [42].

First, we used $\mathcal{P}_{\text{scale}}$ to figure out the number of unique cache lines touched by the TCP fast path, for symbolic packet contents. The answer was 4, 5, 8, and 12 unique cache lines for the lwIP, kernel-bypass, Linux stack `v6.8` and `v6.5`, respectively. $\mathcal{P}_{\text{scale}}$ provides this information automatically, whereas benchmarking or code inspection would have a hard time producing it, because it cannot be gleaned merely by observing the size of the connection-specific `struct`. For example, in Linux, the `struct tcp_sock` occupies 42 cache lines in total, but only a fraction of them are accessed on the fast path.

We then passed this information to $\mathcal{P}_{\text{h/m}}$ and used it to predict when incoming packets were likely to suffer consistent cache misses due to the working set overflowing the LLC. The answer was that this would occur at approximately 91K, 76K, 47K, and 28K concurrent connections for the lwIP, kernel-bypass, Linux stack `v6.8` and `v6.5`, respectively. The small differences between these predictions and simple capacity-based calculations (e.g., 25.6M LLC / (64*4) = 100K connections for lwIP) are due to $\mathcal{P}_{\text{h/m}}$ being able to account for conflict misses in addition to capacity misses.

To verify these predictions, we ran a set of experiments where the transport layer receives and sends packets from/to a fixed set of established connections, and we varied the number of connections. To isolate just the transport layer (which is the code we analyzed), we wrote simple shims for the application and IP layers ourselves. In each experiment, we measured the average latency incurred by packets within the transport layer.

Fig. 7 plots packet-processing latency as a function of the number of connections. For each of the four stacks, there is a clear shift around the number of connections predicted by $\mathcal{P}_{\text{h/m}}$. For instance, the latency for the Linux stack `v6.5` increases by only 64ns from 1K to 26K connections, but increases by 211ns from 26K to 52K connections. Likewise, although less visible in the graph due to Linux's higher latency, the latency for the lwIP stack increases by only 13ns from 1K to 86K connections, and it increases by 50ns from 86K to 125K connections. The shift does not occur exactly at the predicted number of connections, but very close to it: compared to the predicted values of 28K, 47K, 76K, and 91K, we observed the shifts at 26K, 44K, 72K, and 86K, respectively. This difference is expected, because of $\mathcal{P}_{\text{h/m}}$'s set-associativity conflict approximation (§4.2.2) and because cache-mapping policies are proprietary, so $\mathcal{P}_{\text{h/m}}$'s cache model is imprecise.

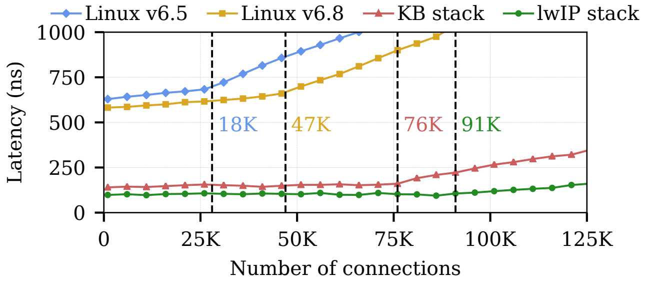

Figure 7: Measured latency for TCP packet processing as a function of the number of connections. CFAR predicted consistent LLC misses to start occurring at 28K, 47K, 76K and 91K connections for the Linux TCP stack `v6.5`, Linux TCP stack `v6.8`, the kernel-bypass (KB) stack and the lwIP stack, respectively.

Conclusion. Based on these results, we conclude that CFAR's $\mathcal{P}_{\text{scale}}$ and $\mathcal{P}_{\text{h/m}}$ projectors enable developers to accurately identify how the working set of third-party code or their own code changes as a function of the workload, without requiring them to run elaborate benchmarks. Given that CFAR can extract distillates in under 30 minutes, such extraction and analysis of distillates can become part of the regular development cycle (e.g., be made part of a continuous-integration pipeline), enabling developers to identify surprising performance behavior early and with relatively little effort.

5.2.2 How does third-party data-structure library code interact with my cache?

System developers often want to use third-party data-structure implementations, but are anxious about how that code will interfere with their own usage of the cache. We used the $\mathcal{P}_{\text{scale}}$ and $\mathcal{P}_{\text{h/m}}$ projectors to show how one can get cache-usage information for the hash-table implementations from Vigor [73] and Klint [60]. The analysis we show here can drive the choice between using one library vs. the other. We did not write the two libraries, but we read their code and *thought* we understood it fairly well.

For the CFAR analysis, we constrained the input space by fixing the maximum capacity of the hash tables to 64K entries. The resulting distillates had a different branch for each possible number of hash collisions, which is bound by the maximum capacity (thus, 64K cases). The conclusion of the CFAR analysis is therefore formally correct only for this maximum capacity. However, both hash-table implementations take the capacity as a configurable parameter, and the resulting memory-access pattern is independent of table capacity. We validated this through code inspection, we just cannot prove it formally using symbolic execution. Thus, like a developer, we proceeded to use $\mathcal{P}_{\text{scale}}$ and $\mathcal{P}_{\text{h/m}}$ assuming that the distillates for the two hash tables provide valid predictions for any capacity, as long as the number of collisions does not exceed 64K. (The experiments validated this assumption.)

The projections proved our expectations about the performance of the two hash tables *wrong*. The two hash tables organize keys, values, and 4 metadata fields in slightly different ways: Vigor stores them as 6 distinct arrays, while Klint packs all 6 fields into a single 64B `struct` and maintains a single array with elements of this `struct` type. At first glance, it appears that the latter always leads to better locality and thus improved performance. However, it turned out that this is not always true.

Applying $\mathcal{P}_{\text{scale}}$ and $\mathcal{P}_{\text{h/m}}$ to the `put()`, `get()`, and `delete()` operations of the two implementations predicts the following: For a `put()` or `get()`, both implementations bring 64B of data into the cache, but Klint does so in 1 cache line, while Vigor does so across 6 cache lines. When the table does not fit in the LLC, Klint suffers 1 LLC miss, while Vigor suffers 6. On the other hand, for a `delete()` call, both implementations touch the same 32B. However, Klint packs them together with other fields into a cache-line-aligned 64B `struct`, so it must bring the full 64B into the LLC, then update the 32B for invalidating the entry; the remaining 32B belonging to the deleted entry will never be reused. For Vigor, even though it brings a full 64B into the LLC, the other 32B belong to a still-valid entry and are likely to be reused, and thus the cost is amortized. As a result, for a range of table occupancies, Klint overflows the LLC and suffers 1 miss, while Vigor fits in the LLC and suffers none. $\mathcal{P}_{\text{h/m}}$ predicts that this range begins at approximately 400K keys and ends at approximately 800K keys, at which point both implementations overflow the LLC.

To verify these predictions, we measured the latency and LLC misses incurred by the `put()` and `delete()` calls of the two implementations. We configured a capacity of 2M entries for both hash tables. Fig. 8 plots Vigor's latency overhead relative to Klint, as a function of table occupancy. As predicted, Klint `put()` is consistently faster, due to better locality. Yet, for occupancies of 400K-800K keys, Klint `delete()` has 30% worse latency than Vigor. As predicted, Vigor incurs no misses in this range, while Klint incurs 1 per `delete()` call. There was one discrepancy between $\mathcal{P}_{\text{h/m}}$ predictions and the outcome of our experiments: for occupancies above 860K, $\mathcal{P}_{\text{h/m}}$ predicted 3 misses per `delete()` for Vigor, whereas we measured only 1 per call. We believe this to be due to Intel's stride prefetcher, which our current cache model does not take into account.

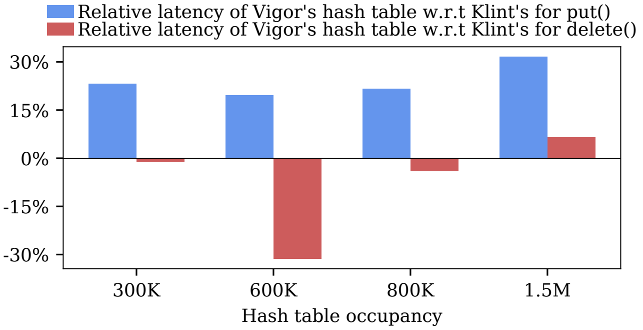

Figure 8: Relative latency (measured) of the Vigor hash table as compared to Klint's, for `put()` and `delete()` calls. Positive numbers indicate that the Vigor table is slower, and vice-versa.

Conclusion. Data-structure libraries often tailor their memory layout to different workloads [12–14]. Those who use the data structures need to understand these choices and the differences between different implementations. Using benchmarks can be tedious (e.g., in the present example, measuring the performance of `put()` and `delete()` for hash-table sizes up to 2M). Instead, CFAR projectors can quickly reveal the differences between how the implementations affect the cache across the entire range of inputs, allowing developers to pick the implementation best suited for their expected workload.

5.2.3 Does my code lead to inefficient access patterns?

We now describe how CFAR's projections helped us uncover two inefficient cache access patterns in the kernel-bypass TCP stack and the Hyperkernel's `mmap()` system call.

Kernel-bypass (KB) TCP stack: Motivated by the recent re-organization of the Linux TCP stack for cache efficiency—in particular, the `struct` that stores connection-specific data—we decided to check if CFAR's projections could help us improve the performance of the kernel-bypass stack as well. To understand how the fast path of the kernel-bypass stack was accessing different fields of the connection-specific `struct` (named `struct pcb` in this stack), we wrote a simple projector that returned the offset (in cache lines) of each access within the `struct pcb` from the base address of the `struct` (Fig. 9).

```
def pcb_offset(seq):
    pcb = sympy.Symbol('pcb')
    # if address is an offset from only the pcb
    # return (address-pcb)/64
    return [(x-pcb)//64 for x in seq
            if sympy.is_constant(x-pcb)]
```

Figure 9: Projector to compute the offset within the `pcb` structure.

Applying this projector to the fast path's `rcv()` and `snd()` calls revealed that there was only a single access to the 5th cache line in the `struct pcb`. Fig. 10 shows the list of cache-line accesses returned for `rcv()` and `snd()`, respectively.

```
# Receive fast path: KB stack
# Only one access to 5th cache line
[1,1,0,0,2,2,3,4,1,2,2,3]
# Send fast path: KB stack
# No access to 5th cache line
[2,3,3,1,1,3,3,3,3,1,2,3,2,2,1,1,1,1,0,0,2,1,2,2,1,0,2]
```

Figure 10: Cache-line accesses for `rcv()` and `snd()` on fast path.

Using the `file:linenum` information that CFAR logs during symbolic execution (§4.1.1), we realized that the field being accessed was `keep_cnt_sent`, which was being updated on the `rcv()` path to indicate that the connection was still live. To optimize this, we re-organized the `struct pcb` by moving `keep_cnt_sent` into the first 4 cache lines and moved some of the timer fields (primarily used during retransmissions) to the 5th line. Fig. 11 shows the list returned by the `pcb`-offset projector after this change, which confirmed that the fast path only accessed the first 4 cache lines.

```
# Receive fast path: KB stack
# No access to 5th cache line
[0,0,0,0,1,1,2,1,0,1,1,2]
# Send fast path: KB stack (updated)
# No access to 5th cache line
[1,2,2,0,0,2,2,2,2,0,1,2,1,1,3,3,3,3,3,3,1,3,1,1,0,0,1]
```

Figure 11: Cache-line accesses after our `pcb` optimization.

We evaluated the impact of this change by running the same experiment we ran in §5.2.1, where we measured the latency of the fast path as a function of the number of connections. Fig. 12 shows the results. Our optimization has a significant impact on the fast path's connection scalability: touching one less cache line enables the TCP stack to support 88K concurrent connections (instead of only 72K) before suffering from a latency increase due to LLC misses.

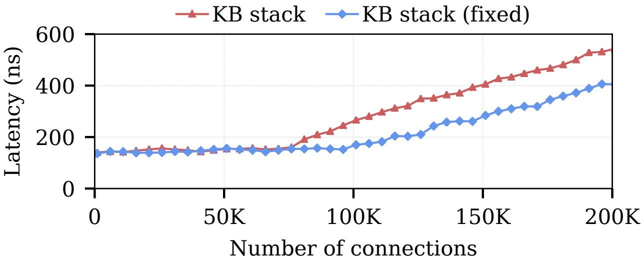

Figure 12: Before-and-after optimization: Latency as a function of the number of connections, for the kernel-bypass (KB) TCP stack.

Hyperkernel `mmap()`: CFAR enabled us to uncover and fix a subtle performance issue in Hyperkernel's `mmap()` implementation: The `mmap()` code performs a four-level page walk, checking for permissions only before it allocates the final page. So, if it is called with invalid permissions, it performs significant unnecessary work (allocates and zeroes out up to 3 new page-table pages, depending on where the walk stops), even if it does not exhibit incorrect behavior (i.e., does not allocate the final page). This brings up to 12KB of data into the L1 cache, which is more than 37% of the 32KB L1 cache in a modern server, so doing this unnecessarily pollutes the cache.

Fig. 13 shows part of the projection for `mmap()` resulting from a $\pi(\Omega) = |\{\lambda(r) = \lfloor r/64 \rfloor : r \in \Omega\}|$ projector. Line 6 corresponds to the scenario where the permissions are invalid, and the walk fails at level 1 (i.e., no page-table page is allocated at that level for the target address). Line 12 corresponds to the scenario where the permissions are valid, and the walk fails at level 2. In the former case, the code touches `201` cache lines, whereas in the latter it touches `202`. So, even though the code need not allocate any pages in the former case, it touches almost identical numbers of cache lines in both cases.

```
 1 def mmap_dcache_num_cache_lines(va,perm):
 2     #State: pid, proc_tbl, pages
 3
 4     if [pages + [proc_tbl+320*pid+16]*4096 + 8*((va>>39)&511)]:
 5         if not (perm & PTE_PERM_MASK):
 6             return 201
 7         return 265
 8
 9     if [pages + [proc_tbl+320*pid+16]*4096 + 8*((va>>30)&511)]:
10         if not (perm & PTE_PERM_MASK):
11             return 138
12         return 202
13     ....
```

Figure 13: Unique data cache lines accessed by `mmap()`.

We fixed the code and ran CFAR again. Fig. 14 shows the new projection: in the invalid-permissions scenario (line 4), the code now touches 3 (instead of >200) cache lines.

Conclusion. The results show that the CFAR distillate, coupled with simple projectors, enables developers to efficiently (i.e., without benchmarking) inspect systems code and identify performance bugs that are otherwise hard to diagnose.

```
def mmap_optimized_dcache_num_cache_lines(va,perm):
    #State: pid, proc_tbl, pages

    if not (perm & PTE_PERM_MASK):
        return 3
    if [pages + [proc_tbl+320*pid+16]*4096 + 8*((va>>39)&511)]:
        return 265
    if [pages + [proc_tbl+320*pid+16]*4096 + 8*((va>>30)&511)]:
        return 202
    ...
```

Figure 14: `mmap` projection after fix.

5.2.4 Can I prove/disprove the absence of side channels caused by secret-dependent memory accesses?

Finally, we used CFAR's $\mathcal{P}_{\text{crypt}}$ projector to analyze the 8 OpenSSL algorithms listed in Table 3. The first 7 are the ones mentioned in the beginning of §5, while the last one is from a previous version of OpenSSL (`v1.1`). We included the latter because it is known to exhibit cache-based leakage (CVE-2018-0737 [55]), and we wanted to test CFAR's ability to identify this behavior (none of the algorithms we analyzed in the latest version of OpenSSL exhibit it). The $\mathcal{P}_{\text{crypt}}$ projector indeed confirmed the cache-based leakage in OpenSSL `v1.1`.

Program	Results
OpenSSL 3.0 AES	Identified *previously unknown branch-based leak*
OpenSSL 3.0 ChaCha	*Proved absence* of secret-dependent branches/mem accesses
OpenSSL 3.0 ECDHE	*Proved absence* of secret-dependent branches/mem accesses
OpenSSL 3.0 MD5	*Proved absence* of secret-dependent branches/mem accesses
OpenSSL 3.0 MD4	*Proved absence* of secret-dependent branches/mem accesses
OpenSSL 3.0 Poly1305	*Proved absence* of secret-dependent branches/mem accesses
OpenSSL 3.0 SHA-256	*Proved absence* of secret-dependent branches/mem accesses
OpenSSL 1.1 RSA	Reproduced *known cache-based leak* (CVE-2018-0737)

Table 3: OpenSSL programs analyzed using CFAR's $\mathcal{P}_{\text{crypt}}$.

We also uncovered a previously-unknown branch-based side channel in OpenSSL `v3.0.0`. The $\mathcal{P}_{\text{crypt}}$ projection revealed that the cipher-block unpadding function used by AES had secret input in the path constraint. To further investigate, we wrote another projector that counts the number of executed instructions. This revealed (Fig. 15) that the number of instructions executed by the function in question depends on the length of the input buffer's padding, making the code vulnerable to padding oracles.

```
def ossl_cipher_unpadblock_num_insns(buf, buf_len, block_size):

  if buf.padding_len == 0:
    return 44
  if buf.padding_len > block_size:
    return 48
  return 57 + 19*buf.padding_len
```

Figure 15: Instruction-count projection reveals that the number of instructions executed by AES's cipher unpadding is influenced by `buffer.padding_length`, which is a secret input.

We reported this to the maintainers, who confirmed it [56]. We submitted a fix, which has undergone multiple rounds of review and is now in the final stages of getting merged.

The instruction-count projection after the fix shows that the number of instructions is now independent of input (Fig. 15), thus proving that it achieves constant-time execution [3].

```
def ossl_cipher_unpadblock_num_insns(buf, buf_len, block_size):
  return 2985
```

Figure 16: AES instruction count after our fix.

Our experience with OpenSSL suggests that incorporating CFAR and its projectors into the development cycle would be beneficial. As it turns out, the side channel we found had been latent in OpenSSL since `v1.1.1`, which was released in 2019. It persisted despite the thorough code reviews that OpenSSL undergoes. Yet, a quick glance at the projection before the fix would have immediately revealed the problem. Perhaps, if distillates and projections were extracted regularly, e.g., as part of continuous integration, more side channels could be detected before making their way into production.

Conclusion. Since the distillate captures all information relevant to how a piece of code accesses memory, CFAR can help developers efficiently reason about more than just performance properties. $\mathcal{P}_{\text{crypt}}$ helps identify both branch- and cache-based leakage in cryptographic code (or prove their absence).

Evaluation summary. CFAR-extracted distillates are 100% accurate. They are useful to system developers because, together with projectors, they give visibility into cache usage in a way that profilers and simulators cannot. Our evaluation shows four concrete instances of such visibility and shows how CFAR enables developers to (1) reason precisely about the cache usage of code they or others wrote, without having to run elaborate benchmarks; (2) quickly identify cache-inefficient access patterns that are otherwise hard to diagnose; and (3) analyze code not only for performance bugs but also for cache-based security vulnerabilities.

6 Related Work

Performance interfaces. CFAR is part of an ongoing effort to augment systems with *performance interfaces* [30–32, 47]; these are meant to enable developers to efficiently reason about performance, just like semantic interfaces (abstract classes, specifications, documentation) enable reasoning about functionality. Some of this work [30, 31] provides visibility into the latency of software network functions, assuming a simple cache model that is appropriate for that particular domain. By providing visibility into the usage of shared micro-architectural structures (namely, the data and instruction caches), CFAR goes a step further: it enables developers to reason about the performance of a broader class of systems code, but also about the performance *side-effects* that a callee can have on a caller due to shared micro-architecture.

CFAR leverages two key ideas from prior work on performance interfaces, particularly PIX [30]. First, just like PIX (and Freud [63]), CFAR represents performance properties as programs that are both human-readable and executable. Second, CFAR's two-phased approach is similar to the separation between the PIX front- and back-end, which separates the performance properties of the code from the environment it runs in. PIX's two-phased approach has also been used by other recent work: `ltc` [47] uses it to provide visibility into the performance of hardware accelerators, while Performal [76] uses a similar approach to verify the performance of distributed systems. That said, CFAR's key technical contributions are the abstractions of the distillates and projections, which are specific to CFAR's focus on cache usage.

Using automated program analysis to reason about performance properties of systems code. Given the recent advances in automated program analysis techniques [27, 33, 37, 39, 64, 71], there is work that leverages such analysis to reason about various performance-related properties of systems code. Violet [28] uses it to find configuration bugs in large cloud applications, Bolt [31] and Castan [57] use it to analyze the latency of software network functions, and Clara [61] proposes using it to analyze the performance impact of offloading programs onto SmartNICs. However, in each of these cases, symbolic execution is coupled with an analysis framework that is specific to the property of interest. In CFAR, we use symbolic execution to extract all the information about how a piece of code uses memory, and we enable developers to write projectors that transform this information into the answers that the developers need.

Understanding the cache usage of systems code. Given the ever growing gap between processor and memory speeds, understanding how systems code uses the cache has been extensively studied. However, we are not aware of any tool that, like CFAR, possesses predictive power across unseen workloads. All prior tools we know of are limited to providing insights about the specific workloads that the tool was run on.

We drew significant inspiration from work in the 90s on abstract execution [40] and memory tracing [21]. Both these efforts aimed to replay the memory trace of a piece of systems code (just like CFAR's distillates), but only for concrete inputs. This is because their goal was to avoid having to store large memory traces required for computer architecture simulations, so they sought to generate this trace on the fly instead. CFAR's distillate thus represents a generalized version of their work, and builds on advances in automated program analysis.

More recent work has focused on building better profilers [10, 17, 35, 43, 49, 59, 69] to help developers fix performance issues that are caused by poor cache utilization. Such systems involve a fundamental trade-off between ease of use, performance overhead, and the level of detail at which they can analyze the execution of the given input workload. The most detailed memory profiler we know of is Memspy [49]: It uses a system simulator to execute an application, which allows it to interpose on all memory accesses and build a complete map of the cache. Thus, it can account for and explain every single cache miss and—using a processor-accurate model—can approximate memory-access latencies. However, Memspy requires porting applications to its simulator, which can be a painstaking task. Additionally, its high performance overhead restricts it to profiling a limited number of input workloads. At the other end of the spectrum are profilers like DMon [35]: These work off-the-shelf for almost any systems code, and have low enough overhead to run continuously in production. Their downside is that they can only be used to monitor a specific subset of events and cannot provide the visibility that MemSpy does.

We see profilers as complementary to CFAR. Distillates and projectors allow developers to quickly understand which workloads might be of interest and cause unexpected cache behavior. Once they narrow this search space, they can use state-of-the-art profilers to study these workloads in greater detail for specific, concrete inputs.

7 Conclusion

Developers need better *abstractions* to reason precisely about the expected performance behavior of their systems. Developers today are forced to manually inspect or profile the system *implementation* directly, which is both time-consuming and error-prone, since most systems today rely on a lot of third-party code. This is in contrast to how developers reason about functionality, where abstractions such as specifications, interfaces and documentation have been widely used for decades.

In this work, we focused on helping developers reason precisely about how systems code interacts with the underlying micro-architecture, specifically the CPU cache. We presented CFAR, a technique that introduces an abstraction that precisely captures what a piece of code does to the micro-architecture as a function of its inputs (the distillate) and provides a simple means of "querying" this abstraction, to help developers efficiently answer diverse questions about cache usage of their own, as well as third-party code, without having to delve into the code's details or run time-consuming benchmarks. We see CFAR as a key step towards augmenting systems with *performance interfaces* that describe the system's performance behavior in a manner that is simultaneously succinct, precise, and human-readable, just like semantic interfaces describe functionality.

We used CFAR to analyze different types of systems code and demonstrated that it can help developers identify performance bugs and security vulnerabilities, as well as understand the performance impact of using third-party code in their systems. CFAR's analysis completes in minutes, making it feasible to integrate CFAR into the software development cycle.

CFAR is publicly available as open-source software at [58].

VeriSMo: A Verified Security Module for Confidential VMs

Ziqiao Zhou[*] Anjali[†] Weiteng Chen[*] Sishuai Gong[‡] Chris Hawblitzel[*] Weidong Cui[*]
[*]*Microsoft Research* [†]*University of Wisconsin-Madison* [‡]*Purdue University*

Abstract

Hardware vendors have introduced confidential VM architectures (e.g., AMD SEV-SNP, Intel TDX and Arm CCA) in recent years. They eliminate the trust in the hypervisor and lead to the need for security modules such as AMD Secure VM Service Module (SVSM). These security modules aim to provide a guest with security features that previously were offered by the hypervisor. Since the security of such modules is critical, Rust is used to implement them for its known memory safety features. However, using Rust for implementation does not guarantee correctness, and the use of unsafe Rust compromises the memory safety guarantee.

In this paper, we introduce VeriSMo, the first verified security module for confidential VMs on AMD SEV-SNP. VeriSMo is fully functional and provides security features such as code integrity, runtime measurement, and secret management. More importantly, as a Rust-based implementation, VeriSMo is fully verified for functional correctness, secure information flow, and VM confidentiality and integrity. The key challenge in verifying VeriSMo is that the untrusted hypervisor can interrupt VeriSMo's execution and modify the hardware state at any time. We address this challenge by dividing verification into two layers. The upper layer handles the concurrent hypervisor execution, while the lower layer handles VeriSMo's own concurrent execution. When compared with a C-based implementation, VeriSMo achieves similar performance. When verifying VeriSMo, we identified a subtle requirement for VM confidentiality and found that it was overlooked by AMD SVSM. This demonstrates the necessity for formal verification.

1 Introduction

Confidential computing has been adopted by major cloud providers with the aim of removing the cloud provider out of the Trusted Computing Base (TCB). This is achieved by leveraging hardware-based Trusted Execution Environments (TEEs), which are encrypted and isolated from the rest of the software stack managed by the cloud provider. In recent years, hardware vendors have introduced confidential VM architectures (e.g., AMD SEV-SNP [1], Intel TDX [19], and Arm CCA [6]) that can run a full VM inside a TEE.

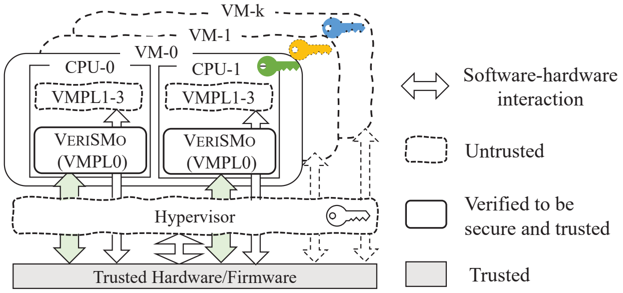

Figure 1: VeriSMo in AMD SEV-SNP architecture

While a confidential VM's confidentiality and integrity are protected from the untrusted hypervisor, it also means that a confidential VM cannot use security features that previously were offered by the hypervisor. To fill this gap, security modules such as AMD Secure VM Service Module (SVSM) were introduced to provide the missing security features in a privileged layer inside a confidential VM. Given the importance of the security of such modules [4, 39], Rust is used to implement them for its known memory safety features. However, using Rust for implementation does not guarantee correctness, and the use of unsafe Rust compromises the memory safety guarantee.

In this paper, we present VeriSMo[1], the first verified security module for confidential VMs on AMD SEV-SNP. Similar to other security modules like AMD SVSM [2], VeriSMo is a privileged software layer that runs inside a confidential VM and provides security features such as code integrity, runtime measurement, and secret management. The isolation between the security module and the guest OS is based on a new privilege dimension called Virtual Machine Privi-

[1] VeriSMo is derived from realism in the arts, particularly late 19th-century Italian opera. Its pronunciation reflects its small size.

lege Levels (VMPLs) on AMD SEV-SNP. VERISMO runs at the highest-privileged VMPL. Unlike other security modules, VERISMO is fully verified for functional correctness, secure information flow, and memory safety. Specifically, VERISMO is implemented in Rust and verified using Verus [22], a program verificaton tool designed for Rust.

AMD SEV-SNP provides confidential VMs with confidentiality and integrity. The former is achieved by encrypting the memory of a confidential VM and the latter is achieved by tracking the ownership of memory pages based on a new mechanism called the Reverse Map Table (RMP). While VERISMO can directly control memory encryption, it has to interact with the hypervisor to maintain the integrity of memory pages. This is because the hypervisor controls the nested page table and the owernship of memory pages in the RMP, while VERISMO is responsible for updating the RMP to validate memory pages assigned to a confidential VM.

The key challenge in verifying VERISMO is that the untrusted hypervisor can interrupt VERISMO's execution and modify the hardware state at any time. This concurrent interference makes it unwieldy to use standard Floyd-Hoare reasoning when verifying that VERISMO enforces the confidentiality and integrity of the VMs. To address this challenge, we divide verification into two layers. The upper layer handles the concurrent hypervisor execution, while the lower layer handles the VERISMO implementation, which is itself concurrent. This allows us to reason about these two different forms of concurrency (hypervisor interference and VERISMO's internal concurrency) using two different techniques:

1. For the upper layer, which we call the "machine-model layer", we define an abstract machine model that represents various physical hardware resources and hypervisor operations. We then prove that steps taken by this abstract machine preserve the confidentiality and integrity of the VMs.

2. For the lower layer, which we call the "implementation layer", we use Rust's ownership checking and Verus's permissions to reason about VERISMO's internal resources as the resources are accessed concurrently by different CPUs.

The interaction between the two layers is managed by preconditions that the VERISMO implementation must satisfy when performing hardware operations and postconditions that the VERISMO implementation can assume after hardware operations. For example VERISMO must satisfy a particular precondition when writing to a page table, and VERISMO can assume a postcondition about a memory page after executing the `pvalidate` instruction on the page. The upper layer can assume that the preconditions are satisfied, so that we can use these preconditions to verify that the abstract machine preserves the confidentiality and integrity of the VMs.

To make the implementation layer's verification scalable, especially with concurrent CPU access, we adopt permission-based reasoning, as suggested by previous research [8, 22, 31, 37]. This method combines ideas from Linear Logic [13] and Separation Logic [36], using access permissions as abstract capabilities for operations like reading and writing. Our approach applies these permissions to create type-safe interfaces for hardware resources, ensuring consistent maintenance of correct permissions during software interactions with these resources. Moreover, these interfaces, verified at the machine model level, guarantee memory safety and operational correctness in concurrent environments.

To enforce security information flow, we introduce a security type that carries possible value sets and security labels for each primitive type. The key concept here is to track a security level to each variable at every privilege level and ensure the proper relationship between the security level in value and the proper access permission in memory.

We built VERISMO mostly from the ground up, with the exception of integrating a verified cryptographic library [35], which we trust completely to avoid unnecessary duplication of verification efforts. We compared VERISMO with a C-based implementation and observed similar performance. It takes roughly 6 minutes to verify VERISMO on a 32-core machine, which shows the efficient proof time achieved through our optimized verification design and the use of Verus which is highly optimized for SMT solving.

In summary, our work makes the following contributions:

- VERISMO is the first verified security module operating within a confidential VM.
- We demonstrate how to verify VM integrity and confidentiality in the presence of a potentially malicious concurrent hypervisor, decomposing the verification into two layers to handle two levels of concurrency.
- We utilize the state-of-the-art Rust-based verification framework, showcasing the feasibility of constructing a verified real-world system using permission-based reasoning in Rust.
- We encode security flow policies using a type system and define safe casting to ensure the confidentiality of secret data while allowing all flexible accesses to secrets. (Section 8.4.1).

2 Background

2.1 AMD Confidential VMs

AMD Secure Encrypted Virtualization (SEV) is a confidential VM architecture. The latest version of AMD SEV, known as SEV-SNP, offers enhanced integrity and confidentiality protections for VMs.

Memory Encryption AMD SEV-SNP encrypts memory using a VM-specific encryption key, and secures the virtual

CPU (vCPU) state by encrypting and storing it in a VM Saving Area (VMSA) when the vCPU is trapped into the hypervisor. To support communication with the outside world (hypervisor or traditional IO devices), SEV allows VMs to selectively control encryption for memory pages by either setting an encryption bit in the guest page table or configuring a special MSR called vTOM.

Reverse Map Table AMD SEV-SNP introduces the Reverse Map Table (RMP) for memory integrity. It is located in the reserved system memory and is updated only with special CPU instructions – `rmpupdate` by the hypervisor or `rmpadjust` and `pvalidate` by the VM. The RMP is indexed by System Physical Addresses (SPAs), and each entry includes a Guest Physical Address (GPA) (as the reverse mapping of the nested page table), the assigned security domain (the hypervisor or a VM), as well as a validation bit to indicate whether the VM has accepted the memory assignment via `pvalidate`. To ensure the memory confidentiality and integrity, a confidential VM must correctly manage its page tables and the RMP.

VM Privilege Levels SEV-SNP introduces VM Privilege Levels (VMPLs) to isolate software running within a confidential VM. VERISMO runs in highest-privilege level—VMPL0, and we use VMPL3 to denote the level for running other softwares inside the VM. A vCPU's VMPL is stored in its VMSA. Different VMPLs share the same guest physical memory but have different permissions. By default, only VMPL0 has full permissions enabled to all guest memory pages. A VMPL can grant a subset of its permissions to a lower-privileged VMPL via the `rmpadjust` instruction. Those permissions are stored in the RMP and are part of the RMP check.

VM Platform Communication Key In AMD SEV-SNP, confidential VMs rely on the hypervisor to forward their messages to the Platform Security Processor (PSP) for tasks such as deriving new keys and generating attestation reports. To prevent attacks from a malicious hypervisor, The PSP uses VM Platform Communication Keys (VMPCKs) to establish secure channels with a confidential VM. These keys are passed to a confidential VM at launch time. VMPL0 has access to all keys and can choose to release some keys to other VMPLs.

VM Secure Interrupts A malicious hypervisor may inject arbitrary interrupts to change the data/control flow of the VM. Without secure interrupts, shared memory might be exploited by the hypervisor to leak sensitive data. For example, a recent research [38] demonstrates that #VC interrupts can leak sensitive data via the shared guest-hypervisor communication block (GHCB). To prevent the hypervisor from injecting arbitrary interrupts into a VM, AMD SEV-SNP introduces two secure interrupt injection modes: restricted interrupts and alternative interrupts. Each VMPL can have its own interrupt mode specified in the VMSA. When restricted interrupts are enabled, the hypervisor can only inject one interrupt type introduced by AMD called #HV. When a #HV arrives at a VMPL, the guest code at that VMPL can refer to a shared #HV doorbell page to check the interrupt type instead of directly jumping to an arbitrary interrupt handler. When alternative interrupts are enabled, the hypervisor cannot inject any interrupts into the VMPL, and the interrupts are always controlled by a higher-privileged VMPL. Thus, VMPL0 must use the restricted interrupt mode for security, while other VMPLs can use either the restricted or alternative interrupt mode.

2.2 Rust and Verus

Rust is a modern programming language that offers high performance and memory safety without requiring a garbage collector. Rust's ownership system enforces memory safety in a way conceptually similar to linear logic or separation logic. Rust is safe by default, meaning the compiler enforces memory safety guarantees. However, for scenarios where assembly code or direct control of memory is needed, Rust provides 'unsafe' blocks, which can cause bugs and memory safety issues [28].

Verus [22] is a verification tool designed for Rust. Verus extends Rust with verification features such as preconditions, postconditions, and loop invariants. For specifying and proving properties of Rust programs, Verus allows Rust developers to define three types of variables—executable, ghost, and tracked variables as well as three types of functions—executable, proof, and specification (spec) functions. The non-executable functions and variables are used by Verus during verification but are erased during compilation.

Ghost variables, which are used in proofs to represent mathematical abstractions such as sets or maps, are not checked by Rust's ownership checker. Tracked variables (referred to as "proof variables" in earlier versions of Verus [22]), on the other hand, are used to represent owned resources or permissions, and are checked by Rust's ownership checker. VERISMO uses tracked variables to represent permissions to access hardware resources such as memory and registers, in a style similar to separation logic or linear logic, but checked with Rust's ownership checker rather than with a dedicated separation logic or linear logic checker.

3 System Design

In this section, we present the system design of VERISMO.

3.1 Threat Model

VERISMO follows the threat model assumed by confidential computing. It only trusts the CPU and assumes that every-

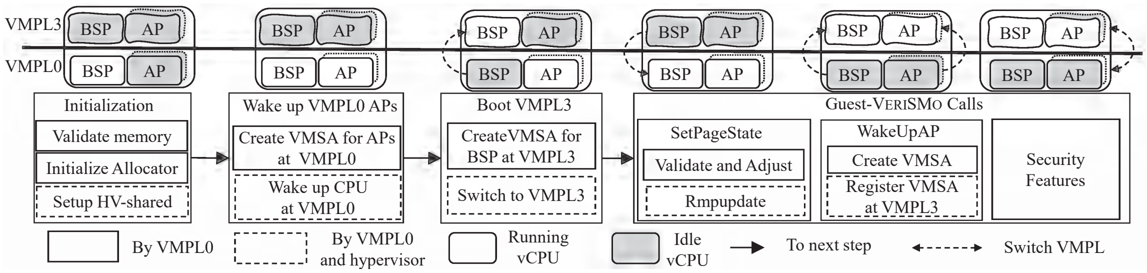

Figure 2: VeriSMo work flow

thing outside of a confidential VM is entirely controlled by an adversary, including the hypervisor. Although the hypervisor can interrupt a VM at any time, it can only inject the #HV interrupts because VeriSMo uses the restricted interrupt mode to prevent malicious interrupt injections. Furthermore, VeriSMo does not trust the guest OS running in the confidential VM. Denial-of-service attacks are possible, as the untrusted hypervisor manages the host and can either shut down the physical machine or opt not to schedule a vCPU for VeriSMo to run. Physical attacks are out of scope, as they are orthogonal to our work.

3.2 Architecture

VeriSMo runs in VMPL0, while the guest operating system runs in VMPL3 (VMPL1 or VMPL2 could also be used, but we choose VMPL3 in this paper). Both VeriSMo and the guest run in the retricted interrupt mode [2], and are thus not vulnerable to the interrupt injection attacks (e.g., [38]).

The work flow of VeriSMo is shown in Figure 2. When a confidential VM is launched, VeriSMo executes first. It reserves private memory for itself and then launches the guest OS. Afterwards, VeriSMo runs in a loop on each processor, waiting for calls from the guest OS.

3.3 Guest-VeriSMo Communication

VeriSMo and the guest OS running on a processor can transition execution to each other by issuing a hypercall to the hypervisor. Furthermore, a per-CPU memory page is shared between VeriSMo and the guest OS so that they can communicate with each other. The hypervisor does not have access to this memory page.

3.4 VeriSMo Guest APIs

The guest OS in VMPL3 must rely on VeriSMo to wake up its application processors (APs) and to validate memory pages, as it lacks these capabilities. Additionally, the guest OS can use VeriSMo-provided security features.

Waking up APs. During the boot time, the guest OS on the bootstrap processor (BSP) calls VeriSMo to activate APs. Upon receiving the request, VeriSMo's code running on the BSP notifies code running on APs. Once receiving the notification, VeriSMo's code running on an AP sets up a per-CPU VMSA page for the guest OS and transitions execution to the guest OS.

Guest Memory Management. While both VeriSMo and the guest OS are capable of sharing memory pages with the hypervisor, only VeriSMo can make memory pages private by validating them in the RMP. To track the state of memory pages (e.g., private/validated or shared/invalidated), VeriSMo requires the guest OS to use VeriSMo-provided APIs to share memory pages with the hypervisor. If the guest OS chooses not to follow this requirement, these shared pages will not be validated by VeriSMo anymore.

Guest Kernel Code Integrity. To assist the guest OS in preventing unauthorized code execution in kernel mode, VeriSMo offers the `LockKernel` API. The guest OS can invoke this API with a list of memory ranges corresponding to its kernel-mode code. VeriSMo will then remove from the guest OS the write permission to the kernel code pages and the supervisor-execution permission to other memory pages. VeriSMo also ensures that this API can be called only once.

Runtime Measurement. To facilitate runtime measurement for the guest OS, VeriSMo provides two APIs, `ExtendPCR` and `Attest`, based on a hash chain. The hash chain's initial value is set to the measurement of the guest OS's starting code and configuration. The guest OS can invoke `ExtendPCR` to extend the hash chain and call `Attest` with a nonce to request an attestation report. VeriSMo assembles the attestation report to include a hardware-attested report for VeriSMo's identity and a VeriSMo-attested report for the hash chain.

[2] The mainstream Linux (v6.8) does not support restricted interrupt injection in either KVM or the guest. We used the Hyper-V hypervisor and our modified guest Linux to enable restricted interrupts with #HV doorbell implementation.

Secret Management. VERISMO provides three APIs to support the guest OS for secret management: `DeriveKey`, `Encrypt`, and `Decrypt`. `DeriveKey` generates an encryption key derived from the current guest runtime measurement. This key is kept in VERISMO and is never discloses to the guest OS. The guest OS can invoke `Encrypt` or `Decrypt` to use this derived key to encrypt or decrypt data.

4 Verification Overview

4.1 Motivation

Traditional software testing can only partially check correctness for certain inputs and cannot formally ensure correctness. Formal verification is the only solution that provides a formal guarantee for the correctness. Below, we demonstrate the need for formally verifying three properties: functional correctness, secure information flow, and VM confidentiality and integrity.

Functional Correctness. Functional correctness defines the desired outcome (i.e., the postcondition) of a function when an input meets certain requirements (i.e., the precondition). In the following code, a key generation function contains a bug that results in a violation of the desired specification.

Listing 1: Incorrect functionality

```
fn GenPrivKey() -> (key: Key)
ensures key.is_random()
{
   return 123; // a constant is not random
}
```

Secure Information Flow. Secure Information Flow defines a safety problem by considering whether the information flow in a system is managed in a way that prevents unauthorized access or leakage of sensitive data. A program is said to be secure if and only if its memory trace and the values of low-security variables are independent of the initial values of its high-security variables. For example, the codes below show the security violation via data flow (left) and control flow (right).

```
low = high % 2
```

```
if high % 2 == 1 {a()} else {b()}
```

VM Confidentiality and Integrity. When a program *P* operating at a certain privilege level accesses memory *M* on a CPU, it is possible that *M* is concurrently accessed by *P* on a different CPU, or by another program at a different privilege level (e.g., the hypervisor). It is important to note that confidentiality and integrity violations within a program *P* can be eliminated through verification of *P* itself. However, the unexpected memory value due to concurrent updates from untrusted programs cannot be prevented. Thus, strict correctness cannot be verified against a specification relying on values from mutable shared memory, which is concurrently accessible by the hypervisor or other VMPLs.

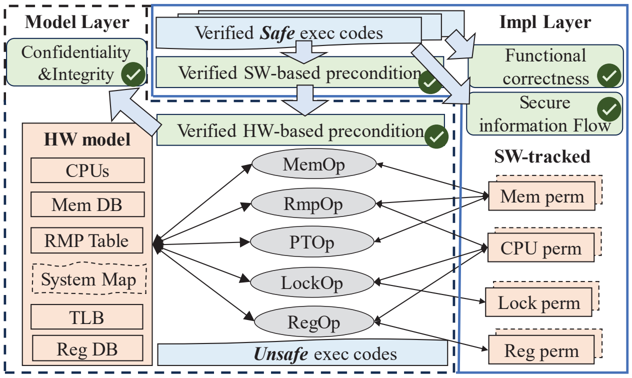

Figure 3: Two layer verification

Listing 2 illustrates an example where an incorrect modification of the page table can lead to the leakage of secrets to the untrusted hypervisor (confidentiality violation) and leave unintended effect in the software (integrity violation). Listing 3 shows a similar violation due to an incorrect RMP change.

Listing 2: Integrity/confidentiality violation via page table change

```
page_table_set_encryption(a_addr, false);
*a = ret_sensitive(); // Leaked result;
do_critical(&a); // Unintended result;
```

Listing 3: Integrity/confidentiality violation via RMP change

```
rmp_adjust(a_addr, READ, VMPL3);
*a = ret_sensitive(); // Leaked result;
rmp_adjust(a_addr, WRITE, VMPL3);
do_critical(&a); // Unintended result;
```

4.2 Verification Design

While we can adapt existing verification techniques to verify functional correctness and secure information flow, verifying VM confidentiality and integrity has its own challenge. The challenge comes from the fact that the untrusted hypervisor can interrupt VERISMO's execution and modify the hardware state at any time. This concurrent interference makes it hard to verify that VERISMO enforces VM confidentiality and integrity. Furthermore, there is another source of concurrency: VERISMO itself is a concurrent program. To handle these two different forms of concurrency separately, we divide verification into two layers: the machine-model layer and the implementation layer (see Figure 3).

In the machine-model layer, we define an abstract machine model that represents various hardware resources. Then we prove that steps taken by this abstract machine preserve VERISMO's confidentiality and integrity. In the implementation layer, we use Rust's ownership checking and Verus's permissions to reason about VERISMO's internal resources as the resources are accessed concurrently by different CPUs. The interaction between the two layers is managed by preconditions that the VeriSMo implementation must satisfy when performing hardware operations and postconditions that it can assume after hardware operations.

5 Machine-Model Layer

In this section, we describe the verification process at the machine-model layer. The goal of this layer is to prove that steps taken by an abstract machine ensures VeriSMo's confidentiality and integrity. Specifically, we need to ensure the following security properties required by VeriSMo.

(1) Ensuring the integrity and confidentiality of VM data in private memory. The hypervisor is unable to alter or explicitly read VM-private memory in the hardware through any sequence of operations by the hypervisor entity.

(2) Maintaining VMPL isolation. VMPL3 is unable to explicitly read VMPL0-private data, and whenever VMPL0 reads its own private data, it obtains the correct data, not data tampered with by VMPL3.

5.1 Abstract Machine Model

Our abstract machine model, Ψ, represents the contents and attributes of hardware resources such as registers, memory, page tables, and the RMP. This model is updated through some transition operations initiated by different entities. Since the model defines the interactions between these entities, we can formally check the preconditions for each operation required for ensuring the desired security properties.

5.1.1 Entities

Our abstract machine model has three entities.

E_0 represents VeriSMo executing at VMPL0.

E_3 represents the guest OS running at VMPL3. E_0 and E_3 share the same memory encryption key.

E_{hv} represents the hypervisor running in the hypervisor mode. E_{hv} does not have access to the memory encryption key of a confidential VM. Sibling guest VMs are ignored because the hypervisor's capabilities are their super set.

Both E_{hv} and E_3 are untrusted and can execute arbitrary code. Therefore, the value read out of the memory shared with E_{hv} or E_3 is treated as unconstrained.

5.1.2 Primitive Operations

Our abstract machine model defines a set of primitive operations (see Figure 3) that can be initiated by different entities to read or modify hardware resources. Each operation represents a single machine instruction, and its behavior is formally defined based on the AMD manual [3]. For instance, we define how the hardware model returns a memory value after nested page table walks and RMP checks.

For each operation, we define a trusted exec function with a single line of unsafe assembly in Rust with its pre- and post-condition. The postcondition reflects the operations's effect and are fully trusted. For instance, the postcondition for `pvalidate` is that the RMP entry is marked as validated. The preconditions of trusted functions are checked in the verification process to prove that, by enforcing the preconditions, the abstract machine state ensures the security properties when E_0's operation is constrained by the preconditions. The completeness of the operation model is important to our verification. Since VeriSMo is not as large as a guest OS, we currently only model critical memory and cache operations under some assumptions. For example, VeriSMo directly uses the guest-hypervisor communication to replace code that may trigger #VC, and always forces a VM termination when a #VC or other unexpected interrupt is triggered. Thus, we do not need to model the potential #VC events when accessing a memory.

5.2 Top-level Security Property Specifications

When proving the security properties (1) and (2), we prove both the confidentiality and integrity theorem outlined in Listing 4 and Listing 5.

Listing 4: VMPL0 confidentiality

```
proof fn proof_confidentiality(Ψ: Machine, e0: Entity,
      e: Entity, va1: Addr, va2: Addr)
requires
  E_0.contains(e0), e0 ≠ e,
  m_inv(Ψ),
  m_read(Ψ, va1, e0).is_Ok(),
  m_read_ret(Ψ, va1, e0).is_Secret(),
  m_to_spa(Ψ, va1, e0) ≡ m_to_spa(Ψ, va2, e),
  m_read(Ψ, va2, e).is_Ok(),
ensures
  m_read_ret(Ψ, va2, e).is_Encrypted();
```

Listing 5: VMPL0 integrity

```
proof fn proof_integrity(Ψ: Machine, Ψ': Machine, e0:
     Entity, va: Addr)
requires
  E_0.contains(e0),
  m_inv(Ψ, e0),
  attack_model(Ψ, Ψ'),
  m_read(Ψ, va, E_0).is_Ok(),
  m_read(Ψ', va, E_0).is_Ok(),
ensures
  m_read_ret(Ψ, va, e0) ≡ m_read_ret(Ψ', va, e0);
```

To prove confidentiality, a critical specification is the SNP machine invariant (`m_inv`) representing whether a machine state is valid. For the integrity proof, we additionally rely on a specification (`model_attack`) that determines whether a state Ψ' is reachable from Ψ under attack. Thus, it is necessary to prove the correctness of both the machine invariant specification (Listing 6) and the attack model specification (Listing 7). This entails consideration of machine model modifications stemming from all possible operations, where only $\mathtt{E}_0$'s operation is constrained by preconditions (`Op::sw_requires`).

Listing 6: Correctness of machine state invariant

```
proof fn proof_machine_inv(Ψ: Machine, Ψ′: Machine, op:
     Op, e0: Entity, e: Entity)
requires
  E0.contains(e0),
  (e0 ≡ e)  ⟹  Op::sw_requires(e, op),
  Ψ′ ≡ m_op(Ψ, e, op),
  m_inv(Ψ, e0),
ensures
  m_inv(Ψ′, e0);
```

Listing 7: Correctness of attack model

```
proof fn proof_attack_model(Ψ: Machine, Ψ′: Machine,
     Ψ″: Machine, op: Op, e0: Entity, e: Entity)
requires
  E0.contains(e0), e ≠ e0,
  m_inv(Ψ, e0),
ensures
  Ψ′ ≡ Machine:op(Ψ, e, op)  ⟹  attack_model(e0, Ψ,
     Ψ′),
  (attack_model(e0, Ψ, Ψ′) && Ψ″ ≡ m_op(Ψ′, e, op))
     ⟹  attack_model(e0, Ψ, Ψ″);
```

5.3 Security Property Proof Sketches

In this section, we describe five critical lemmas and provide a sketch of their proofs, in order to prove the two top theorems and the correctness of critical specifications. It is worth noting that they are fully proved with Verus.

In VERISMO, we classify the guest memory into three sets: VMPL0-Private , VMPL3-Private, and Hypervisor-Shared. The divided memory sets allow us define the security properties for different memory types.

5.3.1 VM-Private Memory

Lemma 1. *Let Ψ represent a machine state in which M is a guest physical memory block that stores value D. Suppose Ψ' is a future state reachable through modifications made by $\mathtt{E}_{\mathtt{hv}}$. Then, if M is VM-private in Ψ, VM's read operation on M in Ψ' either fails or returns the original value D.*

A key invariant property of the RMP is that, once a RMP entry is validated by a VM for a VM-private memory page, the guest physical address (GPA) of this memory page will be either bound to the system physical address (SPA) of the RMP entry or nothing at all, regardless of any operations by $\mathtt{E}_{\mathtt{hv}}$, as long as $\mathtt{E}_0$ does *not* validate the GPA again. It is straightforward to prove this property. If $\mathtt{E}_{\mathtt{hv}}$ makes any changes to the RMP entry, the entry will become invalidated, thus the GPA is not bound to any SPA. If $\mathtt{E}_{\mathtt{hv}}$ does not change the RMP entry, then the GPA remains bound to the same SPA as long as $\mathtt{E}_0$ does not validate the GPA again.

With this property, we can prove the Lemma 1. If *M* is VM-private and validated in Ψ, then the GPA of *M* is bound to an SPA. This implies that the read operation on *M* by either $\mathtt{E}_0$ or $\mathtt{E}_3$ in Ψ' either returns the original value *D* or fails.

This lemma essentially requires that a valid state of Ψ will always ensure the VM-private *M* has unique bound from a GPA to an SPA no matter how the hypervisor changes the nested page mapping, as we discussed in Section 2.1. Such invariant property requires that $\mathtt{E}_0$ does not validate a GPA when it is validated and bound to an SPA in the RMP.

Lemma 2. *Given a machine state Ψ, if a guest physical memory block in VM-private is mapped to a system physical memory M that stores a VM's secret S, then in any future hypervisor-reachable machine state Ψ', $\mathtt{E}_{\mathtt{hv}}$'s read operation on M will return an encrypted version of S.*

At first glance, one may assume that the VM-private memory page requires both the encryption bit in the guest page table and the validation bit in the RMP. However, our verification indicates that the validation bit in the RMP cannot be reliably guaranteed. When proving the lemma, we confirmed that holding the validation bit in the hardware state is not necessary. This implies that a requirement for a 'C' bit in the page table suffices to prove the lemma.

5.3.2 VMPL0-Private Memory

Lemma 3. *Let Ψ represent a machine state in which M is a VMPL0-private guest physical memory block that stores value D. Suppose Ψ' is a future reachable state through modifications made by $\mathtt{E}_{\mathtt{hv}}$ and $\mathtt{E}_3$. Then the $\mathtt{E}_0$'s read operation on M in Ψ' either fails or returns the original value D, and M cannot be read by $\mathtt{E}_3$.*

Since VMPL0-private memory is a subset of VM-private memory, Lemma 1 and Lemma 2 implies that $\mathtt{E}_{\mathtt{hv}}$ cannot read it or tamper its value. Here we focus on $\mathtt{E}_3$. An RMP entry contains access permissions for each VMPL. These permissions control whether a VMPL can read, write, and execute on the memory. Furthermore, the hardware restricts $\mathtt{E}_3$ from modifying access permissions for its own VMPL. To ensure that $\mathtt{E}_3$ cannot access VMPL0-private memory, the verification process requires a precondition to `rmpadjust` that $\mathtt{E}_0$ cannot grant access permission to VMPL3 if the memory is in VMPL0-private.

5.3.3 Correct Guest Address Translation

In addition to RMP updates, updating the page table is also critical for safe memory translation. We must ensure the integrity of the memory translation by considering all possible changes from all entities. We verify it by proving the following lemma. The correctness of our guest address translation helps to prove the top theorem when considering accesses via guest virtual addresses instead of guest physical addresses.

Lemma 4. *Let Ψ represent a machine state in which a guest virtual address GVA is successfully translated to a system physical address SPA by a VMPL0's memory access. Suppose Ψ' is a future state reachable through modifications made by* $\mathtt{E_{hv}}$ *and* $\mathtt{E_3}$*. Then, in Ψ', VMPL0's access to the GVA succeeds with the same translation to SPA or fails.*

Lemma 3 establishes that a GPA for VMPL0-private memory is either bound to a specific SPA or not bound to any SPA. When a GVA is successfully translated to a SPA in Ψ, it implies that the GPA that the GVA is mapped to is bound to the SPA. Therefore, in Ψ', the GPA is either still bound to the same SPA or not bound to any SPA. Since $\mathtt{E_{hv}}$ and $\mathtt{E_3}$ cannot change $\mathtt{E_0}$'s page table, the translation from the GVA to the GPA remains the same. This guarantees that the GVA is either translated to the same SPA or fails.

To simply the implementation layer verification, we also prove the following lemma to ensure the mapping from GVAs to SPAs is one-to-one.

Lemma 5. *For each reachable Ψ, the mapping from a guest virtual address to a system physical address is a one-to-one mapping.*

Since Lemma 3 implies that the mapping from GPAs to SPAs for VM-private memory is one-to-one, we only need to ensure that the mapping from GVAs to GPAs is one-to-one. We prove it by separating memory writes into two categories: normal memory (`mem_write`) and page table memory (`pt_write`). To simplify the proof, we set aside a set of guest physical pages for $\mathtt{E_0}$'s page table (referred to as the PT memory), and enforce that the PT memory is always VMPL0-Private (by updating the precondition to `rmpadjust`). This allows us to define a precondition for `mem_write` and `pt_write` to check that a memory write falls into their respective categories.

A trusted initial assumption we make is that the initial page table for $\mathtt{E_0}$ at launch time is correct in the sense that the page table pages are in the PT memory and the page table enforces a one-to-one mapping from GVAs to GPAs. Then to prove it is true for any reachable Ψ, we prove that any `pt_write` operation preserves this property by adding a precondition to check that the memory write would keep the page table pages in the PT memory and the one-to-one mapping from GVAs to GPAs.

5.3.4 Connecting Machine Model to Implementation

The confidentiality and integrity of the VM-private and VMPL0-private memory, together with the correct page table translation, ensure that the memory content accessed by $\mathtt{E_0}$ through a guest virtual address remains consistent with the content stored in the hardware state. This consistency allows the implementation layer verification to focus on the software-tracked state, eliminating the complexity of having to worry about the actual hardware state. To convert preconditions for primitive operations from hardware-based to software-based in implementation verification, we prove that if an operation succeeds and the operation's software-based constraint is true, the corresponding hardware-based one must be true.

6 Implementation Verification

In this section, we describe the verification at the implementation layer. For simplicity, software in this section refers to the implementation of VeriSMo. We first describe how we use permission-based verification to handle concurrency and scale verification to a large codebase. We then describe how we use information-flow verification to prevent secret leakage.

6.1 Permission-based Verification

In VeriSMo, we incorporate the software constraints derived from the machine model verification into "tracked" permissions defined by Verus[22]. Each resource permission includes an identifier and multiple fields that represent the value or attributes of the resource. To ease the proof process across various memory access scenarios, we opt for implementing fine-grained memory permissions. This approach helps avoid the complexities tied to a single large-size global state (e.g., the hardware abstract model used in Section 5), and simplify the concurrency reasoning using ownership. Moreover, to aid in safe memory sharing, we introduce a lock permission for shared memory. To ensure safe register access, we establish register permissions in accordance with their definitions.

6.1.1 Memory Access Permission

Object-based Memory Permission. We extend the definition of a basic memory permission described in Verus to make all memory access safe in the context of AMD SEV-SNP VMs. A memory permission is defined as a `tracked` variable (`SnpPointsTo`) without the ability to be copied or constructed. By incorporating an appropriate initial assumption to ensure the initial uniqueness of all memory permissions, we can guarantee the uniqueness of each permission throughout the program.

As shown in Listing 8, our extended SNP memory permission consists of three elements: the guest virtual address (`addr`) as the permission identifier, the `value` stored at that address by the software, and the memory attributes (`swattr` and `hwattr`) as seen by both software and hardware. These memory attributes include RMP (`rmp`) and page table (`pte`) values tied to the memory. Furthermore, considering the specific use of page tables, we have added an attribute (`is_pt`) to denote whether the memory serves as a page table. These improvements facilitate efficient management and enforcement of memory safety within the SEV-SNP VM context.

Listing 8: SNP object-based memory permission definition

```
pub ghost struct SnpMemAttr
{ rmp: RmpEntry, pte: PTAttr, is_pt: bool}

pub ghost struct SnpPointsToData<T> {
  addr: int, value: Option<T>,
  swattr: SnpMemAttr, hwattr: SnpMemAttr,
}

pub tracked struct SnpPointsTo<V>
{ _p: marker::PhantomData<V>, _ncopy: NoCopy }

impl<T> SnpPointsTo<T>
{ pub spec fn view(&self) -> SnpPointsToData<T>; }
```

Raw Memory Permission While object-based access permissions provide a user-friendly approach to object-oriented programming, VeriSMo operates as a low-level security module, involving a significant number of raw memory operations.

To effectively support raw memory, it is necessary to establish additional foundational information concerning size, value casting, memory splitting, and merging. This essential ground-truth information is not provided by Verus and is defined by VeriSMo as trusted specifications or axioms:

Object Size Specification. We assume that an object's size is equivalent to its actual memory usage. The precise size value should only matter when an operation has a specific size requirement (e.g., pvalidate requires page-sized) or when size comparisons are necessary (e.g., memory splitting or joining).

Casting between Objects and Bytes. Our trusted proof for casting aims to enforce unique bindings and ensure consistent sizing between objects and their corresponding byte representations.

Raw Memory Split and Merging. During memory splitting and merging operations, byte values and memory ranges are divided or combined, respectively, while memory attributes remain consistent with the original state.

Examples to Convert Unsafe Rust to Safe Verus. To illustrate how to use memory permission to convert Rust's unsafe memory access into Verus's safe memory access operation, we provide two dummy examples using memory primitive functions defined in Listing 9. The examples demonstrate how unsafe accesses can be identified through either verification (ϟ) or Rust's borrow checker (⊗).

The first example (in Listing 10) takes a memory permission reference pointing to a VMPL0-private memory at 0x1000, and thus it can borrow a value at address 0x1000. However, Line 8 cannot change content, since the permission is borrowed as immutable; Line 9 cannot access raw memory at 0x2000 due to the mismatched memory identifier.

Another example provided in Listing 11 demonstrates how the verification process detects unsafe RMP updates, ensuring the valid memory state. It initializes an non-validated memory permission and then assign it to VMPL1 at the end to render the memory accessible to VMPL0. After `pvalidate`, the memory permission remains not ready for other RMP memory operations until the operation is confirmed and the memory content is cleared. The strict requirement leads to a failed assertion at Line 6. Additionally, Line 11 fails since the pvalidate primitive function requires no double validation.

Listing 9: A selective primitive memory-related functions

```
fn borrow<'a>(vaddr: usize, Tracked(mperm): Tracked<&'a
      SnpPointsTo<V>>) -> (v: &'a V)
requires
  mperm@.wf_borrow(vaddr as int),
ensures
  mperm@.spec_read_rel(*v),
{...}
fn replace(vaddr: usize, in_v: V, Tracked(mperm):

     >)
 requires
   mperm@.wf_range((0x1000, PAGE_SIZE)) && mperm@.
      is_init() {
   let mut u64 rflags = 0;
✓let ret = pvalidate(0x1000, 0, 1, &mut rflags,
      Tracked(&mut mperm));
⚡ assert(mperm@.wf());
   if ret == 0 && rflags != 0 { return false; }
✓mem_set(0x1000, PAGE_SIZE, 0, Tracked(&mut mperm));
✓assert(mperm@.wf());
⚡ pvalidate(0x1000, 0, 1, &mut rflags, Tracked(&mut
      mperm));
   let rmpattr = RmpAttr::empty().set_vmpl(1).set_read
      (1).set_write(1);
✓rmpadjust(0x1000, rmpattr, Tracked(&mut mperm));
   if ret  != 0 { return false; }
✓assert(!mperm@.is_vmpl0_private());
   return true;
 }
```

6.1.2 Lock Access Permission

The memory permission we previously described does not entirely address the issue of concurrency reasoning. This challenge emerges because memory permissions, in their current form, do not inherently facilitate the shared write permission for concurrent access. For example, when CPU-A moves a memory permission to CPU-B, CPU-A subsequently loses access to that memory. How to retrieve the memory permission back is unclear without introducing locking or atomic permission mechanisms.

To enable safe concurrent memory access in a relaxed memory model, we choose to implement locking permissions since much of our code relies on locks to protect shared resources without directly using atomic operations. Each shared resource starts with a lock permission which stores a memory permission. When the software acquires a lock, the lock permission is converted to a locked state and returns the stored memory permission so the software can use the memory permission to access the shared resource. When the lock is released, the memory permission is returned back to the lock permission whose state is converted back to an unlock state.

Shared objects typically require an **invariant** to constrain their values. Without proving the invariant, for all verifications necessitating such a constraint, programmers may incur extra execution costs to check if the value meets the requirements. To maintain the invariant for values read after acquiring a lock, we have introduced a precondition in the release API. This precondition mandates that the object associated with the memory permission upholds the invariant whenever the release method is invoked. As a result, the value of the global variable read by a CPU is always in compliance with the invariant. The lock mechanism in VERISMO extends beyond shared memory (see Section 7.2). Listing 12 shows an example to use lock to protect a global variable `gvar` while keeping its invariant (`spec_gvar_inv`). The verified code guarantees that the data borrowed satisfies invariant (Line 12) after acquiring the lock, although the data could be different in two lock transactions (Line 13). Our trusted lock APIs can detect the violation of invariant for `gvar` since it fails the invariant at Line 15.

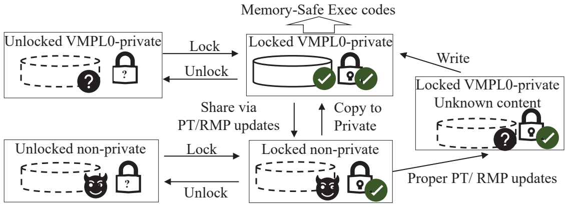

Figure 4: Safe memory access under concurrency

Listing 12: Lock protection

```
1  spec fn spec_gvar_inv() -> spec_fn(u64) -> bool
2  { |v: u64| 0 <= v <= 0xff_ffff}
3
4  fn access_global(Tracked(core): Tracked(SnpCore),
       Tracked(lperm): Tracked(LockPerm<u64>))
5  requires
6    lperm.is_unlocked(spec_gvar) {
7  ✓let (vaddr, Tracked(pt_mperm)) = gvar().acquire(
       Tracked(&mut lperm), Tracked(&core));
8  ✓let val1 = borrow(vaddr, Tracked(&pt_mperm));
9  ✓gvar().release(Tracked(&mut lperm), Tracked(&core),
       Tracked(pt_mperm));
10 ✓let (_, Tracked(pt_mperm)) = gvar().acquire(Tracked(&
       mut lperm), Tracked(&core));
11 ✓let val2 = borrow(vaddr, Tracked(&pt_mperm));
12 ✓assert(spec_gvar_inv()(val1) && spec_gvar_inv()(val2)
       );
13 ⚡ assert(val1 == val2);
14 ✓replace(vaddr, 0x1000_0000, Tracked(&pt_mperm));
15 ⚡ gvar().release(Tracked(&mut lperm), Tracked(&core),
       Tracked(pt_mperm));
16 }
```

6.1.3 VMPL0's Memory Safety

By utilizing the memory permission and the lock permission reasoning, we ensure that our implementation always has safe memory access. Here we describe ownership for VERISMO at a high level utilizing the permissions we described in Section 6.1.1 and Section 6.1.2.

Figure 4 illustrates safe operations for handling memory and lock permissions. When VMPL0-private memory is locked by the software on a CPU, no other entity can concurrently modify it. Therefore, the memory can be considered as private to VMPL0, and the acquire operation will safely grant a memory permission for unrestricted memory access. For memory shared with either the hypervisor or the guest OS, the memory permission obtained upon locking only permits copying and writing, but not borrowing references. For unrestricted operations, developers must either copy the memory to VMPL0-private memory or use rmpadjust/pvalidate operations to transition it to VMPL0-private memory.

6.1.4 Register Access Permission

Similar to memory permissions, we define register permissions for registers. Most registers are privately controlled by the software and thus we usually can maintain a stable invariant property after proper booting steps. Since a CPU has a fixed number of registers, each CPU uses a single permission representing all the CPU's registers together. Some registers need special permission designs.

In the SEV-SNP VM environment, the *GHCB MSR* differs from other registers. While all other registers are owned by the VM, the GHCB can be read and written by the hypervisor. To handle this difference, we introduce a "share" attribute for such registers, treating the values read from these shared registers as unconstrained.

For registers like *IDTR* and *GDTR*, which hold pointers to memory segments, we guarantee that memory ownership is transferred to the hardware upon writing to these registers.

Certain registers, such as the instruction pointer (*RIP*) and stack pointer (*SP*), pose a risk of inadvertently influencing software behavior in dangerous ways. We prevent explicit use of these registers by removing permissions to access them.

CR3 points to the top-level page table. A write operation to *CR3* is required to have tracked mutable permissions for both the page table and all usable virtual memory addresses. This safeguards against incorrect modifications to CR3, as consolidating all memory permissions used by the CPU is complex. VeriSMo does not have a user mode, and has a single page table for its kernel mode code. Therefore its CR3 register is only updated once at the boot time.

6.2 Information-Flow Verification

In addition to guaranteeing safe memory access, it is important to prevent secret leakage through explicit or implicit information flows. In VeriSMo, we define a precise tracking policy to maintain secure information flow by monitoring potential secret guessing spaces for variables.

Types carrying secret guessing space. We define security types to match Rust's primitive types. Each security type includes a value and a set of possible values (`valset`) that an entity can guess from. If the set is complete, the variable is considered a secret to the entity; if the set is singleton, the variable is public to the entity.

VeriSMo only takes three kinds of secrets: the VM communication keys generated by the hardware (Section 2.1), VeriSMo's own private/public key pair (Section 3.4), and symmetric encryption keys for the guest OS (Section 3.4). Since these secrets are exclusively used by trusted cryptographic functions in VeriSMo, we only encounter a limited number of proofs about the set size when invoking cryptograhic functions. With a trusted and formally verified crypto library, our security checking is highly simplified to check whether a variable is fully public or confidential to an entity, similar to taint tracking without over/under-tainting concerns.

We define a security trait that assigns security levels to different data types based on the size of their possible value sets. Primitive types in Rust have security levels equivalent to constants. To use security types like primitive types, we implement standard operator traits and ensure the correct propagation of the guessing space by applying the relevant set operations to the possible value sets. For example, each binary operation 'op' performed between variables a and b ensures the following constraints for the returned result.

$$(a \text{ op } b).\text{valset} \equiv \left\{ \text{val} | \exists (v,u) : \begin{array}{r} v \in \text{valset}_a \wedge \\ u \in \text{valset}_b \wedge \text{val} \equiv a \text{ op } b \end{array} \right\}$$
$$\wedge (a \text{ op } b).\text{val} \equiv (a.\text{val op } b.\text{val})$$

A comparison operation may lead to secret leakage via control flow. Therefore, the comparison operator includes a precondition that requires both variables to be public to all entities. We support the secret downgrade through a trusted function when needed. After a downgrade, a variable's possible value set becomes a singleton and thus can no longer be used as a secret. For instance, if a downgrade operation is applied to a secret key, the key no longer meets a precondition for trusted cryptographic functions, which requires cryptographic key to be a high-security variable, i.e., the possible value set if full.

Re-visit the memory permission for confidentiality. To maintain the confidentiality of secret variables, we impose a requirement that the software must not share them with other entities. To enforce this property, we ensure that every valid memory permission maintains a consistent relationship between the memory's confidentiality attribute (defined by the page table and the RMP) and the security level of the value it carries, as shown below:

$$\forall \text{ entity } \neg\text{memperm.swattr.is\_confidential\_to(entity)}$$
$$\implies \text{memperm.val.is\_constant\_to(entity)}$$

In addition, we cannot use secret data as address for memory access; otherwise, the hypervisor can use control flow to infer the secret. We enforce this precondition for all trusted functions related to memory access.

7 Implementation

We implemented VeriSMo in Rust and verified it with Verus, ensuring that the trusted functions are always used safely, and our implementation is correct. Our implementation is available at `https://github.com/microsoft/verismo`.

7.1 TCB in VERISMO

VERISMO fully trusts a small number of primitive functions, ground-truth axioms, the hardware model specification, the model-based specification defining the safety properties, as well as the specification for functional correctness. These trusted functions wrap unsafe code for interacting with the hardware for calling trusted external libraries (e.g., Rust core, HACL[35]). The size of the trusted code will be reported in the evaluation section. Additionally, VERISMO places trust in Verus and the Rust compiler.

7.2 An example with simplified verification

The permission-based verification not only guarantees memory confidentiality and integrity but also ensures correctness for certain functionalities without introducing additional specifications. Here, we use an example in VERISMO to explain how a lock can automatically protect associated resources and how memory permissions automate functional correctness for a Guest-VERISMO call to update a memory page's attributes.

VERISMO assigns certain memory ranges to VMPL3 and stores their *ranges* (for execution) along with a zero-sized tracked permission *map* (for proof) in a global variable (`OSMEM`). The `OSMEM` is shared by multiple cores and is protected by a lock that guards an invariant, ensuring that a memory page has its tracked permission inside the *map* if and only if the page is within the memory *ranges*.

Extended lock protection. When VMPL3 sends a request to VERISMO to grant or revoke permission for a page, VERISMO needs to acquire the lock to access the tracked permission from `OSMEM`. This automatically prevents concurrent changes to the RMP table for VMPL3's memory without introducing new locks. Here, a single lock protects both the `OSMEM` variable and the memory assigned to VMPL3.

Extended Functional Correctness. Additionally, since the tracked map only stores page permissions from the `OSMEM`-defined ranges, VERISMO must check whether the requested page is within the range to obtain the page permission required for updating the memory's attributes. This automatically ensures that a correct handler will conduct the necessary checks before any update happens.

8 Evaluation

Our performance evaluation is based on the Hyper-V hypervisor. Our experimental machine has an AMD EPYC 7543P 32-Core Processor, which supports SEV-SNP features. We allocated 8 dedicated cores to the host domain using minroot Hyper-V, allowing the hypervisor to assign the remaining 24 CPUs to VMs. This setup prevents unpredictable competition for CPU resources between different domains.

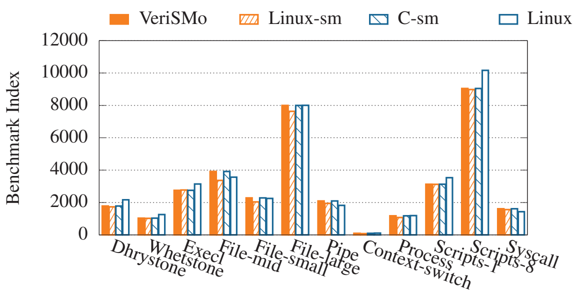

Figure 5: Unix benchmark results

8.1 Performance

To measure the performance of guest-VERISMO APIs, we created a kernel driver that sends these requests to VERISMO. We ran each call 100 times and recorded the average cost per call in Table 1.

Table 1: Microbenchmarking guest-VERISMO APIs

Request	Cycle (*1k)	Time (ms)	STD (ms)
`Switch`	34	0.012	0.002
`ExtendPCR`	37	0.013	0.002
`SetPageShared`	77	0.027	0.002
`SetPagePrivate`	82	0.029	0.002
`AttestPCR`	17633	6.298	4.270
`LockKernel`(8GiB)	4260969	1522	151
`LockKernel`(4GiB)	2201565	786	58

The `Switch` call serves as a test to complete a switch (VMPL3 → hypervisor → VMPL0 → hypervisor → VMPL3), and its cost prevails over some less expensive GVCA calls. The operation to extend a measurement (`ExtendPCR`) is quick, as it only involves adding a value from VMPL3 to the previous one and updating it with a cryptographic hash. `SetPageShared` is relatively more expensive since VERISMO needs to invalidate it and call the hypervisor to make a page shared which triggers additional context switch. `SetPagePrivate` is marginally more expensive than `SetPageShared`, as the former requires an additional rmp change via `rmpadjust`. Attestation is much more resource-intensive than others due to the need for hardware-based cryptograhic signing. Kernel code integrity protection (`LockKernel`), operating on all guest memory, is costly, but it is performed only once per VM session.

8.2 Performance Impact on Guest OS

We used UnixBench to measure the performance of a Linux kernel running with the VERISMO security module at VMPL3. The benchmarking results are presented in Figure 5. The security module introduces almost zero overhead. In contrast, Hecate [12], a compatibility-oriented L1 hypervisor in

Table 2: Lines of code.

	Exec	Spec	Proof	Axiom	Trusted
Verus	906	1361	2388	803	101
Model	0	2194	3188	67	0
HACL	107	7	0	0	90
Macro	2093	-	-	-	-
Common	606	603	2101	55	10
RawMem	640	635	324	105	11
Reg	341	162	22	0	12
Lock	183	145	105	0	7
PageTable	354	261	330	0	1
Alloc	386	164	1003	24	30
Core	3205	1013	3884	14	0

VMPL0, can incur up to a 40% slowdown. This is because our security module does not trap any guest OS's #VC Exception.

In some case, formal verification can be simplified in a less-efficient implementation or with extra runtime checks. Here, we compared VERISMO with two additional prototypes that we implemented, demonstrating no performance trade-off introduced by verification. While those prototypes—'linux-sm' (a modified Linux kernel as security module) and 'c-sm' (C-based security module)—only supports `WakeUpAP`, `SetPageShared`, and `SetPagePrivate` APIs, they serve as baselines for the fully-featured VERISMO. The comparable performance of VERISMO demonstrates that we did not sacrifice performance for the sake of verification.

8.3 Verification Size and Performance

Table 2 shows the number of lines of codes for all used libraries and modules in our code. 'Verus' represents modules VERISMO used from Verus's basic library, 'HACL' wraps 3 functions for encryption and hashing from an external formally verified HACL crate written in C and assembly. 'Core' represents code for VERISMO's core functionalities. The trusted executable code (majorly unsafe code) are from three categories. We only used 31 LOC unsafe Rust for hardware primitive operations. 'RawMem', 'Reg', 'Lock' and 'PageTable' include the trusted primitive operations for memory and registers. 'HACL', 'Common' includes external safe functions with a trusted postcondition. 'Alloc' includes 1 unsafe block to trust the global allocator interface. Although this allocator interface must be trusted, as the Rust compiler depends on it, we have verified the correctness of the implementation of our global allocator. On average, the proof and specification annotations are approximately twice the size of the executable code for the implementation layer. The machine-model layer is reusable if we do not change primitive functions. Verification of both model and implementation layers takes around 6 minutes with a multi-threaded Verus backed by Z3-4.11.2 as the solver running on our test machine with 32 cores. The verification efficiency is due to Verus's optmization for Z3 solver, Rust's ownership checking for automated memory reasoning, and the modularity of our proof code with Verus.

8.4 Security Improvement

Concurrently with our project, AMD SVSM [4] which is now replaced by COCONUT SVSM [39], is an ongoing Rust project to provide a security module in VMPL0 for AMD SEV-SNP VMs. However, they do not apply formal verification and heavily use unsafe Rust features. COCONUT uses 235 unsafe blocks, and AMD SVSM uses 150 unsafe blocks. In contrast, VERISMO uses only 32 unsafe blocks. We did not compare our performance with them since VERISMO runs on a different hypervisor. Since they share the same hardware model as VERISMO, our verification design can potentially be applied to their code.

8.4.1 An Example Bug Detected in VERISMO

Here, we showcase the importance of formal verification, using an unsafe memory update in Listing 13 that we detected via verification. This code handles the `SetPageShared` request from VMPL3. Before modifying the RMP entry for a memory page used by VMPL3, a traditional approach is to check the security of the change by examining whether the content carried in the guest physical page can be released externally. It uses a lock to protect VMPL3's memory to prevent concurrent updates. However, these measures are not sufficient for ensuring VERISMO's confidentiality when taking into account a malicious hypervisor.

Listing 13: Handling a memory state change request

```
fn SetPagePrivate(gpn: u64, attr: RmpAttr, lperm:
      Tracked<LockPerm>) -> Tracked<LockPerm> {
  let gpn = vn_to_pn(gvn);
  let tracked mut lperm = lperm;
✓let osmem = OSMEM.acquire(Tracked(&mut lperm));
✓match osmem_check(osmem, gpn, attr) {
  Ok(i) => {
    let Tracked(mut pperms) = osmem[i].pperms;
  ✓let tracked mut pperm = pperms.tracked_remove(gvn);
  ✓pvalidate(gvn, true, Tracked(&mut pperm), ..);
  ⚡ rmpadjust(gvn, 1, attr, Tracked(&mut pperm), ..);
```

Consider two system physical memory pages: SPN$_0$ and SPN$_3$. SPN$_0$ is mapped to GPN$_0$, while SPN$_3$ is mapped to GPN$_3$. The memory at SPN$_0$ holds VMPL0's secret key, which must remain confidential to VMPL3 and the hypervisor. Meanwhile, the memory at GPN$_3$ is allocated to VMPL3, and thus its access permissions can be adjusted upon VMPL3's requests. VMPL3 could gain access to the secret key at SPN$_0$ using the following steps (with the hypervisor's help):

1. VMPL3 requests VERISMO to transition GPN$_3$ to a shared status. VERISMO fulfills the request by invalidating the target memory and recording that GPN$_3$ is now invalidated since it is assigned to VMPL3.

2. To perform the attack, a malicious hypervisor binds SPN_0 with GPN_3 by executing `rmpupdate` and updating the nested page table to map GPN_3 to SPN_0.

3. When VMPL3 asks VeriSMo to revert GPN_3 back to private, VeriSMo validates the memory page at GPN_3 and adjusts permissions to permit VMPL3 access to the memory. This occurs because VeriSMo incorrectly assumes that GPN_3 was shared and does not contain VMPL0's secret.

As a result of the attack, VMPL3 obtains access to SPN_0 via GPN_3, which violates VeriSMo's confidentiality. The hardware's *failed-to-be-secure* design only detects the attack when there is an attempt to access the memory at GPN_0, as the memory binding for GPN_0 becomes invalid.

Without verification, detecting such a security vulnerability can be challenging. Its solution is straightforward: simply clear a memory page after validating it but before assigning it to VMPL3.

We reported this vulnerability to AMD in early May 2023, which resulted in a security fix [5]. However, COCONUT SVSM [39], which reuses a significant amount of code from AMD SVSM, still had the old buggy code at its early stage.

9 Related Work

Trusted execution environments. Traditional hypervisor-enforced VM isolation no longer meets the minimal trust requirements. This has led to a recent trend of adding an extra software layer as a trusted security monitor to deal with hypervisor-based attacks. Examples include Keystone [23], Komodo [11], and the Intel TDX module [18], which enforce enclave isolation and provide security features. Arm CCA [6] goes a step further by relying on two external layers for VMs: a Realm Management Monitor (RMM) for managing realms and a separate monitor for facilitating interactions between the RMM and the hypervisor. However, the issue of separating security domains within an enclave remains largely unaddressed. Different from these solutions, the security module [2, 4, 39] for AMD SEV VM [1] is isolated from both hypervisor and other in-TEE softwares in a VM.

Model checking. Formal methods can be applied to both model-level (i.e., model checking) and implementation-level verification. Model checking tools (e.g., SPIN[17], Tamarin[30]) formally checks some properties based on an abstract model of a system design (e.g., [15, 20]) to prove the correctness. Consequently, the correctness is proved without directly connecting to the implementation itself.

Software verification. Software projects (e.g., [11, 16, 29, 35, 40]) can be implemented in verification-friendly languages, such as Dafny [25] and F*[34], to enable end-to-end verification for both model and implementation. Many OS projects (such as [7, 10, 14, 21, 24, 26, 32]), based on unsafe assembly or C , are verified in proof languages. The implementation-level verification is made possible through a trusted language transformer from unsafe C. Due to the nature of unsafe C, however, their memory safety proofs require more effort than proofs about Rust. A recent study [9] uses verification to check secure information flow for confidential computing but assumes memory safety by requiring no unsafe Rust in code, which is not applicable to OS-level code.

Security model for verified OS. OS-level verification efforts ([7, 11, 14, 21, 26, 33]) typically focus on the traditional security model, either with a trusted hypervisor or without one. Some recent efforts, such as [27], have verified the security of the Arm CCA, ensuring the proper implementation of the RMM firmware for isolating multiple enclaves or VMs. Different from those works, We use the permission-based method to verify proper memory access, encoding both the state of the memory and the security level of its content. This approach simplifies our proof and streamlines our verification process, eliminating the need for additional abstract layers for proving concurrency and information flow. In addition, we verify memory accesses without extra proof efforts for the safe portion of the Rust code.

10 Conclusion

We developed and implemented VeriSMo, the first verified security module for confidential VMs enabled by AMD SEV-SNP. Operating at the highest privilege level, the security module provides protection to the guest while maintaining its own confidentiality and integrity, even in the presence of an untrusted concurrent hypervisor. Our verification process validated the security and correctness of the security module software, building upon our specifications of the AMD hardware primitives. Utilizing Rust's ownership and borrowing, the verification showcased the application of concepts from Verus's permission model on a large scale, encompassing thousands of lines of verified concurrent executable code. Our evaluation demonstrated that our security module is efficient and our verification is scalable.

Acknowledgments

We thank Verus team for sharing their insights into permission-based reasoning and providing desired features for verifying VeriSMo. The detailed reviews we received from OSDI'24 and the feedback from our shepherd Nickolai Zeldovich helped us greatly improve the paper.

Validating the eBPF Verifier via State Embedding

Hao Sun

Zhendong Su
ETH Zurich

Abstract

This paper introduces *state embedding*, a novel and highly effective technique for validating the correctness of the eBPF verifier, a critical component for Linux kernel security. To check whether a program is safe to execute, the verifier must track over-approximated program states along each potential control-flow path; any concrete state not contained in the tracked approximation may invalidate the verifier's conclusion. Our key insight is that one can effectively detect logic bugs in the verifier by embedding a program with certain approximation-correctness checks expected to be validated by the verifier. Indeed, for a program deemed safe by the verifier, our approach embeds concrete states via eBPF program constructs as correctness checks. By construction, the resulting state-embedded program allows the verifier to validate whether the embedded concrete states are correctly approximated by itself; any validation failure therefore reveals a logic bug in the verifier. We realize *state embedding* as a practical tool and apply it to test the eBPF verifier. Our evaluation results highlight its effectiveness. Despite the extensive scrutiny and testing undertaken on the eBPF verifier, our approach, within one month, uncovered 15 previously unknown logic bugs, 10 of which have already been fixed. Many of the detected bugs are severe, *e.g.,* two are exploitable and can lead to local privilege escalation.

1 Introduction

The Extended Berkeley Package Filter (eBPF) [32, 37] allows untrusted user space extensions to be executed in kernel space. This mechanism has been broadly adopted by modern operating system kernels to flexibly implement various specialized tasks, including filtering [43], profiling [28], and security monitoring [15], among others [23, 54]. To ensure the safety of the untrusted extensions, a static checker [8] (verifier) is utilized to rigorously validate their integrity. In this work, our primary focus is on the eBPF verifier in the Linux kernel, which is mature and has successfully been applied in various contexts. The eBPF verifier employs abstract interpretation [20], a process where it traverses the program and gathers approximations across different abstract domains to identify potentially invalid behaviors. Due to its intricate checking mechanism, the verifier has evolved into one of the most complex components within the eBPF subsystem.

The correctness of the eBPF verifier is of utmost significance. The eBPF subsystem provides extensibility by granting restricted kernel space code execution capability to user space, which is enforced by the verifier. These restrictions are crucial as they limit memory access and control flow in programs, thereby preventing the kernel from being impacted by potentially harmful extensions. However, logic bugs in the verifier can compromise these restrictions, leading to unsafe programs being loaded. Indeed, the verifier's vulnerabilities are attractive to attackers as these bugs have a higher likelihood of being exploited to inject malicious programs into the kernel [1–3]. We will demonstrate, in Section 2.2, the exploitation of one such bug we found, a simple incorrect type cast in the verifier, to achieve local privilege escalation. Therefore, detecting and rectifying logic bugs in the eBPF verifier is critical to the overall kernel security.

Given its importance, existing work applies formal verification to several components of the verifier. For example, Agni [45] generates verification conditions for the range analysis of the verifier, and other work [44, 52] aims to verify the `tnum` domain [35]. These efforts have provided strong guarantees for the correctly verified components. Nevertheless, given its complexity, obtaining specifications, either manually or automatically, is intrinsically challenging even for a portion of the verifier [18]. Consequently, these checked specifications may be incomplete [9] or diverge from the implementation [4], *e.g.,* we still uncovered logic bugs in the verified range analysis. Moreover, these components are relatively small, and the verifier is constantly evolving with new algorithmic enhancements and features. Previous work has also applied automatic testing on eBPF [25, 26, 42]. For instance, Syzkaller [47] has been incorporated into the eBPF upstream and has identified many memory errors in the eBPF system call. Yet, they encounter challenges in detecting logic bugs due to the lack of effective test oracles [24], namely methods to automatically determine whether a program should be accepted or rejected by the verifier.

Observation. In essence, the verifier checks eBPF programs by tracking states at different locations along each possible execution path within its abstract domains, *i.e.,* the verifier state (approximation). The checking procedure on each execution path can be modeled as verifier state transitions:

$$A_0 \rightarrow A_1 \rightarrow ... \rightarrow A_{n-1} \rightarrow A_n$$

The verifier state transition corresponds to a set of concrete state transitions on the corresponding execution path:

$$S_0 \rightarrow S_1 \rightarrow ... \rightarrow S_{n-1} \rightarrow S_n$$

Each concrete state S_i must be contained in the corresponding approximation A_i; otherwise, it is a verifier bug since attackers can manipulate such a concrete state, thereby breaking the verifier's conclusion. The key observation is that, to ensure the conclusion is correct, the verifier must over-approximate all possible concrete states at each program point. In other words, any concrete state not contained in the approximation can invalidate the conclusion. The property is fundamental and can be harnessed as an effective test oracle to validate the correctness of the verifier without requiring specifications. The ensuing challenge is how to determine whether or not concrete states are contained in the approximation.

State Embedding. This paper introduces state embedding, a novel and effective mechanism for validating the eBPF verifier. Our key insight is: one can effectively detect logic bugs by embedding a program with the aforementioned approximation-correctness checks that are expected to be validated by the verifier itself. State embedding contrasts pairs of programs, P and P'. Initially, a program P, accepted by the verifier, is executed to profile its concrete states. Next, P' is crafted by embedding sinks that contradict these observed states into P, challenging the verifier to validate it. A correct verifier should reject P' since a valid approximation must include the observed concrete states, thus accepting P' reveals a logic bug. More concretely, given an accepted program P and a profiled concrete state S. Corresponding to S is a variable A representing the verifier's approximation. P' is constructed by embedding the following program construct:

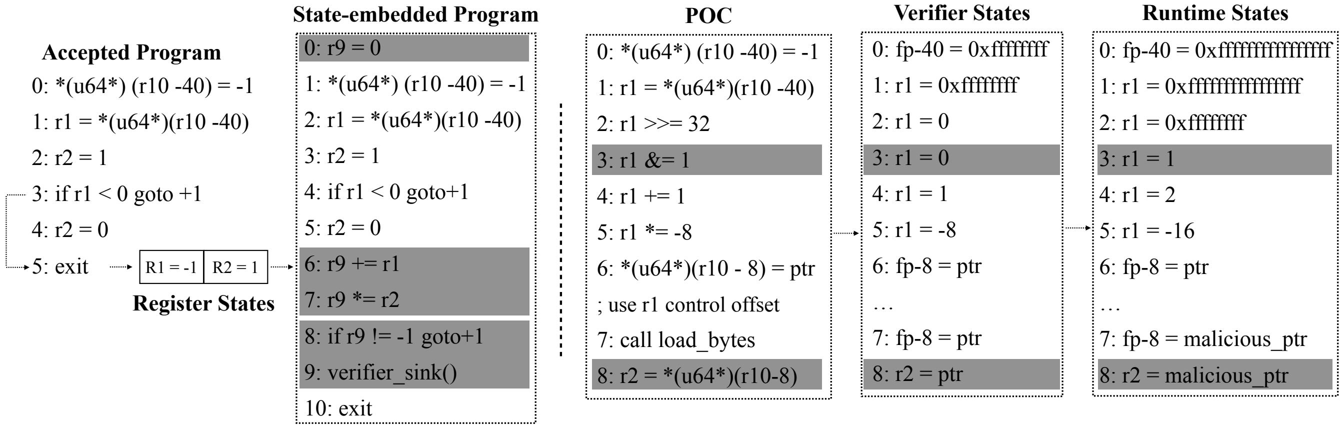
$$\textbf{if } S \in A \textbf{ then } \textit{verifier\_sink}()$$

The condition directs the verifier to check if the concrete state S is indeed contained within its approximation A, and *verifier_sink*() refers to any incorrect operation; encountering this during validation signals an error, indicating that S is correctly contained in A. One can easily realize the construct by utilizing the if-condition statement with equality comparison; we defer to Section 3.1 for concrete examples. Thus, P' can be applied to validate the verifier V: $\mathcal{P} \rightarrow \{\textit{safe}, \textit{unsafe}\}$, where marking P' as *unsafe* due to the triggered sink confirms the inclusion of S in A; conversely, deeming P' safe indicates a failure in capturing S within A, *i.e.,* a verifier's logic bug.

Realization. We realized state embedding as a practical tool, which we call SEV, and applied it in validating the eBPF verifier. First, for an eBPF program accepted by the verifier, SEV executes and profiles the program to gather its register states at each basic block. Second, to efficiently embed each state, we utilize the following optimization (which will be further elaborated in Section 3.1). At each basic block, a folding function is generated to fold the corresponding concrete register states into a global variable. A state-embedded program is synthesized by inserting the folding functions and embedding the concrete values of the global variables. Finally, the resulting program is used to validate the verifier; indeed, any failure to detect the sink indicates a logic bug in the verifier. Our evaluation results show that state embedding is highly effective. Within one month, we discovered 15 logic bugs exclusively in the verifier. This is a significant result considering that the verifier is primarily around 20,000 lines of code and, as aforementioned, has been partially verified. In addition, the verifier has gone through extensive security scrutiny and testing [7, 46]. Moreover, most of the bugs found are critical. For instance, two bugs are exploitable, where one allows users with `CAP_BPF` [41] to obtain root privilege and has existed for four years, and the other enables users with `CAP_PERFMON` [19] to obtain root privilege, both affecting kernel v5.10.33 and later.

State embedding significantly complements existing work. In comparison, our approach has several distinct advantages: (1) SEV treats the verifier as a grey-box rather than a black-box by inspecting the verifier states, which allows fine-grained detection of logic bugs; (2) by transforming and taking the state-embedded programs as input, the verifier automatically checks if the concrete states are contained, thus the approach requires little domain knowledge and is practical; (3) in general, one can easily embed rich concrete states, yet to detect all the sinks, the verifier must correctly collect approximations encompassing all the embedded states, thus being effective; and (4) state embedding can detect diverse logic bugs that lead to discrepancies between concrete states and approximations, *e.g.,* the bugs we found are located in various components including range analysis, stack access validation, *etc.* The key contributions of our work are:

- We propose state embedding, a novel and highly effective mechanism for detecting logic bugs in the eBPF verifier.
- We present SEV, a practical realization of state embedding, and apply it to stress test the eBPF verifier.
- We demonstrate state embedding's effectiveness by uncovering 15 previously unknown logic bugs in the eBPF verifier with 10 already fixed and many being critical.



Accepted Program

```
0: *(u64*) (r10 -40) = -1
1: r1 = *(u64*)(r10 -40)
2: r2 = 1
3: if r1 < 0 goto +1
4: r2 = 0
5: exit
```

State-embedded Program

```
0: r9 = 0
1: *(u64*) (r10 -40) = -1
2: r1 = *(u64*)(r10 -40)
3: r2 = 1
4: if r1 < 0 goto+1
5: r2 = 0
6: r9 += r1
7: r9 *= r2
8: if r9 != -1 goto+1
9: verifier_sink()
10: exit
```

POC

```
0: *(u64*) (r10 -40) = -1
1: r1 = *(u64*)(r10 -40)
2: r1 >>= 32
3: r1 &= 1
4: r1 += 1
5: r1 *= -8
6: *(u64*)(r10 - 8) = ptr
; use r1 control offset
7: call load_bytes
8: r2 = *(u64*)(r10-8)
```

Verifier States

```
0: fp-40 = 0xffffffff
1: r1 = 0xffffffff
2: r1 = 0
3: r1 = 0
4: r1 = 1
5: r1 = -8
6: fp-8 = ptr
...
7: fp-8 = ptr
8: r2 = ptr
```

Runtime States

```
0: fp-40 = 0xffffffffffffffff
1: r1 = 0xffffffffffffffff
2: r1 = 0xffffffff
3: r1 = 1
4: r1 = 2
5: r1 = -16
6: fp-8 = ptr
...
7: fp-8 = malicious_ptr
8: r2 = malicious_ptr
```

Figure 1: SEV performs state embedding by (1) profiling the concrete states of registers at each basic block, *e.g.,* R1 and R2; (2) folding R1 and R2 to R9 (#6 and #7); (3) embedding the concrete state of R9 (#8) and the verifier sink (#9). The instructions #8 and #9 implement the program construct and are the approximation-correctness check. The verifier interprets the if-condition #8 by validating if the runtime value -1 is within the approximation of R9, *i.e.,* determining if R9 could be -1, in which case the sink would be reported; otherwise, the verifier jumps from #8 to #10 and skips the sink. During validating the state-embedded program, the verifier skips the sink due to the logic bug. The root cause is sign information loss at #1. The POC program manipulates the state of R1 (#2 and #3), making the verifier believe R1 equals zero, whereas at runtime, it equals one. Consequently, the program overwrites the valid pointer stored on the stack with a malicious pointer (#6 and #7), thereby achieving arbitrary access.

2 Background and Illustrative Example

2.1 eBPF

eBPF is a register-based virtual machine that enables user space to extend the kernel dynamically. The user space first writes programs consisting of a sequence of eBPF instructions and loads the program with the `bpf()` system call. Programs operate on 11 registers (R0 to R10) and a fixed-size stack with four major types of instructions, namely load, store, arithmetic, and branch. An example program is presented in Figure 1. eBPF is adopted across different privilege levels, from unprivileged users [13] to those with certain capabilities [19, 41], and to fully privileged users. For instance, the `CAP_BPF` capability allows using eBPF with minimal privilege, widely applied in container scenarios. Consequently, the extensions are untrusted and a verifier is employed to validate their safety.

In a nutshell, the verifier traverses each execution path, interpreting every instruction in its abstract domains. Programs exhibiting any form of invalid behaviors, such as infinite loops and out-of-bounds access, are rejected. To strive for both soundness and precision, the verifier employs sophisticated algorithms to track program states. For instance, it gathers pointer types, register liveness, scalar ranges, *etc.* Scalar ranges are tracked using five abstract domains: four interval domains for different signs and bit-sizes, and the tristate number (`tnum`) domain [35] to model bit-wise operations. Scalar ranges are derived by combining information across these domains. The verifier models pointers based on region types and offsets, categorizing the former into more than twenty types, while tracking the latter using a variable. Furthermore, the verifier undergoes continuous updates by maintainers with new features and algorithms. The above features make the verifier the most complex component within the eBPF subsystem.

2.2 Illustrative Example

The key idea of our approach is to embed concrete states in programs such that when taking the state-embedded programs as input, we leverage the verifier to check whether the concrete states are contained in the approximation, thereby detecting logic bugs. In this section, we use an example to showcase how state embedding enables the detection of a subtle logic bug caused by a simple incorrect type cast. We also demonstrate the exploitation of the bug to highlight the significance of the verifier's correctness.

The Bug. The left segment of Figure 1 shows a valid eBPF program accepted by the verifier. Without effective test oracles, existing approaches would simply drop the case and proceed to the next iteration, since the program does not contain invalid behaviors. In comparison, SEV further utilizes state embedding to validate the verifier's approximation of the program, thereby uncovering this bug. Figure 2 shows the root cause and the patch proposed by us to fix the bug.

eBPF programs can spill registers or immediate values to the stack, and the verifier tracks the state of the stack accordingly. For the instruction `*(u64*)(r10-40)=-1` shown in the accepted program, the verifier marks the state of the accessed

```

   } else if (reg && is_spillable_regtype(reg->type)) {
```

Figure 2: A logic bug detected by SEV. During spilling immediate values on the stack, the verifier incorrectly casts the `i32` immediate value to `u32` type, thus losing sign information. We proposed this patch to drop the cast, since `__mark_reg_known()` accepts `u64` type, the compiler would correctly promote integer type and propagate sign information. The patch has been accepted in the upstream and back-ported to the stable kernels.

stack slot as a known scalar value. However, during this process, the verifier incorrectly casts the immediate value from `i32` to `u32` and then sets the state of the stack slot, which is `u64`, to the casted value, causing lost sign information and the state of the stack slot being updated to an incorrect value. As depicted in Figure 1, when storing `-1` to the stack, the verifier incorrectly marks the corresponding stack slot as a value whose higher 32 bits are all zero, *i.e.,* losing sign information. Subsequently, when loading the same stack slot back, the verifier state of the destination register does not match the original register, *i.e.,* the concrete value `-1` is not contained in the approximation. Figure 2 demonstrates the patch to fix the bug, which has been merged to the upstream and back-ported to the stable kernels, given its security impact.

In general, detecting logic bugs in the verifier poses significant challenges due to the following characteristics:

- **Hard to notice:** The abstract domains utilized by the verifier are complex and challenging to comprehend thoroughly, and the cyclomatic complexity of its tracking logic is high. To pinpoint logic bugs, one needs to precisely understand the verifier states and inspect them following the tracking logic. Conducting such a process is difficult, *e.g.,* the aforementioned incorrect type cast is likely to be overlooked.

- **Hard to detect:** Existing work treats the program under testing as a black-box, yet logic bugs of the verifier are likely to be silent errors. For instance, the behavior of the program demonstrated is correct, which simply accesses the stack within bounds and operates the registers, and in this sense, the verifier's conclusion seems justified. However, as shown by our approach, the verifier's approximation contains a subtle flaw, which is challenging for existing approaches to detect.

State Embedding. To enforce the safety of the program, the verifier must track the over-approximation of program states on each execution path, yet a concrete state not contained in the approximation can invalidate the conclusion. Based on the observation, our approach systematically transforms the program to embed concrete states within certain program constructs and utilizes the verifier to validate whether the aforementioned property holds during the checking process.

Step 1: The first step of state embedding is to profile concrete states, as illustrated in Figure 1. For a program accepted by the verifier, we execute and profile concrete states at each basic block of the execution path. Since the if-condition at #3 holds at runtime, the program jumps to #5, where we collect the concrete states of registers. The concrete states of R1 and R2 must be contained in the verifier's approximation.

Step 2: The second step performs state embedding. In practice, the collected state information is rich, and directly embedding each state makes the verifier fork and explore paths multiple times, potentially leading to redundant checks. We adopt folding to efficiently conduct state embedding. First, we initialize R9 (#0), a reserved register that holds the folded concrete state. Then, we generate a folding function at each basic block, which consists of arithmetic instructions that fold the collected states into the single register R9. The folding function in Figure 1 has two instructions #6 and #7, which fold R1 and R2 into R9. The value of R9 is calculated during the generation by evaluating those arithmetic instructions with the concrete states, which, in the example, equals `-1`. Finally, the instruction #8 and #9 implement the program construct, which embeds the folded concrete state with the if-condition instruction that compares R9 with its value `-1` and the verifier sink. The condition makes the verifier compare the folded state with its approximation of R9. The sink would be detected if the verifier deems `-1` is within the approximation.

Step 3: Subsequently, we can take the state-embedded program as input to the verifier to detect the logic bug. During the checking process, the verifier initially collects the program states from #0 to #4, where it incorrectly tracks the approximation of R1 (#1 and #2). Such an issue would be captured as the concrete state of R1 is folded into R9. Since the verifier determines `r1<0` not hold, it proceeds from #4 to #5. At #6 and #7, the verifier folds R1 and R2 into R9, where it erroneously concludes that the only concrete value within the approximation of R9 is zero. Therefore, the folded concrete state `-1` would not be contained in the approximation of R9, causing the verifier to skip the sink at #9. Consequently, we have found the logic bug in the verifier.

Our approach embeds concrete states within certain program constructs and utilizes the verifier to validate the approximations. State embedding provides two distinct advantages:

- **Fine-grained:** State embedding views the verifier as a grey-box rather than a black-box since it performs fine-grained validation on the verifier states. For the aforementioned example, which is overlooked by the existing approaches and even by the experienced maintainers, our approach further validates the approximations with the profiled concrete states.

- **Practical:** Our approach validates if the aforementioned property holds by embedding concrete states and utilizing the verifier to compare the states against the approximations. Therefore, state embedding requires little domain knowledge and is more practical.

The Exploit. The right segment of Figure 1 depicts a proof-of-concept (POC) that exploits the bug to obtain root privilege. In essence, the POC uses the bug to manipulate the verifier's knowledge about the program. Since the verifier incorrectly believes that the higher 32 bits of R1 are zero, which are in fact all one at runtime, the POC first constructs an evil register by right-shift and logic AND operations (#2 and #3). These operations make the verifier conclude R1 equals zero, while at runtime it equals one. Then, the POC stores a valid pointer on the stack and invokes a helper function that allows eBPF programs to load user space data to their stack. By using the evil register as the length parameter, the POC makes the verifier think that only 8 bytes are stored on the stack, while in fact it stores 16 bytes, thus overwriting the pointer with the user-controlled pointer. Finally, the POC achieves arbitrary access with the malicious pointer, while the verifier erroneously believes the program is operating the original valid pointer.

Since eBPF programs are executed in kernel space, the POC can perform various malicious operations, *e.g.,* overwriting credentials of the current task struct for privilege escalation. Our full POC enables users with `CAP_BPF` to achieve root access, and kernels v5.10.33 and later are affected. After we submitted the patches that fix the bug, we also received positive feedback from the maintainers of the eBPF subsystem:

> *"...I owe you a big thanks as well since this helps with our internal process. So thank you in advance!"*

It is important to highlight that the aforementioned exploit accomplishes all the malicious operations through the subtle bug, a simple incorrect type cast in one line of the verifier's code. In addition to the presented bug, we also found another exploitable bug allowing users with `CAP_PERFMON` to obtain root privilege, arising from incorrect tracking of memory accesses with variable offsets. The capability mechanism in Linux grants users the minimum privileges for specialized tasks, yet these bugs undermine this rule, posing significant security concerns. Notably, in the POC programs for both bugs, the number of instructions used to manipulate the verifier's knowledge is less than ten, further demonstrating the severity of the bugs found. This illustrates that our approach can detect critical logic bugs by leveraging the verifier to perform fine-grained validations on its approximations.

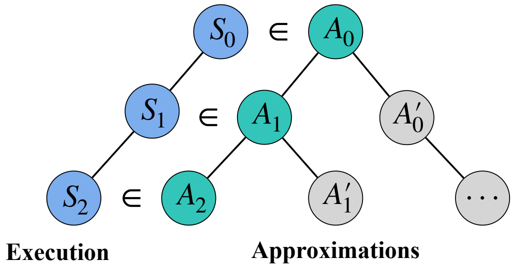

Figure 3: The verifier tracks program states on each possible path as shown in the right part, and the runtime execution corresponds to one of the paths. Each concrete state S_i must be contained in the approximation A_i; otherwise, operations on the non-contained states could be unsafe, *i.e.,* a logic bug.

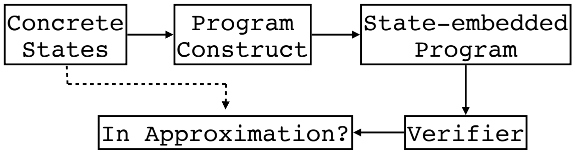

Figure 4: Our approach validates whether concrete states are contained in the approximation for logic bug detection by (1) embedding the concrete states in the program with the construct; (2) taking the state-embedded program as input to the verifier; and (3) leveraging the verifier to validate the states against the approximation.

3 State Embedding and SEV

In this section, we introduce state embedding, a folded variant, and describe our implementation of SEV.

3.1 State Embedding

State embedding is based on one fundamental observation: the concrete states must be contained in the corresponding approximations of the verifier, as shown in Figure 3. The goal of state embedding is to validate if this property holds during validation. As depicted in Figure 4, to achieve this, the approach executes and profiles an accepted program P, lacking inputs and external interactions, to collect concrete states, which remain consistent across multiple executions. Since those states are profiled from a real execution, they establish the ground truth that the corresponding approximations must properly contain them. Next, P is transformed to P' by embedding sinks that contradict those observed states. When taking P' as input, the verifier, following the same path as the real execution, compares the embedded concrete states against the approximations, thereby automatically validating its own correctness.

At the conceptual level, given a program P, a concrete state S, and the variable A holding the state (the approximation from the verifier's perspective), a state-embedded program P'

is synthesized by embedding the following program construct at the corresponding program location:

$$\textbf{if } S \in A \textbf{ then } \mathit{verifier\_sink}()$$

The $\in$ in the program construct is an abstraction of the operators in the program, for which the verifier interprets to check whether the concrete state S is contained in the approximation A or not. The $\mathit{verifier\_sink}()$ represents the operations, where the verifier reports errors. By embedding the program construct and taking P' as input, the verifier interprets the construct to check if the embedded state S is within A properly. The verifier sink in the construct is an indicator for the containment of the concrete state S.

Proposition 3.1 *State embedding does not introduce any invalid operations except for the sink.*

The aforementioned program construct does not introduce incorrect operations to the original accepted program except for the verifier sink. When interpreting the embedded construct, the verifier state A_i would be split into two states A_j and A_k, where the former follows the branch-taking path of the if-condition thus detecting the sink, and the latter continues the original execution path. Since the original program is considered safe under the approximation of A_i and $A_i = A_j \cup A_k$, *i.e.,* A_i is a superset of both A_j and A_k, the program is also considered safe with A_k. Therefore, the sink is the only expected error for a state-embedded program.

Corollary 3.1 *Failure to detect the sink indicates a logic bug in the verifier.*

More concretely, for a verifier V: $\mathcal{P} \rightarrow \{safe, unsafe\}$, since the original program P is considered safe by the verifier, $V(P') = unsafe$ with the sink being reported implies that the verifier correctly deems S is within the approximation A; on the contrary, $V(P') = safe$, *i.e.,* failure to detect the sink, indicates the concrete state S being missed from the approximation A, *i.e.,* a verifier logic bug.

Here we demonstrate the semantics of each part in the program construct with an example. In general, the verifier interprets concrete operators in the program in its abstract domain. Many concrete operators are available to implement the abstraction $\in$. For instance, as shown in Listing 1, one can utilize the if-statement with an == comparison to realize the construct; other comparisons, such as greater-equal (>=) or less-equal (<=), are also feasible, as per the implementation. The instruction writing to the read-only register R10 is an instance of the verifier sink in eBPF programs, and assertion failure can be used in other scenarios. After embedding, the verifier interprets the if-statement by validating if S is within the approximation of A to determine if the branch should be taken, in which case the sink would be reported.

```
...original program
The verifier checks if S is within A, when
interpreting the following if-statement.
if (S == A)
    verifier_sink();
...
```

Listing 1: Example of the program construct.

Folded Variant. A straightforward realization of state embedding is by profiling the program to collect concrete states and subsequently embedding the states with the corresponding program construct multiple times. However, directly embedding each state encounters two challenges: (1) the verifier may halt early at the first detected sink, leaving other sinks unchecked; and (2) the inserted sinks make the verifier fork exploring paths, introducing redundant checks. We propose a folded variant to embed the states in conjunction with one sink efficiently. For each concrete state in an execution:

$$S_0 \rightarrow S_1 \rightarrow \dots \rightarrow S_{n-1} \rightarrow S_n$$

we do not directly embed each S_i into the program. Instead, we generate a folding function f_i for each of them, which consists of simple computation operations, *e.g.,* ALU operations in eBPF programs, and hold the folded concrete state $\widehat{S}$ in a global variable $\widehat{A}$:

$$\widehat{S_1} = f_1(\widehat{S_0},\ S_1) \rightarrow \dots \rightarrow\ \widehat{S_n} = f_n(\widehat{S}_{n-1},\ S_n)$$

Finally, we embed the folded state $\widehat{S_n}$ once with the following program construct:

$$\textbf{if } \widehat{S_n} \in \widehat{A} \textbf{ then } \mathit{verifier\_sink}()$$

Since only the folded state is embedded, the verifier forks once. The bug-detecting capability of this variant is equivalent to the original form since incorrect approximations are likely to be propagated to the approximation of the global variable during the continuous testing campaign. The variant provides further benefits, *e.g.,* to detect the sink, the verifier needs to not only correctly track states for the original program, but also properly simulate the folding functions.

3.2 The SEV Implementation

We applied state embedding to detect logic bugs in the eBPF verifier. Algorithm 1 illustrates the major workflow. In each testing iteration, SEV first utilizes the program generator that we developed to obtain eBPF programs accepted by the verifier (lines 4-6), and then executes and profiles the program to collect the register states at each basic block (line 7). We follow established compiler testing methodologies [31] by utilizing deterministic, closed eBPF programs that require only a single round of profiling and the profiled states are consistent across executions. Based on the concrete states,

Algorithm 1: Workflow of SEV

```
1  Procedure Validate():
2      $LogicBugs \leftarrow \emptyset$
3      while not terminate do
4          $P \leftarrow$ NextProg()
5          if Verify($P$) = reject then
6              continue
           // Profile states at basic block
7          $S \leftarrow$ Profile($P$)
           // Embed the concrete states
8          $P' \leftarrow$ StateEmbedding($P$, $S$)
           // Validate the eBPF verifier
9          if Verify($P'$) = accept then
10             $LogicBugs \leftarrow LogicBugs \cup P'$
```

SEV transforms the program to inject folding functions at each basic block and embed the folded concrete state (line 8). Finally, the state-embedded program is used as input to the verifier (line 9), and a logic bug is detected if the program is accepted (lines 10-11), *i.e.,* the verifier is incapable of detecting the sink. The aforementioned loop continuously tests the verifier with state-embedded programs.

SEV first needs to obtain eBPF programs that can pass the verifier. We devise a program generator to facilitate state embedding, adhering to the established program generation approaches [50]. First, we ensure the instruction encoding and the control flow of a generated program are valid by following the instruction specification [6] and representing a program as a structured graph, thereby avoiding being rejected early. Next, we synthesize the program by combining several basic structures, *e.g.,* if-else block and back-edge, and leveraging lightweight global state information, such as register and stack slot states, to generate instructions reflecting realistic usage patterns. We categorize a register state into several types, including uninitialized, scalar value, and pointer, and synthesize operations accordingly, *e.g.,* generating pointer accesses or offset operations if a register stores a pointer. The generator continuously provides programs for the testing campaign.

We implemented a tracer based on the existing kernel infrastructures to profile programs. The tracer intercepts the execution of programs at each basic block and captures the instruction index and the register states, which are appended into an internal state buffer. The tracer interface is exposed via a virtual device so that the user space can utilize the functionality flexibly and access the buffer via `mmap()` for shared memory. For each accepted program, SEV executes it with the tracer enabled and decodes the buffer in user space.

Algorithm 2 presents SEV's implementation of state embedding. The inputs are the accepted program and the concrete states at each basic block collected with the tracer. We first initialize the folded state (line 2), and R9 is reserved to ensure its availability for storing this value. The algorithm maintains a map associating each basic block with its folding function (line 3). The collected states are essentially a basic block trace in conjunction with the states, where the basic block could appear multiple times due to loops. By using the map, the algorithm ensures the folding function is generated once for each basic block. The folding function is generated by synthesizing various eBPF arithmetic instructions for each collected register (lines 6-8). We consider all the ALU instructions the verifier can accurately track, excluding the division and all unary operations. Folding functions are generated by randomly selecting those operations applied to non-zero registers, preventing the state from being easily reduced to zero. The folded state is updated by calculating the folding function with the concrete states (line 9). Finally, the state-embedded program is generated by inserting each folding function in the corresponding basic block and embedding the folded state with the instructions (lines 10-11), as shown in Listing 2.

Algorithm 2: State Embedding

```
1  Function StateEmbedding(Program P, States S):
2      $FoldedState \leftarrow$ Initialize()
       // Basic block to folding function map
3      $FoldingFns \leftarrow \emptyset$
4      foreach $BB$, $Regs \in S$ do
5          $F \leftarrow FoldingFns[BB]$
6          if $F$ not exists then
               // Generate folding function
7              foreach $Reg \in Regs$ do
8                  $F \leftarrow$ GenALU($F$, $Reg$)
           // Update Folded State
9          $FoldedState \leftarrow F(Regs, FoldedState)$
       // Insert the folding functions
10     $P' \leftarrow$ InsertFoldingFns($P$, $FoldingFns$)
       // Embed the folded state
11     $P' \leftarrow$ EmbedFoldedState($P'$, $FoldedState$)
12     return $P'$
```

```
if r9 != FoldedState goto+1
r10 = 0
```

Listing 2: The instructions used for embedding the folded state and the verifier sink in eBPF programs.

The first instruction in Listing 2 makes the verifier validate whether the folded state is contained in the approximation of R9. The second instruction is the verifier sink, an illegal operation where the verifier reports a "writing to the read-only register R10" error. The sink is skipped if the folded state is not contained, indicating a logic bug. The state-embedded program can thus be used for validating the verifier.

4 Evaluation

In this section, we evaluate the effectiveness of state embedding by applying SEV to detect logic bugs in the eBPF verifier. Highlights of our results are as follows:

- **Considerable bugs:** We have found 15 previously unknown logic bugs solely in the eBPF verifier.
- **Diverse bug types:** The root causes of the bugs are various and located in different components of the verifier.
- **Critical severity:** Most of the bugs found by SEV are critical, posing various security implications.

We believe that the quantity and quality of the bugs found by our prototype SEV have demonstrated the effectiveness of state embedding in uncovering logic bugs in the verifier.

4.1 Evaluation Setup

Environment. All the bug-finding experiments were conducted on a Linux server with a 64-core AMD Ryzen Threadripper 3990X Processor, where each core has two threads, and the memory size of the server is 256 GiB. The version of the host Linux kernel is v5.15. To ensure that these experiments did not affect the host system, we conducted our testing within multiple virtual machine instances. These instances were created using QEMU version 6.2.0, with KVM employed to provide acceleration. The guest environment in each instance consisted of a minimal Debian distribution disk image, and the system was booted using the compiled kernels. In addition to incorporating common kernel configurations, we also enabled the eBPF subsystem-related options [5].

Kernel Version. We chose the eBPF upstream repository for testing, and the reasons are as follows: (1) the uncovered logic bugs in the upstream are likely to be previously known, and thus should be fixed immediately; (2) testing upstream enables the detection of bugs that may impact various past stable versions; and (3) testing the upstream kernel prevents newly introduced bugs being merged into subsequent releases. In addition to the built configuration previously mentioned, we also patched the kernel and enabled related options since we modified the eBPF interpreter `bpf/core.c` to intercept the execution of eBPF programs for state tracing.

Testing Process. SEV is designed to automatically execute the entire testing process. Initially, after configuring the disk image and the kernel for testing, SEV determines the appropriate QEMU command line and subsequently initiates the virtual machine using the specified kernel. Upon successful booting of the virtual machine, SEV proceeds to the testing phase. This involves the generation of eBPF programs and the validation of the verifier using state-embedded programs. A shared directory is established to transfer the testing results between the host and the guest. Subsequently, SEV checks the liveness of the virtual machine and restarts the whole campaign if it detects the system is not alive. We utilized SEV to test the eBPF upstream with the aforementioned testing process for one month.

Bug Triage. We triage and deduplicate all the bugs found based on their root causes. In principle, any failure to detect the sink in the state-embedded programs indicates a logic bug in the verifier. When SEV reports such a case, we further inspect it to locate the root cause. During the testing campaign, SEV retains the original program, the captured runtime states, and the corresponding state-embedded program when a logic bug is identified. We inspect the programs to pinpoint the instruction where the approximation of the verifier mismatches the runtime states, and then analyze the preceding instructions to collect related operations that produce the operands for the culprit instruction. The culprit instruction in conjunction with related operations enables us to locate the incorrect verifier logic. Finally, one can look into those parts of the verifier and analyze the root cause.

4.2 Quantitative Results

Bug Number. We applied SEV to test the eBPF verifier for one month and triaged the discovered bugs based on their root causes as mentioned in Section 4.1. Note that we only reported unique bugs to the eBPF mailing list, and only bugs with different root causes are counted in our evaluation. As a result, we have found 15 unique logic bugs in the eBPF verifier within one month, of which 10 have been fixed at the time of paper submission. The number of found bugs is significant considering: (1) the codebase of the eBPF verifier is relatively small compared to other subsystems, *e.g.,* it mainly contains 20,000 lines of code; (2) the verifier has undergone thorough security scrutiny by the community and is one of the most extensively tested components in the kernel, *e.g.,* eBPF self-tests [7] contain a large set of programs covering different corner cases to test the verifier; and (3) previous research efforts have applied verification on parts of the eBPF verifier [44, 45, 52]. The aforementioned results demonstrate that our approach is highly effective in uncovering logic bugs.

Furthermore, compared to manual testing, which requires substantial effort to keep up with the development of eBPF, our approach can continuously test the eBPF verifier along with its frequent updates and modifications. Existing testing tools like Syzkaller can uncover memory issues in the eBPF subsystem, yet they encounter difficulties in logic bug detection due to the lack of effective test oracles. While formal verification provides a strong guarantee, synthesizing specifications for the verifier is inherently complex, whereas SEV utilizes state embedding to automatically uncover logic bugs in the verifier without requiring specifications. Therefore, state embedding uniquely complements existing approaches.

Table 1: Number of bugs found by SEV in different locations.

Bug Location	Range Analysis	Memory Access	State Prune	CFG Check	Other
#	6	3	2	2	2

Bug Types. In general, logic bugs in the verifier can be classified into two categories: (1) incorrectly accepting unsafe programs, *i.e.,* soundness bugs, and (2) incorrectly rejecting safe, correct programs, *i.e.,* completeness bugs. The former introduces potential security issues, *e.g.,* allowing malicious programs to be loaded, while the latter forces developers to heavily refactor their programs to mitigate the verifier's imprecision. Overall, we have found 12 soundness bugs and three completeness bugs. Table 1 shows the bug details.

Our approach can detect various soundness bugs in the verifier for the following reasons. eBPF supports four major types of instructions, including load, store, ALU, and jump operations. For ALU and jump, the eBPF verifier mainly performs range analysis and pointer arithmetic checks. Since these operations are conducted on the registers, logic bugs in those components mainly result in incorrect approximation of register states. SEV can directly detect those logic bugs because our approach validates if the concrete states are contained in the approximation. For example, six of the bugs found are related to range analysis. For logic bugs in load and store checks, although we do not profile all the memory accessible to eBPF programs, SEV can still detect bugs in these areas because incorrect tracking on those states can be propagated to the approximation of registers. For instance, three of the bugs found are related to memory access validation, including the incorrect stack spill checking illustrated in Figure 1. Furthermore, we also uncovered logic bugs in other components, *e.g.,* the state pruning procedure.

SEV can also uncover completeness bugs as an additional design benefit. As detailed in Section 3, state embedding does not introduce any incorrect operations except for the sink. If the verifier rejects state-embedded programs for reasons other than the sink, it indicates the presence of a completeness bug. More broadly, the idea of state embedding can be specifically tailored for completeness bug detection. For example, replacing the sink with valid operations in the transformed programs would ensure their correctness, thereby highlighting any inaccuracies in the verifier's rejection of these programs. Completeness bugs not only interfere with development but also reflect potential implementation issues in the verifier. SEV uncovered three such bugs, where two are related to control flow graph checking, and the other is inconsistent stack access validation. While these bugs may not directly pose security issues, they significantly impact the usability of eBPF. For instance, one bug we discovered causes the verifier to erroneously reject a set of programs due to a specific control flow pattern, despite these programs being correct.

These results underscore the effectiveness of state embedding in identifying a diverse array of logic bugs, and generally, state embedding can detect logic bugs that result in a divergence between the approximations and the concrete states.

Bug Impact. Logic bugs within the eBPF verifier hold critical implications. All of the 15 bugs found by SEV are located within the verifier, specifically in `verifier.c`, and most of them are critical. We have demonstrated that two of the found bugs are exploitable, and each can be exploited to achieve local privilege escalation. Beyond these, other uncovered bugs have diverse implications. For example, some bugs in the range analysis can circumvent the verifier's enforcement that the return values of certain programs must be within specified ranges, thereby potentially affecting the caller. The bugs in the state pruning procedure can be used to load programs containing infinite loops, leading to system hangs.

4.3 Assorted Bug Samples Found by SEV

To further demonstrate the characteristics of the uncovered bugs, we highlight several examples in this section.

Figure 5a: The range analysis is an important component of the verifier since it is the foundation for various safety checks, *e.g.,* memory access check and control flow validation. Figure 5a shows a logic bug found by SEV in the range analysis, where the verifier incorrectly tracks registers' states after simulating the fall-through path of the branch condition. The root cause is the verifier's inability to correctly handle the `JSLE` instruction when comparing a range with a non-overlapping constant. More concretely, R9 is initialized at first and updated subsequently, and the range of R8 and the value of R4 are non-overlap at #6, after which the verifier incorrectly marks R8 and R9 as constant values. After the arithmetic operations (#7 and #8), the runtime value of R9 is one at #9, which differs from the verifier's approximation, a constant zero. The bug can break the verifier's restriction. For instance, the verifier enforces that the return value of certain program types can only be zero to not modify the caller states, yet the bug leads to programs with arbitrary return values being loaded. After we reported the bug, the maintainers also enhanced the return value-checking logic in the verifier.

Figure 5b: The verifier allows privileged users to load programs with back-edges and detects and rejects infinite loops during checking. SEV uncovered a logic bug in the verifier that incorrectly rejects programs with well-defined structures. For the program shown in Figure 5b, the verifier rejects it, reporting an incorrect back-edge from #3 to #4. However, such an error is not accurate, since #3 to #4 is not a back-edge. Furthermore, the behavior of the program is correct as the loop in the program is bounded. The root cause is that the control flow-checking procedure of the verifier is incapable of handling the structure pattern of the program. The bug

```
0: (b7) r9 = -2                      ; R9=-2
1: (37) r9 /= 1                      ; R9=scalar()
2: (bf) r8 = r9                      ; R9=scalar(id=1) R8_w=scalar(id=1)
3: (56) if w8 != 0xfffffffe goto pc+4 ; R8=scalar(var_off=(0xfffffffe;
                                          0xffffffff00000000))
4: (65) if r8 s> 0xd goto pc+3       ; R8=scalar(smax=13)
5: (b7) r4 = 2                       ; R4=2
6: (dd) if r8 s<= r4 goto pc+1       ; R4=2 R8_w=0xfffffffe
7: (cc) w8 s>>= w9                   ; R9=0xfffffffe R8=scalar()
8: (77) r9 >>= 32                    ; R9=0
9: (57) r9 &= 1                      ; R9=0
10: (95) exit
```

(a) A bug in the verifier's range analysis.

```
0: (b7) r4 = 0x35
1: (b7) r8 = r4
2: (05) goto+2
3: (1f) r9 -= r4
4: (1f) r9 -= r8
5: (0f) r8 += r4
6: (a6) if r8 < 0x64 goto-4
7: (bf) r0 = r9
8: (95) exit
```

(b) A bug in the CFG checking.

```
0: (bf) r0 = r10               ; R0=fp0
3: (18) r5 = 0x1d00000025      ; R5= 0x1d00000025
2: (bc) w9 = w0                ; R9=scalar(var_off=(0x0; 0xffffffff)
3: (47) r9 |= -12              ; R9=scalar(var_off=(…; 0xb))
4: (0f) r9 += r0               ; R9=fp(off=0, u32_min=-12)
5: (76) if w5 s>= 0xfffffff6 goto pc+16  ; R5=0x1d00000025
6: (72) *(u8 *)(r9 -221) = -19   ; stack_depth=221
7: (95) exit
```

(c) A bug in the stack depth tacking.

```
0: (18) r4 = map_ptr
1: (18) r1 = 0x1d
2: (55) if r4 != 0x0 goto pc+4
3: (1c) w1 -= w1
4: (18) r9 = 0x32
   (00) reserved_code
5: (56) if w9 != 0xfffffff4 goto pc-2
6: (95) exit
```

(d) A bug in the jump target checking.

Figure 5: Assorted eBPF programs that trigger logic bugs. The left part of each sub-figure shows the eBPF instructions and the content after each semicolon presents the verifier's approximations, illustrating the bug cause. `scalar()` and `fp()` show that the tracked value is a scalar and stack pointer, `var_off()` is the `tnum` domain, and `stack_depth` is the tracked depth of used stack.

causes all the correct programs with this structure pattern to be rejected, thus requiring heavy code refactoring to mitigate the verifier's bug. The inserted folding functions triggered the bug, demonstrating the additional advantages of the folded variant of state embedding. The bug has been fixed and the patch was back-ported to the stable kernels.

Figure 5c: The verifier tracks the stack depth of the program and uses this information to subsequently allocate the stack area before execution, thus the correctness of the calculated stack depth is important. However, SEV uncovered that the verifier incorrectly overlooks the variable offset in stack accesses, leading to the collected stack depth being smaller than the size that the program may access at runtime. As illustrated in Figure 5c, at first, R9 is a scalar with a minimum value of -12, and the tracked range information is correct. The instruction #4 adds the stack pointer to R9, thereby making R9 a stack pointer with a variable offset. The verifier incorrectly marks the stack depth of the program as 221 at the stack writing instruction #6 without considering the variable offset of R9, *i.e.,* its possible minimum value. The bug has existed for four years and is exploitable for privilege escalation.

Figure 5d: Most instructions of eBPF adopt basic encoding with an eight-byte length, while a special kind of load instruction uses the wide instruction encoding and appends a second eight-byte immediate, the code of the second part is the reserved code. The target of jump instructions in eBPF programs must be within bounds and be a valid instruction. However, SEV detected a logic bug in the verifier that reports programs containing invalid jump targets with an incorrect reason. As depicted in the figure, the instruction #4 is a special load that uses the wide instruction encoding and its second part contains the reserved code. The program incorrectly jumps from #5 to the second part of #4, *i.e.,* jumping into the reserved code, yet the verifier incorrectly reports that the program contains an invalid load instruction. The root cause of the bug is that the verifier overlooks the special case while checking the jump target.

```
0: (18) r9 = 0x00000018         ; R9= 0x18
1: (85) call get_cgroup_id#123 ; R0=scalar()
2: (5c) w9 &= w0                ; R9=var_off(…;0x18)
3: (b5) if r0 <= 0xfffffffb goto pc+3
                                ; R0=var_off(…;0x3)
4: (5d) if r9 != r0 goto pc+2   ; R0=-4 R9=-4
5: (c7) r9 s>>= 23              ; R9=-1
6: (95) exit
```

Figure 6: A logic bug in the verifier.

Figure 6: SEV also uncovered that the range analysis of the verifier is incapable of correctly handling equality comparison when the ranges of two operands do not overlap. This issue is exemplified in Figure 6. At #2 the mask of R9 is 0x18, and the verifier determines all the bits of R9 are known to be zero except for the fourth, and the fifth bit (unknown). The mask of R3 is 0x3, where only the lower two bits are unknown and all the other bits are one, and thus the range of R9 and R3 are non-overlap. However, the verifier erroneously assigns both R0 and R9 as -4 after the if-condition with equality comparison at #4, where the runtime value of R9 consistently remains 0x18, *i.e.,* a logic bug in the verifier.

4.4 Throughput Impact

SEV synthesizes state-embedded programs by profiling runtime states using the tracer mentioned in Section 3 and subsequently integrating the generated folding functions and embedding the folded concrete state. In this section, we evaluate the performance impact of SEV on three key aspects: the influence of profiling on program execution speed, the effect of state embedding on the verification time, and the overall impact on testing throughput.

The evaluation procedure is as follows. First, SEV is utilized to continuously generate programs. For accepted programs, we execute them both with and without the tracer and compare the execution times in both scenarios to determine the impact of the profiling. Subsequently, we embed the concrete states and measure the difference in verification time between the state-embedded program and the original program. To account for any nondeterministic factors, the above process is repeated multiple times for each program. Finally, to ascertain the impact on testing throughput, we run SEV with and without the profiling and state embedding. All the comparisons are carried out over a 24-hour period, and the average results are compiled and reported.

The evaluation results show that the average impact of profiling on program execution is 5.3%. This relatively minor impact is primarily due to the profiling being performed at the basic block level, where the tracer efficiently appends the states to a shared buffer. In terms of the verification time, the impact of state embedding results in an average increase of 17.2%. The minimal complexity added to the original program by state embedding, which involves arithmetic operations and a single embedding of the sink, contributes to this increase. Notably, the overall impact on testing throughput is only 1.6%. This lower impact, compared to program execution and verification time, is because state embedding is conducted only after programs are accepted, an infrequent event. In addition, the embedding constitutes a small part of the entire testing campaign, which also includes the generation, test case persistence, *etc.* In summary, we conclude that state embedding imposes a reasonable overhead and the impact is well within expectations, given its ability to uncover logic bugs.

4.5 Discussion

Coverage Impact. Coverage in our context involves two aspects: (1) in the generated programs (raw coverage), and (2) in the verifier (induced coverage), where the former may affect the profiling stage and the latter is related to the testing sufficiency. To ensure a stable raw coverage, we adopt closed eBPF programs as mentioned in Section 3.2 that require only a single round of profiling. For the induced coverage, we cover the verifier's functionality with the program generator, and optimizing the induced coverage is orthogonal to this work.

False Positives/False Negatives. As illustrated in Section 3, in principle, state embedding does not introduce any invalid operations to the original program except for the embedded sink. In practice, our approach has not resulted in any false positives, *e.g.,* the found bugs pose certain security implications. Being a testing technique, our approach can suffer from false negatives. The major reason is that state embedding requires programs accepted by the verifier, yet the generator may not be able to explore a diverse, thorough search space. Our main goal in this work is to detect a wide range of logic bugs with the principled idea, *i.e.,* concrete states being contained in the approximation. In addition, the inserted arithmetic instructions may hinder some non-contained states, albeit with a low likelihood. SEV operates within a continuous testing loop, which therefore inherently enhances the detection of such anomalies over time, even if a specific combination of state values momentarily evades detection.

Verifier Changes. The eBPF subsystem is undergoing continuous updates, incorporating new features as it develops. Despite these changes, state embedding remains widely applicable and is not limited to specific static checkers. Our implementation, importantly, does not depend on the internal workings of the verifier. This is because SEV mainly transforms the accepted programs to embed concrete states, after which the program is delivered to the verifier for validation. Changes within the verifier, such as new abstract domains, primarily affect how the state-embedded program is validated, while the transformation remains unaffected.

State Pruning. The state pruning procedure [12] in the verifier evaluates the current state against the known safe states to determine redundancy, thereby pruning explored paths. However, this technique cannot be applied to eliminate extra paths for direct embedding. When comparing states, the verifier performs a detailed analysis of registers marked as precise. The registers of inserted sinks are marked precise, yet their value ranges vary between the branch-taken and fall-through paths, making them unprunable. Folding addresses this by embedding the folded state once at the end of the program.

5 Related Work

eBPF Verification. Existing work [16] applies formal verification to several components of the eBPF verifier, significantly advancing the verifier's correctness. For instance, recent efforts [52] have proved the soundness of the implementation of the tristate number in the verifier, and we did not detect any bugs in the corresponding location, *i.e.,* `tnum.c` in the kernel. However, `tnum` is a small component of the verifier, which mainly contains 200 lines of code. Agni [45] is more ambitious, aiming to verify the range analysis of the verifier, which consists of 2,100 lines of code. The tool automatically converts the C source code to SMT formulas and utilizes SMT solvers to detect discrepancies between the specification and the implementation. The work concludes that the tool proved the soundness of range analysis in Linux v5.19, the latest version when the work was conducted. Beyond reasoning about the correctness of the verifier, Jitterbug [34] applies automated verification on the eBPF JIT compiler.

Nevertheless, devising specifications for the eBPF verifier automatically or manually is challenging and requires deep domain knowledge. Consequently, the synthesized specifications can be incomplete or inconsistent with the implementation. For example, while Agni aims to perform verification on the verifier's range analysis, the generated verification conditions are incomplete [4, 9, 10, 14]. Indeed, we identified logic bugs in this component within the same kernel version. In comparison, state embedding has the following unique advantages: (1) our approach does not require predefined specifications, but utilizes state embedding to perform fine-grained checks for logic bug detection; (2) state embedding is capable of testing various components not just the range analysis, *e.g.,* SEV also uncovered bugs in the memory access validation; and (3) since we leverage the verifier to check whether the concrete states are contained in the approximation, our approach is agnostic to the verifier's internal and can be applied along with its fast changes. Therefore, our approach significantly complements the existing work.

Static Analyzer Testing. Some work [27, 53] proposes to detect bugs in static analyzers by collecting the information of both analyzers and programs and directly comparing them. For example, Wu et al. [49] propose to profile pointer alias at runtime and compare the information directly with the knowledge from the alias analysis algorithm. Similarly, Buzzer [26] extracts the verifier log, conducts an offline comparison between the log information and the collected map value, and uncovered one logic bug. However, this direct comparison approach requires: (1) collecting and parsing both the runtime information and the analyzers' states, and (2) correctly conducting the comparison, which requires substantial domain knowledge to interpret the verifier states and is coupled with concrete implementations. In comparison, SEV only profiles program states at each basic block and utilizes state-embedded programs to enable the verifier to conduct the validation, thus being efficient and agnostic to verifiers. In addition, Bugariu et al. [17] propose to test abstract domains by interactively invoking operations and using the mathematical properties of the domains as test oracles. However, applying this approach in the eBPF verifier is challenging: (1) the verifier is integrated into the kernel and does not support interactively invoking its internal operations, and (2) the eBPF verifier does not provide a specification and mixes up the abstract operators in one domain with the refining operations [45], thus the mathematical properties summarized are not directly applicable in this context.

Differential Testing. α-Diff [29] conducts differential testing between several static analyzers to identify logic bugs in them. However, this approach hinges on the precondition that the precision of static checkers is comparably high and that reference implementations are well-established. Except for the verifier in Linux, Gershuni et al. [22] propose a potential reference verifier. Yet, it lacks support for some important features, *e.g.,* various modes of basic ALU instructions, and experiences precision issues [11]. Therefore, using the tool for differential testing would be ineffective in detecting logic bugs in the kernel verifier. Furthermore, our approach differs significantly from differential testing methods and is an instance of metamorphic testing. α-Diff relies on multiple checkers and does not provide ground truth for each variant it produces. In contrast, state-embedded programs contain the ground truth by construction, eliminating the need for other reference verifiers.

Assertion Generation. Existing work aims to automatically generate assert statements to detect logic bugs [48, 51], establishing input-output relationships using program analysis or deep learning. In contrast, our approach does not aim to assert input-output relations, which is nontrivial for the verifier's logic bug detection, but to validate a core property: the concrete states must align with the verifier's approximations. It embeds concrete states into the program, leveraging the verifier to conduct the containment checks. Therefore, state embedding fundamentally differs from assertion generation, in terms of both intent and methodology.

Kernel Fuzzing. Fuzz testing [21, 30, 38] is an effective approach and has been applied in kernel scenarios. For instance, Syzkaller [47] is capable of testing the eBPF subsystem by invoking the `bpf()` system call with random arguments. It has been integrated into upstream testing and has uncovered many memory errors [46]. Similarly, another work by iovisor [25] employs libfuzzer [36] to generate random byte sequences for testing the verifier. BVF [42] captures memory errors in eBPF programs with sanitation to indirectly detect correctness bugs. Nevertheless, existing fuzzers [33] highly rely on sanitizers to capture bugs [39, 40], and they experience difficulties in the verifier's logic bug detection. Therefore, our approach complements the existing fuzzing work and state embedding can be utilized for direct logic bug detection.

6 Conclusion

In this paper, we have introduced state embedding, a novel and effective technique for logic bug detection in the eBPF verifier. Our approach systematically transforms the program to embed concrete states. The state-embedded program can subsequently be used to test the verifier by validating whether or not concrete states are contained in the approximation of the verifier. By applying state embedding in testing the eBPF verifier, our prototype SEV has successfully uncovered 15 logic bugs—many are critical, and two are exploitable for local privilege escalation—demonstrating the effectiveness of our approach.

Acknowledgments

We thank the anonymous OSDI reviewers and our shepherd, Ken Birman, for their valuable feedback on the earlier versions of this paper. Furthermore, we are grateful for the comments and suggestions from our colleagues at ETH Zurich.

Using Dynamically Layered Definite Releases for Verifying the RefFS File System

Abstract

RefFS is the first concurrent file system that guarantees both liveness and safety, backed by a machine-checkable proof. Unlike earlier concurrent file systems, RefFS provably avoids termination bugs such as livelocks and deadlocks, through the *dynamically layered definite releases* specification. This specification enables handling of general *blocking scenarios* (including ad-hoc synchronization), facilitates *modular* reasoning for *nested blocking*, and eliminates the possibility of circular blocking.

The methodology underlying the aforementioned specification is integrated into a framework called MoLi (Modular Liveness Verification). This framework helps developers verify concurrent file systems. We further validate the correctness of the locking scheme for the Linux Virtual File System (VFS). Remarkably, even without conducting code proofs, we uncovered a critical flaw in a recent version of the locking scheme, which may lead to deadlocks of the entire OS (confirmed by Linux maintainers). RefFS achieves better overall performance than AtomFS, a state-of-the-art, verified concurrent file system without the liveness guarantee.

1 Introduction

This paper presents RefFS, a concurrent file system with a mechanized proof of both safety and liveness properties. Liveness means that each operation of RefFS provably terminates under the assumption of fair scheduling. The proof rules out a wide range of bugs that occur in concurrent file systems [67], such as deadlocks, livelocks, and infinite loops.

Proving the absence of termination bugs is important, because they are too subtle to be correctly handled by developers. For instance [5], a task might not deadlock with another task via a direct ABBA[1] pattern, but instead through a complex circular dependency chain involving multiple tasks. A wide range of other termination bugs [54] occur, posing a threat to the software system. Once triggered, these bugs can lead to serious consequences, such as a system hang [16].

Testing and program analysis techniques (see §2 for more detail) have been used to detect (a subclass of) termination bugs. Although effective in practice, they cannot cover all possible cases. Formal verification is a promising approach. Researchers have made tremendous progress in concurrent file system verification [20, 101] and liveness verification [43, 56, 74]. Yet, modular liveness verification (focusing on one operation or one line of code at a time) of concurrent file systems remains an open problem.

In principle, proving liveness requires a well-foundedness argument [2, 60], i.e., within a finite number of steps, some progress event happens. For a sequential program, a well-founded metric such as the remaining steps of the program measures its progress [46, 66]. With each step, the metric must decrease, but not infinitely. Hence, the program provably terminates after running out the metric.

Unfortunately, proving liveness for a concurrent file system still faces the following challenges. First, the approach should support general *blocking scenarios*. A thread that is blocked in a busy waiting loop (e.g., to acquire a lock) cannot achieve progress by its own steps, but relies on the steps of *other* threads (e.g., the thread owning the lock). We aim for general busy waiting loops. This should be distinguished from work [12, 48] that supports only lock primitives, ignoring ad-hoc synchronization, which is common in file systems (see §2).

Furthermore, it is important to support modular reasoning, even though *nested blocking* causes progress dependencies between threads. Consider the following case. An `unlink` operation owns `parent` and requests `child`. Thread t_1 that tries to acquire `parent` is blocked by `unlink`, which itself is blocked by another thread t_2 that owns `child`. A metric for t_1's progress towards acquiring `parent` would include not only `unlink`'s steps to release `parent`, but also t_2's steps to release `child`. The latter contributes to t_1's progress *indirectly*. Explicitly considering such indirect steps hampers modularity. This issue becomes more pronounced with more threads chained by nested blocking.

Last but not least, the approach should prevent *circular nested blocking*. While an intuitive approach might specify a static order for nested blocking, the complexity of file systems introduces *diverse* and *dynamic* blocking order. On the one hand, file systems exhibit diverse nested blocking scenarios, with different blocking orders and concurrently executed by multiple threads. On the other hand, these nested blocking scenarios exhibit dynamic order, i.e., the exact rank of some specific blocking event cannot be known statically. For instance, the parent-child nested blocking of `unlink` refers to a dynamic set of inode pairs as a file system evolves. Two inodes with parent-child relation may swap their positions, ex-

[1] One acquires locks in the order of AB while another in the order of BA.

hibiting opposite orders in `unlink`. In `rename`, the blocking order of old and new parents is also unknown in advance. To avoid circular dependency, formally capturing the blocking order is essential but extremely challenging.

To meet such challenges, this paper makes the following contributions:

- A methodology for proving liveness, based on an acyclic waits-for graph. A vertex refers to an action waited by a blocked thread. The blocking thread must definitely fulfill the action. A directed edge represents a waits-for dependency between actions. To avoid circular dependencies, the waits-for graph must be acyclic.

- The dynamically layered definite releases (*DLDR*) specification, which supports modular liveness reasoning about concurrent file systems, with the following key ideas. (1) *Definite release* specifies that an acquired lock will always be released. (2) It proves termination of ad-hoc busy waiting lock loop based on a metric-decreasing idea. (3) We assign each definite release a layer, and allow a definite release to wait for only a higher-numbered one. Acquiring a lock waits only for the definite release of the lock (direct steps); layers decouple dependencies between definite releases (indirect steps), achieving modular reasoning. (4) The layering has two components: one follows the file system hierarchy (a parent may wait for a child), which is acyclic by definition; a *temporary dependency* models the non-deterministic blocking order in rename, and ensures acyclicity by construction.

- A protocol-level proof of Linux VFS's locking scheme based on an extension of the *DLDR* specification. The proof follows the Linux directory locking documentation [29]. We found a serious deadlock flaw; it was confirmed and fixed (we prove the fix correct).

- The MoLi framework for verifying termination and functional correctness of concurrent file systems. MoLi supports (1) definite releases with dynamic layers to achieve modular termination reasoning, and (2) non-atomic abstract operations to model non-atomic implementations. The framework is mechanized in Coq to ensure the reliability of the verification. Currently, MoLi does not support crash safety. MoLi's soundness has been formally proved on paper (a mechanized Coq proof is left as future work).

- The RefFS file system, the first modularly-verified concurrent file system with termination guarantees. RefFS supports highly concurrent path traversal using reference counting (refcount) [30]. Users are not bothered by the more fine-grained behaviors because the abstraction of RefFS hides refcounts, locks, and internal data structures, and exhibits atomic directory lookups.

The rest of this paper is organized as follows. §2 motivates this work with a study of termination bugs. §3 explains the MoLi methodology. §4 introduces the *DLDR* specification and its extension to directory locking in Linux. §5 describes the MoLi framework. §6 presents RefFS's design and verification. §7 evaluates RefFS and MoLi. §8 relates MoLi to previous work. §9 concludes.

2 Motivation

2.1 Study of Termination Bugs

Termination bugs cover a wide range, from non-concurrent ones (such as infinite loops) to concurrent ones (such as deadlocks and livelocks). A recent survey [16] on security vulnerabilities in file systems shows that about 7% of CVEs are related to non-termination. A prior study [67] on file system patches reveals that up to 40% of concurrency bugs are due to deadlocks. Deadlock-related semantic bugs are hard to diagnose, e.g., misuse of the `GFP_KERNEL` flag [70], and may hurt the system for years.

From a verification perspective, this raises several important questions: (1) How can one classify these bugs based on the challenges they pose for verification? (2) What are the primary classes of termination bugs? (3) What makes these bugs dominant and challenging to avoid? Answering these questions can help focus our verification efforts. Therefore, we performed a comprehensive study of termination bugs in Linux file systems (from 2020 to 2023). We collected 213 bugs in total by reading commit messages of patches [54]. We make the following observations.

Bug classification. Termination bugs can be classified based on whether they are concurrency bugs or not. 18% of termination bugs are non-concurrent. They include infinite loops or recursion, due mainly to logic mistakes (e.g., missing checks [82]) or generic errors (e.g., inappropriate truncation [42] or overflow [94]). 82% of termination bugs are concurrent. Within concurrent bugs, 95% of them are deadlocks and 5% are livelocks. Deadlock occurs when a thread becomes blocked, waiting for a specific action that never happens, and none of the involved threads can make progress. In livelock, a thread is constantly delayed, resulting in an inability to make progress.

Let us now look into deadlocks to understand the underlying factors contributing to their prevalence.

Ad-hoc synchronization. 46% of deadlocks (all percentages hereafter are relative to deadlocks) involve ad-hoc synchronization, where a thread is waiting for a specific event, such as transaction completion [11], flushing of dirty inodes [9], or other custom synchronization points [76, 90]. Deadlock analysis tools commonly focus on well-known and structured synchronization patterns, e.g., lock acquisition and release, but ad-hoc synchronization often lacks such patterns, which makes it challenging to analyze and detect.

Nested blocking. 21% of deadlocks are of type AA, where a thread is blocked by itself [25, 72]. The remaining 79% involve nested blocking. Nested blocking occurs when a task that is blocking another task, gets blocked itself. For instance, nested acquisition of locks may cause nested blocking. 42% of deadlocks involve *both* nested blocking and ad-hoc synchronization [1, 24]. 23% of deadlocks involve at least three concurrent tasks [4, 7]. To prevent such bugs, it is necessary to examine, not only the local blocking order, but also the absence of global, circular dependencies within the system. However, existing approaches often fail to present a global order of dependencies, hampering the ability to detect such deadlocks effectively.

Dynamic order. 8% of deadlocks exhibit a dynamic blocking order, where the exact order between two blocking events cannot be predetermined. For instance, object removal (`unlink`/`rmdir`) acquires inode locks in a parent-child order, with the definitions of "parent" and "child" based on the current state of the file tree. As the file tree evolves, the set of inode pairs that satisfy this parent-child relationship dynamically changes. Similarly, many other data structures, such as the forest structure in BTRFS and various list implementations, also exhibit dynamic blocking order. These scenarios further contribute to the complexity of the issue. Even for experts in the domain, mistakes still occur [10, 86, 87], highlighting the difficulty of effectively managing these complexities.

To summarize, this paper focuses primarily on addressing the deadlock-related challenges in file systems, i.e., ad-hoc synchronization (§4.1), nested blocking (§4.2), and dynamic order (§4.3). We briefly discuss the support for livelocks (§4.5) and non-concurrent bugs (§5.3).

2.2 Limitations of Previous Work

There are a number of program-analysis-based techniques that aim at detecting deadlock [51, 91], livelock [13] or infinite loop [15, 17] respectively. Although effective in practice, their common problem is false positives. Programmers still have to manually confirm or reproduce the bug.

Various fuzzing-based testing tools [38, 50] can also reveal termination bugs. However, they and previous program-analysis tools cannot avoid false negatives.

For instance, the Linux kernel has a runtime validator to check locking correctness [31]. Users inform the validator of the hierarchy (a fixed order) between lock objects. This has the following drawbacks. First, the validator does not recognize ad-hoc synchronization. Second, it does not provide a general principle on how to handle dynamic locking order, whose hierarchy cannot be predetermined. Third, the annotations by developers may be wrong or insufficient, giving rise to both false positives [95] and false negatives.

Some efforts support deadlock-freedom (DF) verification [12, 48, 62, 93]. They track dependencies between blocking primitives to prevent circular blocking. This approach treats deadlock-freedom as a safety property, and does not prevent livelocks or non-termination of critical sections. They often assume known lock primitives, and do not apply to ad-hoc synchronization.

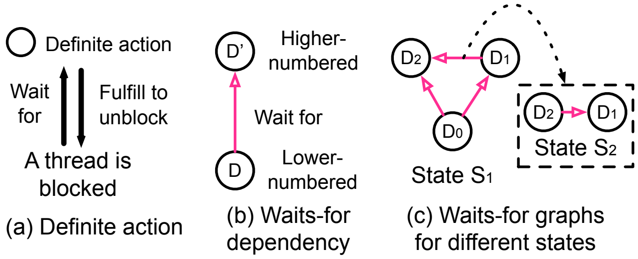

Figure 1: **The MoLi methodology for proving termination.** Waits-for graph consists of definite actions (vertices) and waits-for dependencies (edges). In (c), the dependencies between $\mathcal{D}_1$ and $\mathcal{D}_2$ are different at different states.

Some of these DF efforts [14, 61] also have limited support for dynamic lock orders. They consider only situations where a lock order change has *local* effects, i.e., it suffices to locally check some ordering constraints of the current operation to ensure acyclicity, without considering concurrent operations. For instance, for a rotation of a balanced tree, it suffices to check only the relations between the moved nodes, to ensure a global tree-based partial order. However, in a file system, it is necessary to check the absence of circular dependencies globally after the order change, which requires nontrivial concurrency reasoning (see §4.3 for more detail).

There is theoretical work [32, 64] to help reason about general blocking scenarios. LiLi [64] proposes a program logic to support the verification of starvation freedom and deadlock freedom. But LiLi does not support layered reasoning (see §4.2), and thus does not allow modular reasoning over nested blocking (i.e., verifying each line of code independently). TaDA Live [32] introduces layers to capture blocking orders, but it does not support layer changes caused by concurrent operations. Neither TaDA Live nor LiLi has a mechanical framework or an executable implementation.

3 The MoLi Methodology

Our approach to proving liveness is to exhibit an acyclic waits-for graph. A vertex is an action that a blocked thread is waiting for. A directed edge represents a waits-for dependency between actions. The waits-for graph shrinks as follows (we will discuss its growth in §4.5). Vertices with out-degree zero (not waiting for anything) must be unblocked to be removed from the graph. New vertices become leaves and are unblocked. Consequently, all waited actions eventually happen, creating progress for the blocked threads. Below, we discuss how this approach handles the challenges of file systems.

To support general blocking scenarios, MoLi borrows ideas from previous work [64]: a thread t is blocked when another thread does not fulfill the unblocking action that t is waiting for (e.g., releasing the lock or finishing the transaction); thus, the specification should describe actions that one thread will definitely fulfill (Fig. 1a). All such definite actions should be specified by proof authors, and constitute the vertices of the waits-for graph (Fig. 1c).

In nested blocking, a definite action, e.g., releasing lock $\texttt{L}_1$ by thread t, gets blocked and waits for another definite action, e.g., releasing lock $\texttt{L}_2$ by another thread. We represent this waits-for dependency as a directed edge. To capture acyclicity, MoLi requires proof authors to layer vertices so that a vertex only waits for a *higher-numbered* vertex (Fig. 1b). For instance, proof authors can define the layers as the reverse topological order of the waits-for graph.

To capture the dynamic order of nested blocking, MoLi allows to define layers *dynamically* according to the system state. For instance (Fig. 1c), definite action $\mathcal{D}_1$ waits for $\mathcal{D}_2$ in one state, while this dependency may be the opposite in a different state. The layers reflect the waits-for dependencies of the current state.

To ensure acyclicity despite layer changes, MoLi enforces a *dependency condition* on layers: for any ongoing dependency between definite actions, their layer relation represents this dependency and stays unchanged despite state changes. For instance, as long as definite action $\mathcal{D}_1$ waits for $\mathcal{D}_2$, the layer of $\mathcal{D}_1$ must remain less than $\mathcal{D}_2$ despite state changes. Because all ongoing dependencies are immune to state changes, the system is never in danger of circular dependency.

We now explain in more detail how to apply this methodology to a concurrent file system.

4 Dynamically Layered Definite Releases

Directory locking refers to the locking scheme used for directory operations. Ensuring its correctness is important yet challenging. We tackle the challenges by introducing the dynamically layered definite releases specification (§4.1-4.3). Then, we apply the specification to the Linux Virtual File System (VFS) (§4.4) and discuss how to support delay (§4.5).

4.1 Definite Release

The rule for concurrent access in a Linux FS is to protect each inode with its own associated, fine-grained lock. A thread t acquiring a lock may be blocked by another thread holding the lock. To prove t's termination, we need to show that t will eventually become unblocked. Consider the code snippet in Fig. 2a[2]. The code traverses from the cur directory and looks up the name path[i] to find the next inode. The lookup is protected by holding the lock on cur, and the lock is released afterward. Assume all threads only execute this piece of code.

```
// Pre: no lock owned
while(path[i]!=NULL)
  lock(cur);
  next=lookup(cur,path[i]);
  if (next==NULL) {
    unlock(cur); return;}
  unlock(cur);
  cur=next; i++;
}
```

(a) traversal loop.

```
def lock(cur):
  int i;
  i=getAndInc(cur.next);
  while(i!=cur.owner){}

def unlock(cur):
  cur.owner=cur.owner+1;
```

(b) ticket lock.

Figure 2: **Single locking in path traversal.** Termination of lock(cur) relies on other threads releasing the lock by increasing cur.owner.

A fair lock, such as a ticket lock (Fig. 2b), is used to ensure termination; every thread lines up for the lock by getting a ticket. A thread acquires the lock if its ticket equals owner, and releases the lock by increasing the owner. The question is why the lock(cur) statement would terminate.

Blocking is caused by the absence of environmental behavior, e.g., not releasing the lock. To prove termination, the specification should describe the certainty of some state transition. For lock-based blocking, we propose a domain-specific specification called *definite release*.

Definition 1 (Definite Release)

> **Definite release** says, for some thread t and lock, if t owns the lock, t will eventually release the lock.

Definite release is inspired by the *definite action* notion proposed by LiLi [64], which can characterize an action that will definitely happen. However, one key difference is that definite action in LiLi does not support layered reasoning, and thus cannot modularly handle nested locking (see §4.2).

Specifically, definite release ($\mathcal{D}$) specifies a state transition: "t owns the lock" ⇝ "t releases the lock", where, informally, the notation ⇝ states that the state transition *eventually* happens. Definite release supports busy-waiting lock loops (not just lock primitives). For instance, definite release of a ticket lock can be formalized as $(\texttt{owner} = \text{t}.\texttt{i}) \leadsto (\texttt{owner} = \text{t}.\texttt{i} + 1)$, where t.i means the local variable i of thread t.

Rely-guarantee style reasoning. Definite release establishes a protocol that helps reason about the termination of locks as follows. First, once acquired, the release of a lock must be **guaranteed** by each thread. Second, to prove the termination of a lock, a thread may **rely** on some other thread releasing the lock. However, the above protocol does not avoid circular reasoning, which is usually unsound in proving termination. For instance, in a deadlock, each thread relies on the other to release, but this is circular and will never happen. LiLi's approach fixes this by requiring that each thread fulfills a definite release *without* waiting itself for any definite release.

Definite release achieves thread-modular verification of Fig. 2, focusing on one thread at a time, rather than explicitly considering steps of concurrent threads. **Rely**: if thread t is

[2] This simplified version is incorrect because it omits reference counting; we will fix this in §6

```
// Pre: no lock owned
lock(parent);
child=lookup(parent,name);
lock(child);
// Perform checks and
// do unlink/rmdir
...
unlock(parent);
```

Figure 3: **Code snippet for nested locking in `unlink/rmdir`.** The release of `parent` may be blocked by the acquisition of `child`. Code for error handling omitted.

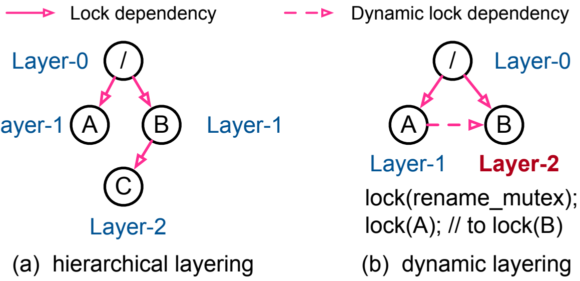

Figure 4: **Waits-for graphs and layerings.** Hierarchical layering accounts for parent-child lock dependencies. Dynamic layering captures the dynamic lock dependencies in `rename`.

blocked, spinning inside the **while** loop of `lock`, t relies on definite release, i.e., the increase of `owner` by lock holder; t can acquire the lock, because it needs to wait for a finite number of definite releases only. **Guarantee**: once t acquires the lock of `cur`, assuming that `lookup` terminates, t guarantees to fulfill the release without waiting for any definite release.

4.2 Hierarchical Layering

Some file system operations require nested locking (holding one lock and requesting another). For instance, consider the algorithm for removing an inode (in `unlink` or `rmdir`) in Fig. 3. The algorithm acquires `parent` to look up `child`. The lock on `parent` does not protect its children. To check whether `child` can be removed, we acquire `child`. When the operation finishes, it releases `parent`.

Unfortunately, in such nested locking, the release of the first lock may be blocked waiting for the release of the second lock. Hence, the guarantee of the first lock's definite release no longer holds.

If we stick to LiLi's approach in §4.1, we cannot prove the first lock by using its definite release, but have to specify more fine-grained actions that can definitely happen without waiting for any actions. For instance, acquiring `parent` may have to wait for (1) the release of `child` if the thread that owns `parent` is blocked requesting `child`, and (2) the release of `parent` if the thread that owns `parent` is not blocked. As a result, the proof for `lock(parent)` explicitly considers how `lock(child)` would be unblocked first, which is not modular. A modular approach would verify each line of code separately. The evaluation in §7.2 shows that LiLi's approach may cost 7 times the proof effort (measured in the lines of Coq) than our modular approach presented below.

We define *lock dependency* as below.

Definition 2 (Lock Dependency)

For nested locking in order of `A` and `B`, the definite release of lock `A` may depend on the definite release of lock `B`. This defines the **lock dependency** relation from `A` to `B`.

Intuition on termination. Lock dependency coincides with waits-for dependency (§3). Fig. 4a shows the possible lock dependencies in a file system as a *waits-for graph*. There is a lock dependency from a parent to its child, as shown by the directed edge. The dependencies extend transitively to the parent's descendants. For example, `root` has a lock dependency on `B`, which has a lock dependency on `C`. If the waits-for graph ever contains a cycle, the system is deadlocked.

The good news is that this waits-for graph so far follows the file system tree, so the dependency chain ends at the leaf inodes. The definite release of a leaf inode does not wait for anything. The definite releases of other inodes in the chain occur one by one in the leaf-to-root direction. Consequently, the definite release of all inodes must happen, ensuring that the parent-child nested locking terminates.

Hierarchical layering for definite releases. It is not harmful for definite releases to have dependencies *as long as* the dependencies are not circular. To formalize this intuition, we choose to assign a layer to each definite release, and allow a definite release to wait only for a *higher-numbered* one. In a file system, we use *hierarchical layering* — the layer of an inode's definite release (an inode's layer in short) is the length of the path from `root`. For instance, in Fig. 4a, `root` is assigned 0, and after each hop, the layer increases by one.

More formally, hierarchical layering can be represented as below. A *layer function* $\mathcal{HL}$ takes the inode number `inum` and file system state `FS` to return `inum`'s layer under `FS`. If `inum` is reachable from the root, distance computes the length of path (with type *Nat*) from the root to `inum` under `FS`. The layer is undefined otherwise.

$$\mathcal{HL}(\texttt{inum},\texttt{FS}) \overset{\text{def}}{=} \text{distance}(\text{root}(\texttt{FS}),\texttt{inum},\texttt{FS}) \quad \text{if defined}$$

For a well-formed `FS`, each inode is reachable from the root following a unique path, i.e., each inode has a uniquely determined layer. Hence, inodes are totally ordered, and dependencies are not circular for any well-formed `FS` (assume `FS` does not change for now). Users specify the well-formedness of `FS` as invariants (e.g., each child has only one parent), and prove that invariants always hold.

Modular reasoning with layering. Each thread should still **guarantee** to release an acquired lock. But its fulfillment can wait for a *higher-numbered* definite release. Hierarchical layering ensures the wait is not circular. A thread proves the termination of a `lock` statement independently by only **relying** on definite release of the lock.

```
def lock_rename(d1,d2):
1 if(d1==d2){
2   lock(d1);return;}
3 lock(rename_mutex);
4 if(ancestor(d2,d1)){
5   lock(d2);
6   lock(d1);
7   return;
8 }
9 lock(d1); TDep:=(d1,d2)
10 lock(d2); TDep:=None
11 return;
```

Figure 5: **Nested locking in `lock_rename`.** The locking order is dynamic, e.g., `lock_rename(d1,d2)` and `lock_rename(d2,d1)` may acquire `d1` and `d2` in an opposite order. Code in gray boxes captures the dynamic order using ghost state. These locks are released when `rename` exits.

Layering decouples the dependency between definite releases and enables modular reasoning for Fig. 3. When t is blocked inside `lock(parent)`, t relies on definite release of `parent`, and proves termination by considering only `parent`'s internal waiting queue, without looking into other code. t proves `lock(child)` similarly. After t acquires `parent`, its definite release requires to prove `parent`'s layer is less than `child`, which is true by definition of layers.

4.3 Dynamic Layering

The `rename` operation moves an inode (more precisely, the subtree with the inode as root) from its old parent to a new parent. It needs to acquire the locks of both directories to ensure atomicity. The function `lock_rename` in Fig. 5 is a simplified version of the implementation of Linux VFS (ignore the code in gray boxes for now). If the two directories are the same, it only needs to acquire one lock. To avoid concurrent issues, VFS requires a cross-directory `rename` to acquire the global per-filesystem lock `rename_mutex`. Holding `rename_mutex` prevents another cross-directory `rename` from changing the ancestry relationship. Furthermore, to not conflict with the parent-child order, if one directory is the ancestor to another, it acquires the ancestor first. If not, the locking order does not matter, so the code chooses a default order, i.e., old parent first (`d1` before `d2`).

Dynamic lock dependency. In contrast to the parent-child lock dependency, the lock dependency in `lock_rename` cannot be predetermined. Specifically, prior to acquiring `rename_mutex`, the lock dependency between `d1` and `d2` is *not stable* since other threads might dynamically alter it. Once `rename_mutex` is acquired, the lock dependency becomes fixed. If `d2` is an ancestor to `d1`, the lock dependency is from `d2` to `d1` as shown in lines 5-6. Otherwise, it is from `d1` to `d2` as shown in lines 9-10. Furthermore, after lines 6 and 10 where the code has acquired the respective locks for `d1` and `d2`, we can remove the dependency between them, because one of them no longer waits for the other.

Intuition on termination. The waits-for graph remains acyclic during `lock_rename`, which ensures termination. Before `lock_rename` executes, the graph is tree-shaped. Then there is a dynamic lock dependency between `d1` and `d2`. According to the locking rules in `lock_rename`, this dynamic lock dependency is not from a child to its ancestor, and thus does not form a cycle with existing parent-child dependencies. Finally, removing the dynamic lock dependency will not introduce a cycle. The acyclicity of the waits-for graph ensures that definite releases happen in order, despite dynamically-changing lock dependencies. The code terminates, because all definite releases are guaranteed to be satisfied.

Dynamic layering. We propose *dynamic layering* to capture the lock dependency in `lock_rename`. The layer for each inode is defined as the length of the *longest* path from the root in the waits-for graph. For instance, after the introduced dynamic lock dependency (drawn as a dashed arrow) in Fig. 4b, the longest path from `root` to `B` is `root`-`A`-`B`, so the layer for `B` is now 2.

To encode dynamic layers, we leverage *ghost state* [75], a commonly used verification technique. Ghost state is added by users in the abstract model to assist the proof, which does not influence (or exist in) the concrete program. We introduce a *temporary dependency* `TDep`, a globally unique value that tracks the lock dependency introduced by `lock_rename`. `TDep` is an option type of a pair of inums, i.e., either `None` or $(\texttt{inum}_1, \texttt{inum}_2)$ representing there is a lock dependency from $\texttt{inum}_1$ to $\texttt{inum}_2$.

Dynamic layering $\mathcal{DL}$ is defined below. $\mathcal{DL}$ takes `inum` to return its layer under *full state* `S`, where `S` includes file system state `FS` and ghost state `TDep`. The root inode has layer 0. If there is no dynamic dependency to `inum`, i.e., `inum` does not equal the second item in `TDep` (written $\texttt{TDep.inum}_2$ for simplicity), `inum`'s layer is one plus its parent's layer. If `inum` equals $\texttt{TDep.inum}_2$, its layer is one plus the larger layer between the hierarchical layers (as defined in §4.2) of its parent and $\texttt{TDep.inum}_1$. Otherwise, the layer is undefined.

$$
\begin{aligned}
&\texttt{S} = (\texttt{FS}, \texttt{TDep})\\
&\mathcal{DL}(\texttt{inum}, \texttt{S}) \overset{\text{def}}{=}\\
&\begin{cases}
0 & \text{if } \texttt{inum} = \text{root}(\texttt{FS})\\
\mathcal{DL}(\texttt{par}, \texttt{S}) + 1 & \text{if } \exists \texttt{par}, \text{parent}(\texttt{par}, \texttt{inum}, \texttt{FS})\\
 & \quad \wedge \texttt{inum} \neq \texttt{TDep.inum}_2\\
\max\{\mathcal{HL}(\texttt{TDep.inum}_1, \texttt{FS}), & \text{if } \exists \texttt{par}, \text{parent}(\texttt{par}, \texttt{inum}, \texttt{FS})\\
\quad \mathcal{HL}(\texttt{par}, \texttt{FS})\} + 1 & \quad \wedge \texttt{inum} = \texttt{TDep.inum}_2\\
\text{undefined} & \text{otherwise}
\end{cases}
\end{aligned}
$$

This definition focuses on inode locks. For the per-filesystem lock `rename_mutex`, we also specify a definite release, whose layer is a special minimum value so it can depend on all other definite releases.

The code in gray boxes (Fig. 5) presents feasible updates to `TDep`. Only the thread that holds `rename_mutex` can set `TDep`, and `TDep` is `None` when no thread holds `rename_mutex`. `TDep` is set to `(d1,d2)` after `lock(d1)` in line 9 to represent the upcoming lock dependency from `d1` to `d2`. Note that we do not need to set `TDep` after `lock(d2)` in line 5 because the lock dependency from `d2` to `d1` is already present in the waits-for graph due to transitive parent-child dependencies. We set `TDep` to `None` after line 10 to remove the lock dependency.

Reasoning with dynamic layering. Each `lock` statement still enjoys a modular proof by relying on its definite release. The guarantee of definite release can wait for a higher-numbered definite release. Now, taking state changes into consideration, we must further prove that the dependency relation (i.e., layer relation) stays unchanged during the wait. We call this the *dependency condition*.

The dependency condition is vital to acyclicity. Note that a circular dependency can happen only if a state change introduces a direct or indirect dependency opposite to an existing dependency. However, the dependency condition forbids this, by requiring the dependency relation to be stable.

Let's prove the dependency condition for Fig. 3. When a thread has acquired `parent`, and gets blocked by `lock(child)` at line 4, `parent`'s definite release waits for that of `child`. The dependency condition requires to show that `parent` is lower-numbered than `child`, even in the presence of concurrent operations modifying file-system state. This is the case because (1) the current thread holding `parent` prevents a concurrent `unlink`/`rmdir`/`rename` from removing `child` and (2) according to the definition of $\mathcal{DL}$, `child`'s layer is greater than or equals `parent`'s layer $+1$.

4.4 Directory Locking in Linux VFS

To understand whether dynamic layering scales to more directory locking orders in VFS, we extend dynamic layering to cover all the nested locking scenarios mentioned in the Linux documentation [29]. The extra lock dependencies that have not been discussed yet are the following: (1) the *dir-to-non-dir* dependency, from a directory to a non-directory, and (2) the *inode-pointer* (i.e., inode address) dependency, from a non-directory to a non-directory with larger inode pointer. For instance, (1) link creation locks the parent and then the non-directory source, or (2) rename locks the source and the target when they are non-directories.

To capture these dependencies, a layer could either be (`Dir`, *nat*) for a directory with its dynamic layer ($\mathcal{DL}$ defined in §4.3), or (`NonDir`, *addr*) for a non-directory with its inode address. Comparison rules are:

- (`Dir`, *nat*) $<$ (`NonDir`, *addr*) for the *dir-to-non-dir* dependency;
- (`NonDir`, $addr_1$) $<$ (`NonDir`, $addr_2$) iff $addr_1 < addr_2$ for the *inode-pointer* dependency;
- (`Dir`, n_1) $<$ (`Dir`, n_2) iff $n_1 < n_2$.

These rules give a total order of layers, because a directory is always acquired before a non-directory and the two groups are ordered by dynamic layers and inode pointers, respectively.

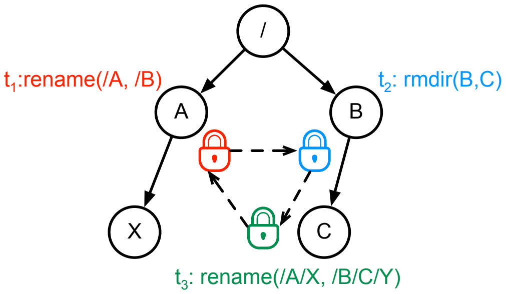

Figure 6: **A deadlock bug in Linux VFS.** Locking order according to increasing inode pointer order is (`C`, `A`, `B`), which conflicts with parent-child order (`B`, `C`).

When layers do not change, deadlocks will not happen if the code acquires locks in this total order (this can be easily verified). When considering layer changes, one proves the dependency condition to prevent circular dependency. We have shown the reasoning for the most challenging case, i.e., `rename` in §4.3. Proof of all other cases is provided in [99].

Doing the proofs helped us uncover a flaw in a recent version of the locking scheme (commit 28ecee [53]). Apart from locking the two parents, `rename` may also need to lock the source inode (under the old parent) to be renamed, and the target inode (under the new parent) if it already exists. The locking rules before commit 28ecee used to be:

- locking the source if it is a non-directory;
- locking the target if it exists;
- (if one need to lock both) locking them following the order mentioned above, i.e., directory before non-directory, and non-directories in inode pointer order.

However, commit 28ecee additionally locks the source even when it is a directory, for the purpose of updating its pointer to the new parent. For a non-cross-directory rename, this introduces a new, dynamic order between source and target subdirectories that is not protected by `rename_mutex`. Commit 28ecee takes it for granted that locking source and target subdirectories (and also two parents) in inode pointer order would be enough to establish a total order between directories.

However, the problem is that inode pointer order is not transitive with parent-child order, as shown in Fig. 6. Specifically, assume the inode pointer order is `C` $<$ `A` $<$ `B` (all are directories) and assume three operations have finished path-name lookups. t_3 owns `rename_mutex` and `C`, and requests `A`. t_1 owns `root` and `A`, and requests `B`. t_1 owns `B`, and requests `C`. Now, there is a deadlock. The maintainer confirmed this [98].

The fix [87] is to acquire the source subdirectory only in the cross-directory rename case, because a non-cross-directory rename does not change the parent of the source. The locking of source and target subdirectories is now protected under `rename_mutex`, and we can capture this order by constructing a dynamic layering (see [99] for details).

We found this flaw when we failed to define the dynamic layering specification for the scheme. Indeed, having a formal specification that effectively captures lock dependencies is crucial. Such a specification not only aids in conducting formal proofs, but also enhances our fundamental understanding of the system. Interestingly, even without engaging in code proofs, the specification itself can help uncover practical bugs and vulnerabilities.

4.5 Discussion about Support for Delay

A thread will not terminate if it is infinitely delayed in an infinite loop. For example, when a thread requests an unfair lock, e.g., test-and-set lock, other threads repeatedly preempt the lock first. Delays are benign as long as there is whole-system progress, e.g., the thread that preempts the lock can make progress. To allow benign delays, while preventing infinite delay without whole-system progress, previous work [64] proposed the concept of token transfer. The basic premise is that each thread is assigned a finite number of tokens. When a thread causes delays for other threads, it should either show progress itself or consume its tokens.

Let us go back to the discussion in §3. The waits-for graph grows due to normal execution or delay; either case has a decreasing metric that shows progress. When a thread normally executes, although it may get blocked by a **while** loop, its code size decreases. We assume a fixed but arbitrary number of threads to ensure the waits-for graph does not grow infinitely. In the delay case, a thread is made to execute more steps and may get blocked, but the delaying thread shows progress or consumes its tokens.

The mechanism for delay is necessary for proving the absence of livelock, where a thread is constantly delayed in infinite loops. This pattern does not appear in RefFS. For the sake of simplicity in presentation, we will omit these details.

5 The MoLi Framework

5.1 Overview

The MoLi framework verifies the functional correctness and termination of file systems based upon the following ideas.

- MoLi expresses correctness with *termination-preserving refinement* [66], which means that all observable events (e.g., output and termination events) from the implementation (i.e., concrete data structures and operations) must also be produced from the abstraction (i.e., logical layouts and abstract operations over them). Hence, functional correctness and termination of implementation is ensured, provided the abstraction is correct in these aspects. Termination-preserving refinement also helps build proofs in a layered way, i.e., low-level code can be replaced by its abstraction in a higher-layer proof. For instance, the proof of applications can use the abstraction of file systems.
- MoLi supports *compositional* concurrency reasoning with *rely and guarantee conditions* [35, 49]. A rely condition specifies the interference that a thread will accept from the other threads. A guarantee condition specifies the transitions that a thread will make. If the rely condition of a thread is implied by the guarantee of all other threads, and each thread is individually correct, then the concurrent system is correct.

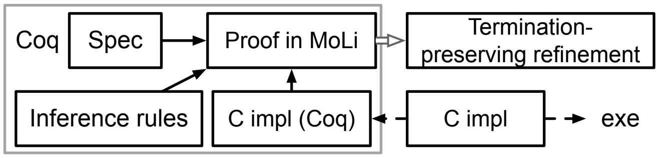

Figure 7: **The MoLi workflow.** Users provide a specification. MoLi helps users develop code proofs with inference rules.

MoLi supports modular liveness reasoning with layered definite actions. Fig. 7 shows the workflow of MoLi. MoLi is a framework built on Coq. MoLi supports the verification of C language (the Coq model of C language follows an existing framework [101]). Users specify the specification (§5.2), and then follow the inference rules provided by MoLi to manually perform the Hoare-style verification (§5.3). The framework is sound, which ensures that the proof implies the termination-preserving refinement.

5.2 Specification in MoLi

A specification includes the abstraction, rely-guarantee conditions, invariants, definite actions, and the layer function, as defined next.

Abstraction. The abstraction includes the abstract representation of the concrete state and abstract operations (*Aop*) on it. An abstraction can hide implementation details, which is easier to check and less error-prone than the concrete implementation. MoLi provides a specification language, which allows users to write non-atomic abstract operations. The language has standard commands such as **while** and **if**, and is suitable for expressing abstract operations: (1) the language's state includes the abstract state and a local *abstract stack*, which maps variables to *abstract values*, e.g., lists; (2) the language supports user-supplied primitives that model atomic transitions of abstract state; (3) it also supports atomic block $\langle C \rangle$ where C executes atomically (see §6.1 for an example).

State. In MoLi, state includes not only the concrete state accessed by the implementation, but also several auxiliary parts, i.e., the specfication language's state, tokens, and ghost state. MoLi uses *tokens* as local state to ensure termination (as explained in §5.3). Users may also introduce *ghost state*, which exists only in the abstract model, to assist verification.

Rely/guarantee conditions (R/G) and invariants (I). R and G

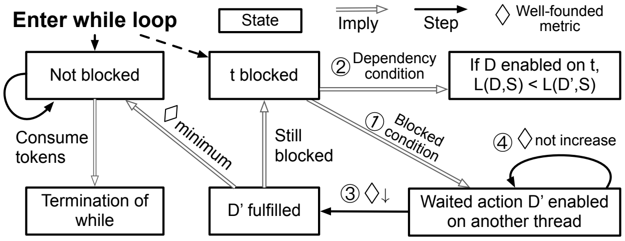

Figure 8: **Logic for termination of a while loop.** Users specify the number of *tokens* and a *well-founded metric* $\Diamond$. In the non-blocking case, tokens strictly decrease for each iteration. In the blocking case, $\Diamond$ strictly decreases whenever a waited definite action ($\mathcal{D}'$) executes. When $\Diamond$ decreases to its minimum, the thread is no longer blocked. The dependency condition enforces an enabled definite action ($\mathcal{D}$) waits only for a higher-numbered one ($\mathcal{D}'$).

define the allowed state transitions and are checked at each step: one checks that (1) the current thread's state transitions satisfy G, (2) the pre-/post-conditions of a command stay true, even when a concurrent thread changes the state, as long as this change is allowed by R, and (3) I specifies an invariant on state, which must remain true under all transitions. R/G and I define the concurrency protocol. Previous efforts [35, 101] provide more detail.

Definite action and layer function. A *definite action* describes a state transition, written $P \rightsquigarrow Q$, which means that, once assertion P is true, (1) Q will eventually hold, and (2) P is preserved by both current and environmental thread until Q holds. The second condition ensures that P may not become false until the definite action is fulfilled. A definite action is called **enabled** when P holds. A *layer function* $\mathcal{L}$ takes a definite action and a state $\mathtt{S}$ to return a layer if defined.

5.3 Verification in MoLi

The judgement $\mathcal{L},\mathcal{D},R,G,I \vdash \{P \wedge Aop\}C\{Q \wedge \mathtt{skip}\}$ means (1) starting from the precondition P, the operation C must terminate to reach the postcondition Q, and meanwhile (2) an abstract operation terminates (from *Aop* to `skip`), simulating the concrete operation C. Here, both P and Q imply the invariant I and specify the consistency relation between the concrete and abstract state. MoLi provides inference rules to help users prove the judgement holds. A top-level rule, called the OBJECT rule, proves the well-formedness of the specification and the judgement for each method of the object. The OBJECT rule establishes termination of the implementation and abstraction, and a termination-preserving refinement between them. To verify each method, users follow inference rules of C language statements to step through the program.

Most rules for C language, e.g., **sequence** and **if** rules, are standard and similar to previous work [35, 101]. We explain the WHILE rule (see Fig. 8 and the simplified rule below).

Termination of a* while *loop. The WHILE rule requires establishing the judgement of the loop body (see the first line of the rule). Assuming the loop body can terminate, we check whether the loop is blocked by other threads. Based on that, the logic uses different strategies to ensure termination, i.e., consumption of tokens in the non-blocking case and decrease of metric by executing definite actions in the blocking case.

$$\frac{\begin{array}{l}\mathcal{L},\mathcal{D},R,G,I \vdash \{P \wedge B\}C\{P\} \\ \text{if not blocked, consume tokens} \\ \text{if blocked, prove conditions ①-④} \\ \text{(see ①-④ in the text and Fig. 8)}\end{array}}{\mathcal{L},\mathcal{D},R,G,I \vdash \{P\}\textbf{while } (B)\{C\}\{P \wedge \neg B\}} \ (\text{WHILE})$$

If the **while** loop is not blocked, we must show the **while** loop can iterate for only a finite number of rounds. Following previous efforts [46, 64], we require that each iteration consumes resources called *tokens*. Users specify the number of tokens before the **while** loop. The loop terminates after exhausting its tokens. For instance, the traversal **while** loop in Fig. 2a can iterate only a finite number of rounds, bounded by the length of `path`, which specifies the number of tokens.

In contrast, if a thread t is blocked, its termination relies on definite actions of other threads. Users define a well-found *metric* (i.e., that cannot infinitely decrease) for the **while** loop. Whenever a definite action happens, the metric must decrease. When the metric decreases to its minimum, the thread is no longer blocked. Specifically, users prove the following.

① **Blocked condition**: if t is blocked, t must be waiting for some definite action $\mathcal{D}'$ (to be specified) to happen, which is enabled on another thread.

② **Dependency condition**: if t has an enabled definite action $\mathcal{D}$, its layer must stay *less* than that of $\mathcal{D}'$ until $\mathcal{D}'$ is fulfilled.

③ **Metric decrease**: whenever $\mathcal{D}'$ is fulfilled, the metric decreases.

④ **Metric non-increase**: the metric never increases.

Let us prove the termination of ticket lock in Fig. 2b under the above conditions. Suppose a thread t is blocked in the **while** loop of `lock(cur)`. A precondition is that t does not own `cur`. Then we can prove ① t waits for the definite release of `cur`, which is enabled on another thread. If t has enabled definite actions, e.g., t has acquired other locks, the layer function must have captured these lock dependencies. With the layer function, users prove ② the layers of owned locks are stably less than `cur` until t's ticket equals `cur.owner`. One can specify the well-founded metric as `t.i-cur.owner`, which measures the distance from t's ticket to the current owner. ③ The metric decreases whenever an environment thread increases `cur.owner`, and ④ never increases. When the metric decreases to zero, the loop terminates.

Lock abstraction. We can prove the termination of lock implementations with the WHILE rule. But MoLi follows recent work [65], and provides a specialized inference rule for fair locks (e.g., ticket lock) to ease the burden. The abstract state of a lock is an integer `L`, whose value is either `0` when available or `t` when owned by thread `t`.

The reasoning of a lock operation is similar to the WHILE rule, only with a different metric non-increase condition: the metric never increases under transitions where the lock keeps being unavailable. We allow the metric to increase when the lock is available, because a fair lock guarantees that, if the lock becomes available for a finite number of times, a thread will eventually become the first to the lock.

Definiteness of definite actions. The WHILE rule assumes that a definite action will be fulfilled once enabled. To meet this assumption, the OBJECT rule checks two things.

- **Well-formedness**: all steps preserve an enabled definite action of some thread except that the thread itself may fulfill the definite action.
- **Postcondition restriction**: the postcondition of an operation implies no enabled definite actions.

MoLi requires an enabled definite action to be fulfilled because the following conditions hold.

- When an operation terminates, it must be fulfilled according to the **postcondition restriction**.
- Whenever the thread is blocked in a **while** loop, the proof of **while** loop ensures the termination by only relying on higher-layer definite actions according to the **dependency condition**; intuitively, this will not introduce unsound circular dependencies, so those higher-layer definite actions can indeed be fulfilled.
- The thread is proved to terminate, and thus fulfills the definite action itself due to **well-formedness**.

Soundness. After users prove each operation by following the inference rules, the framework constructs an *overall termination metric* for each thread, and shows that the overall metric strictly decreases. The overall metric combines several metrics that users have provided in their proofs.

- The totally ordered layering of definite actions ensures that the waits-for graph shrinks until the thread's waited definite action is not blocked.
- The well-founded metric for a **while** loop measures the progress from the execution of the waited definite action, until the **while** loop is not blocked.
- The **while** loop tokens count down the iterations.

We have formally proved the following main theorem (see [100] for the full pen-and-paper proof).

```
// Error handling omitted
// Def of Inode omitted
struct inodelock{
  Inode *inode;
  int refcount;
  lock lk;
}

def getilock(ilock):
  ⟨ilock->refcount++⟩

def putilock(ilock):
  ⟨ilock->refcount--;
  if(ilock->refcount==0){
    free(ilock);
  }⟩
```

```
def traversal(cur,path):
  local i=0, ret;
  getilock(cur);
  while(path[i]){
    ret=lookup(cur,path[i]);
    cur=ret;i++;}
  return cur;

def lookup(par,name):
  local child;
  lock(par);
  child=find(par,name);
  getilock(child);
  unlock(par);
  putilock(par);
  return child;
```

Figure 9: **Reference counting and traversal in RefFS.** By holding a refcount in hand, `lookup` requests `par` without worrying `par` has been freed.

Theorem 1 (Main Theorem)

Given the implementation and abstraction, if there exist *rely*/*guarantee* conditions, an *invariant*, *definite actions* and a *layer function*, such that for each operation C of the implementation and corresponding abstract operation Aop, the judgment $(\mathcal{L},\mathcal{D},R,G,I \vdash \{P \wedge Aop\}C\{Q \wedge \texttt{skip}\})$ holds w.r.t. the pre-/post-conditions by applying inference rules, then the implementation ensures termination and is a termination-preserving refinement of the abstraction.

6 Design and Verification of RefFS

RefFS is a concurrent in-memory file system running on FUSE. We verify its interfaces that manipulate the file system structure (e.g., `mkdir`/`mknod`, `rmdir`/`unlink` and `rename`), and that perform input and output to files (e.g., `open`, `read`, `write` and `close`). This covers most common operations.

6.1 Implementation and Abstraction

RefFS reuses code from a previously verified concurrent file system, AtomFS [101], e.g., the internal functions that operate on directories and files. However, RefFS uses reference counting (refcounting) for traversal, which is more fine-grained and provides better performance than lock coupling used by AtomFS. Consequently, the rename implementation, file-descriptor-based interfaces and abstraction of RefFS are different from AtomFS, as explained below. We also prove liveness guarantee of RefFS.

Refcounting. In Fig. 9, struct `inodelock` wraps over an inode with a lock for protecting the struct, and a reference count for resource reclamation. The `refcount` field counts the references to the struct. `getilock` increases `refcount` by one. `putilock` decreases `refcount` by one and frees the struct when `refcount` becomes zero. In other words, `refcount` can prevent use-after-free as long as a thread still holds a `refcount` that other threads may not decrease (i.e., `refcount>0`). We use the atomic block notation $\langle C \rangle$ to represent that command C executes atomically. This is achieved with locks (not shown in the code).

To correctly implement refcounting, RefFS takes care of the following aspects.

① **Initialization**: when allocated, an inode's `refcount` is initialized to 1, marking that there is one reference in its parent's directory entry; this `refcount` is decreased when the inode is removed from its parent (the root's initial reference cannot be decreased).

② **Reference increase**: a thread can increase the `refcount` of an inode when it already holds its `refcount` (a thread can directly increase the `refcount` of root).

③ **Reference decrease**: a thread can decrease a `refcount` that belongs to the thread, e.g., the thread has increased the `refcount` previously.

④ **Reference counting**: each thread decreases the `refcount` that it no longer needs, and the value of `refcount` equals the number of all references combined.

③ is the key to stablizing `refcount>0` and preventing use-after-free, because if a thread has increased a `refcount`, other threads may not arbitrarily decrease it. The above refcounting protocols are formalized as rely/guarantee conditions and invariants, and proved for RefFS.

Let us see how the `traversal` function in Fig. 9 obeys and leverages the above protocols. The precondition specifies that either `cur` is `root`, or the current thread holds a reference to `cur`, so that `traversal` can increase the `refcount` of `cur` (②). The code invokes `lookup` for each item of the path. `lookup` can request `par`'s lock without worrying that `par` is freed, because the code holds `par`'s refcount (③). After having found the `child` in `par`, the thread holds a reference to `child`, due to owning the directory entry of `child` in `par`. Therefore, it can increase the `refcount` of `child` (②). It then releases `par`'s lock and refcount (③ and ④).

Refcounting provides the following performance benefits.

- During path traversal, there are intervals where an operation has searched the parent directory and is about to lookup the child directory. The operation does not need to nestedly lock parent and child to protect the child from being freed during the interval. Instead, `traversal` prevents use-after-free by holding a `refcount` of child. This creates more parallelism because concurrent operations can bypass each other during path traversal.
- Some operations use a file descriptor (FD) to directly access an inode, and leverage refcounting to prevent use-after-free. For instance, `open` increases the `refcount` of the target inode, and returns the inum as FD, thereafter, `read` and `write` operations can directly access the inode.

```
def rename(src,sn,dst,dn):
... //Traverse common
  path of src and dst
rel=pathrel(src,dst);
if(rel!=0){
  lock(rename_mutex);}
... //Traverse to get
  src and dst directories
if (rel==0){
  lock(sdir);
} else if(rel==1){
  lock(sdir);
  lock(ddir);
} else {
  lock(ddir);
  TDep:=(ddir,sdir)
  lock(sdir); }
...
//If dn exists in ddir
TDep:=(sdir,dchild)
lock(dchild);
TDep:=None
...
```

Figure 10: **Highlighting lock acquisitions of RefFS `rename`.** `pathrel(src,dst)` returns 0 if `src` equals `dst`, returns 1 if `src` is a proper prefix of `dst`, and returns -1 in other cases. Depending on the result, the code decides whether to acquire `rename_mutex` after traversing the common path of `src` and `dst`. Code in gray boxes updates ghost state.

Refcounting brings challenges for liveness reasoning because we need to consider more intricate lock dependencies of FS operations. Specifically, when using lock coupling (concurrent operations cannot bypass each other), an operation that starts the traversal first would not be blocked. This is not the case with refcounting: an operation may be blocked by another operation that bypasses it, or by a file-descriptor-based operation. Nevertheless, MoLi's modular verification approach effectively manages the complexities.

Rename implementation. In Fig. 10 (ignore the code in gray boxes for now), `src`/`dst` is the path to the old/new parent, and `sn`/`dn` is the name of source/target. `rename` first traverses the common path of `src` and `dst` (using `traversal` in Fig. 9). After getting the reference of their least common ancestor, the algorithm decides whether this is a cross-directory rename by comparing `src` and `dst`. If they are not equal (or cross-directory), the code acquires `rename_mutex`. The code then traverses the *remaining* path to get the references of the old and new parents. Holding `rename_mutex` ensures that the relative position between the two directories will not be changed by concurrent renames. Therefore, one may use the path arguments to know whether they are ancestors to each other, e.g., if `src` is a proper prefix of `dst`, this means that `sdir` is an ancestor to `ddir`. The code acquires the lock of the ancestor first. Otherwise, it will acquire them in a default order. If the target (i.e., `dchild`) already exists, the code acquires its lock.

Non-atomic abstraction. The abstraction of RefFS consists of abstract file system state and abstract operations. The abstract file system, called `AFS`, is a mapping of inode number (inum) to an *abstract inode*. An *abstract inode* is either a file (a list of bytes) or a directory (a mapping of name to inum).

For an operation that needs path traversal, the correspond-

```
def MKDIR(path,n):
1 local cur=root,tmp,i=0;
2 while(path[i]){
3  ⟨tmp=lookup(cur,path[i]);
4  if(tmp==NULL){
5    return -1;}
6  cur=tmp;i++⟩}
7 ret do_mkdir(cur,n);
```

Figure 11: **Abstract operation `MKDIR` of RefFS.** `MKDIR` consists of a series of atomic directory lookups (line 3-6) and an atomic critical section (line 7).

ing abstract operation hides as much implementation detail as possible (e.g., hiding refcount, locks and internal data structure), and guarantees atomic directory lookups and an atomic fulfillment of the operation after locating the target inodes. Fig. 11 shows the abstract operation `MKDIR`. `lookup` and `do_mkdir` primitives model atomic transitions of the abstract file system. We simplify the abstract operation by grouping the loop body (lines 3-6) into an atomic block.

6.2 Verification of RefFS

We use ghost state, the temporary dependency `TDep`, to assist the proof, as introduced in §4.3. In Fig. 10, code in gray boxes updates it. `TDep` is set to `(ddir, sdir)` before line 14 to represent the upcoming lock dependency between them. `TDep` may be updated to `(sdir,dchild)` before line 18 to establish the lock dependency from `sdir` to `dchild`. `TDep` is reset to `None` after line 18.

The termination proofs include the checks in the OBJECT rule and the termination proof of locks and while loops. Since while loops are not blocked in RefFS, their proofs are trivial.

Definiteness check. The well-formedness of definite releases holds because once a thread holds a lock, all steps keep the fact true until the thread releases the lock itself. The post-condition of each operation specifies that the thread does not own any lock, so it must be the case that definite releases are fulfilled before the thread reaches the end.

Proof for locks. When thread t is blocked in `lock(L)`, t waits for the definite release of `L` (specified as $\mathcal{D}'$). The metric is 0 when `L` is available and 1 otherwise. The following holds. (1) Blocked condition: some thread t' holds `L`, so $\mathcal{D}'$ is enabled on t'. (2) Dependency condition: the dynamic layering ensures that for any lock that t owns, its layer is stably lower than `L`. (3) Metric decrease: when `L` is released, the metric decreases. (4) Metric non-increase for the lock: when `L` is not available, the metric stays 1 and never increases.

7 Evaluation

This section empirically answers several questions:

- Can RefFS provide good performance for real-world applications, and does reference-counting perform better compared with lock-coupling (§7.1)?
- Compared with previous work, how modular are the termination proofs using MoLi (§7.2)?
- How much is the verification effort (§7.3)?
- Can MoLi help eliminate bugs in practice (§7.4)?

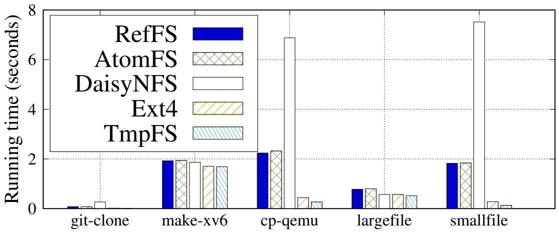

Figure 12: **Applications.** The figure shows the running time of different applications, i.e., git, make and cp. Largefile operates on a big file with 10MB. Smallfile operates on 10K files with 1KB size.

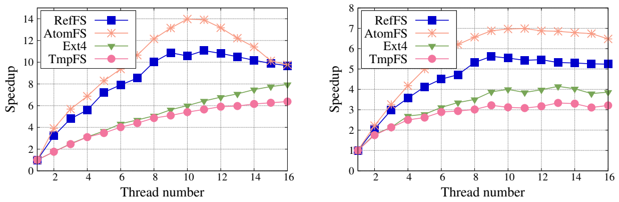
7.1 Performance Evaluation

Experimental setup. We run all of the experiments on a server machine (AWS EC2 i3.metal instance) with 72 cores (2.3GHz), 512GB DRAM, and a local 15,200GB SSD (8 disks) running Linux 5.15.8. We limit our experiments to one 36-core socket to avoid variability. We compare the performance of RefFS to the widely-used disk file system ext4 [84], the verified concurrent file system AtomFS [101], the verified concurrent NFS server DaisyNFS [20], and an in-memory file system tmpfs. All the file systems use in-memory storage.

Application performance. RefFS is complete enough to run many kinds of realistic software, including Vim [85] and GCC [37]. To evaluate application performance, we select two microbenchmarks and three application workloads: LFS microbenchmark [71, 77], cloning the git repository of xv6-public, compiling the sources of the xv6 file system with a makefile and copying the source code of qemu. These workloads are also used by previous verified file systems [22, 101]. The application workloads use only a single core.

In Fig. 12, RefFS achieves similar results to AtomFS, and better performance than DaisyNFS in most cases, due to the network I/O overhead of DaisyNFS. The worse performance of RefFS compared with tmpfs and ext4 is due mainly to the lack of fine-grained optimizations, e.g., highly optimized path traversals and optimized structures for data and metadata. Running RefFS with FUSE also introduces overhead. These issues can be overcome by more engineering.

File system scalability. We adopt two commonly used workloads in Filebench [36], Fileserver and Webproxy, to measure the scalability of RefFS. We evaluate with 16 cores and increase the number of threads used in the workloads. We do not evaluate DaisyNFS because its in-memory disk can only



(a) Scalability on Fileserver. (b) Scalability on Webproxy.

Figure 13: **Scalability of RefFS.** The overall scalability of RefFS is similar to AtomFS.

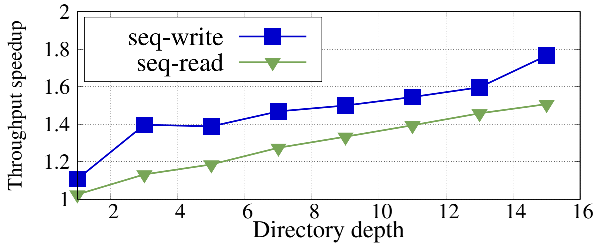


Figure 14: **Speedup of RefFS over AtomFS.** RefFS achieves higher speedup over AtomFS as the directory depth increases in LargeFile benchmarks.

support about 400MB of space, while the scalability tests consume more than 3GB in many cases.

The speedup results are in Fig. 13. RefFS can scale up to 9 cores. AtomFS shows a similar scalability, but the actual throughput (not shown in figure) of RefFS is better than AtomFS at all loads (1.08–1.43x higher in Fileserver and 1.03–1.32x higher in Webproxy). RefFS's performance is worse than ext4 and tmpfs, as expected.

Other benefits of reference counting. AtomFS uses lock coupling to traverse the path even for read and write operations. In RefFS, reference counting allows read and write to directly access the inode because `open` has increased the inode's reference. To show the benefit of this, we evaluate RefFS and AtomFS using LargeFile benchmarks under different depths of directories. In Fig. 14, with the depth increase, the speedup of RefFS over AtomFS becomes higher in both seq-write and seq-read tests in LargeFile.

Table 1: Lines of Coq proof for verifying RefFS.

Component	**LOC**	**Component**	**LOC**
Abstraction and aops	.1K	Invariant	.7K
Rely/guarantee	.4K	Code	.4K
Layered definite releases	.1K	Proof	32K
Total			**33.7K**

7.2 Modularity of Termination Proofs

Dynamically layered definite releases allow to verify each lock separately, and reuse the termination proofs for all each lock statement. To evaluate the benefits, we also use the non-layered definite actions (LiLi's approach in §4.1) to verify the termination of a lock statement in RefFS. The crucial difference is that the non-layered approach has to reason globally about the dependency chain.

Suppose there is a lock dependency chain of `root` → `B` → `C` as shown in Fig. 4a, where each thread in the chain owns a lock and requests the next lock except the last thread. Now suppose t wants to acquire `root`'s lock. To prove t's progress, LiLi's non-layered approach needs to prove how the chain gets shorter until t can acquire `root`. The following complexities exist.

In LiLi's approach, one must specify actions that can definitely happen on their own. In this case, t first waits for the lock release of `C`. Defining the action needs following the dependency chain, which requires a proof that the chain is free of cycles. Proving this fact in a general situation requires establishing global invariants, adding to the proof burden. The resulting definite action is very fine-grained and less intuitive.

Furthermore, to show the progress created by the fine-grained definite action, one should define a decreasing metric. However, the definition of the metric is unavoidably complex. Defining it as the length of the dependency chain does not work. Because after lock `C` is released, the thread that owns `B` acquires `C`, and may go on requesting other locks, thus getting involved in a even longer dependency chain. As a result, defining this metric requires considering a thread's local progress (e.g., its remaining steps), and the length of the dependency chain, with the former prioritized before the latter (we omit further detail). This poses a significant proof burden in the metric-decrease and metric-non-increase proofs.

By contrast, the specification and termination proof for a lock statement with our layered approach (see §6.2) focus only on the lock. The extra proof burden is the dependency condition, which requires to show any owned locks are lower-numbered than the lock to acquire. This proof is usually trivial with dynamic layering. Code proofs in Coq have confirmed the analysis—the non-layered approach needs 3K LOC while the layered approach requires less than 0.4K LOC.

7.3 Verification Evaluation

Verification effort. MoLi reuses the code from CRL-H [101] framework, including the support for C language and concurrency reasoning. MoLi's extension mainly devotes to the logic for termination and the model of non-atomic abstract operations, which is about 3K LOC. Table 1 shows the lines of proof for verifying RefFS. RefFS also reuses AtomFS's internal functions inside the critical section and their proofs, except that now we also verify termination.

Trusted computing base and tests. Our work has some trusted parts. The abstraction of RefFS is trusted. VFS, FUSE, C compiler, C implementation of a lock and memory allocator of glibc are trusted. Termination proof assumes a fair scheduler and a sequentially consistent hardware model. We also test RefFS with xfstests, a comprehensive file system testing suite, which reports no bugs.

Limitations. Our prototypes of MoLi and RefFS still have limitations. Currently, RefFS is an in-memory file system and does not consider crashes. In general, the reasoning for termination is orthogonal to crashes because the recovery procedure will restore the state to re-execute the code. Hence, the termination proof still applies to the non-crash setting. When a crash happens in the middle of a program, what MoLi does not consider is the termination of the recovery procedure, whose precondition is the crashed state. To support crash safety, one may combine the techniques in DaisyNFS [18–20].

MoLi does not support reasoning about termination in the presence of interrupts or exceptions. Similar to crash safety, supporting them requires considering intermediate states.

RefFS has simplified read access to use exclusive locks. Nevertheless, we can use read-write locks in RefFS and reason with their implementations in MoLi.

7.4 Bug Discussion

We discuss whether MoLi can help find practical bugs. Non-concurrent termination bugs such as logic and low level programming errors [59, 83] will fail the proof, because one cannot define a well-founded metric that decreases for each iteration. In AA-deadlocks [25,58,72], when a thread requests for a lock again, the layer of the waited action (definite release of the lock by other threads) is not larger than that of enabled action (definite release of the lock by the current thread), which will violate the dependency condition. In deadlocks caused by nested blocking [6,23,39,97], proof authors either fail to define the layers, or define the wrong layers, later finding that the layers cannot pass the dependency condition proof.

For deadlocks with dynamic orders [3, 8, 55, 96], MoLi allows defining state-dependent dynamic layers to precisely represent such orders. Therefore, such bugs can be discovered during proofs. For deadlocks that involve ad-hoc synchronization [24,52,69], MoLi's general notion of definite actions can specify and verify them, similar to the bug types above.

These bug patterns also exist in other domains, e.g., memory management [27] and network [45] subsystems in an OS, database and web applications [68]. Therefore, we believe MoLi is also applicable to these domains.

8 Related Work

Starting from the seminal work of seL4 [57], these years have witnessed tremendous progress on the verification of systems, including operating systems [40,73,80], distributed systems [43,78,92], file systems [21,22,47,79] and many others [26,28,63,81,88,89]. Yet, only few of them guarantee systems' liveness, and none of the proposed frameworks could be used for concurrent file systems.

VSync [74] relies on a special *await loops* shown in lock implementations, and proposes *await model checking* to automatically verify the termination of lock primitives, even under weak memory models. It does not support general while loops. VSync relies on a specific client library for correctness; the client library may still not cover all corner cases, especially for large-scale systems such as file systems.

CCAL [41] has been used to verify the termination of an MCS lock [56] by organizing the implementation into layers. However, it does not provide a program logic to guide the proofs, so it is unclear how CCAL can be used to prove the termination of concurrent file systems.

Ironfleet [43] verifies distributed systems with a blend of TLA and Hoare style automated verification. However, this methodology does not have the power for concurrency and termination verification in file systems. Ironfleet's reduction approach for concurrency verification relies on implementation being atomic, but file systems, e.g., RefFS, are not atomic. On termination, Ironfleet does not consider blocking and dynamic lock dependencies as shown in file systems.

Reference counting, a widely used technique in Linux, has also caused many severe bugs [44]. Various methods (e.g., invariant-based [33,34] and anti-pattern based [44]) have been proposed to detect these bugs. Although effective in practice, they still suffer from false positives and false negatives. Our work verifies the correctness of refcounting by showing the implementation using it can refine an abstraction where its details are hidden.

9 Conclusion

This paper has presented MoLi for verifying concurrent file systems. It supports the dynamically layered definite releases specification, with which we verify RefFS, the first modularly verified concurrent file system with termination guarantee. We also for the first time formally prove the correctness of directory locking scheme in Linux VFS. The formal specification has helped us uncover real Linux bugs in practice.

Acknowledgments

We sincerely thank the anonymous reviewers for their valuable comments. We are especially grateful to our shepherd Marc Shapiro, whose suggestions significantly improved this paper. We thank Xinyu Feng and Hongjin Liang for discussions on the metatheory of MoLi. This work is supported by the National Natural Science Foundation of China (No. 61925206 and 62132014). Abstract

Modern clouds depend crucially on an extensible ecosystem of thousands of controllers, each managing critical systems (e.g., a ZooKeeper cluster). A controller continuously *reconciles* the current state of the system to a desired state according to a declarative description. However, controllers have bugs that make them never achieve the desired state, due to concurrency, asynchrony, and failures; there are cases where after an inopportune failure, a controller can make no further progress. Formal verification is promising for avoiding bugs in distributed systems, but most work so far focused on safety, whereas reconciliation is fundamentally not a safety property.

This paper develops the first tool to apply formal verification to the problem of controller correctness, with a general specification we call *eventually stable reconciliation*, written as a concise temporal logic liveness property. We present Anvil, a framework for developing controller implementations in Rust and verifying that the controllers correctly implement eventually stable reconciliation. We use Anvil to verify three Kubernetes controllers for managing ZooKeeper, RabbitMQ, and FluentBit, which can readily be deployed in Kubernetes platforms and are comparable in terms of features and performance to widely used unverified controllers.

1 Introduction

Modern clouds are powered by cluster managers such as Kubernetes [12], Borg [89], ECS [73] and Twine [87]. These systems manage large-scale cluster resources and all applications running atop them. Architecturally, these systems comprise a collection of *controllers* that implement all the cluster-management logic based on the *state reconciliation* principle [4, 30]. Controllers are loosely coupled microservices, each monitoring the cluster state and continuously reconciling the *current* cluster state to match a *desired* state. In Kubernetes for example, controllers manage everything from system resources (e.g., pods, data volumes, networking, and stateful services) to application lifecycles (e.g., provisioning, upgrades, and scaling). There is a thriving ecosystem of thousands of domain-specific controllers that extend Kubernetes [46, 47, 60, 81, 84]. All these controllers perform critical operations, making their correctness paramount.

Implementing correct controllers is immensely challenging, due to the enormity of cluster state space and the complexity of failure events (e.g., node crashes, network interruptions, and asynchrony issues). Recent automated controller testing tools [44, 85] found many bugs with severe consequences such as system outages, data loss, and resource leaks in popular Kubernetes controllers. Buggy controllers have caused many production incidents [45, 57, 71, 74].

This paper addresses the controller correctness challenge with two major contributions: (1) *eventually stable reconciliation*, a general specification for controller correctness which we develop as a liveness property, and (2) Anvil, a framework for implementing practical controllers and formally verifying that a controller implements eventually stable reconciliation. We have developed and verified practical Kubernetes controllers for managing critical systems using Anvil.

Challenges and contributions. Addressing controller correctness with formal verification poses several challenges. The first challenge is to define a correctness specification that is generally applicable to diverse controllers, powerful enough to preclude a broad range of bugs, and concise enough for manual inspection, together with appropriate assumptions that make it possible to implement the specification. The second challenge lies in proving that the controller implements this specification: controllers are complex, feature-rich real-world systems that do not have pen-and-paper proofs that we can reference. This problem is exacerbated by the fact that controllers run in a complex and dynamic environment, where the controller must handle unexpected faults, asynchrony, and conflicts when interacting with other controllers.

We present Eventually Stable Reconciliation (ESR) as a general specification of controller correctness (§3). ESR is a liveness property, which states that a controller should *eventually* reconcile the cluster to a desired state, and then *always* keep the cluster in the desired state. ESR captures the essential functionality that controllers should provide in a precise language, and it precludes a broad range of bugs caused by factors like inopportune failures and conflicts with other controllers. ESR is also realistic and captures the necessary premise to reach the desired state. We formalize ESR as a concise Temporal Logic of Actions (TLA) [58] formula.

A common challenge in proving liveness is that the proof depends on subtle *fairness assumptions*, including assumptions about possible faults. Overly strong assumptions (e.g., the controller can crash at most once) lead to weak correctness guarantees, and overly weak assumptions (e.g., the controller can keep crashing forever) make liveness verification untenable. Anvil employs an assumption that covers a broad range of fault scenarios—an arbitrary number of faults can happen, but eventually faults stop happening. This assumption is similar in spirit to partial synchrony [40] but for faults.

To prove that a controller satisfies ESR, one must consider the controller's interactions with the environment in which it runs. Anvil models this environment, including the shared cluster state, asynchronous network, other controllers, and a realistic fault model (§4.3). The environment model also encodes assumptions on fair scheduling and faults. Anvil abstracts general liveness reasoning patterns in the environment into reusable lemmas to reduce proof effort (§4.4).

With the reusable models and lemmas provided by Anvil, developers can prove that the controller makes progress from any cluster state towards potential desired states in the presence of asynchrony, faults, and conflicts with other controllers. We present a proof strategy to disentangle the challenges of proving ESR (§5), which divides the proof into two lemmas: (1) starting from any possible state resulting from potential interleaving of previous execution and faults, the controller progresses towards the desired state in a stable environment, and (2) the environment eventually becomes stable. Both lemmas can be proven using the temporal proof rules that Anvil provides (under the fairness assumptions). We have applied this proof strategy to verify three controllers using Anvil.

Implementation. We implemented Anvil for verifying Kubernetes controllers on top of Verus [61], an SMT-based deductive verification tool for Rust. With Verus, developers can implement controllers in Rust and formally verify their implementations. Verus does not support temporal logic reasoning, so Anvil provides a TLA embedding on top of first-order logic (§4.2) to enable TLA-style temporal reasoning.

We used Anvil to implement three practical Kubernetes controllers for managing ZooKeeper, RabbitMQ, and FluentBit (§6). These controllers can readily be deployed in real-world Kubernetes platforms; they provide feature parity and competitive performance w.r.t. existing mature, widely used (but unverified) controllers. The verification effort is manageable, with the proof-to-code ratio ranging from 4.5 to 7.4 across the controllers. The verification process exposed deep bugs in both our early implementations and unverified reference controllers. Although Anvil is primarily designed for liveness verification, it also supports safety verification; we prove a safety property specific to the RabbitMQ controller: the controller *never* performs unsafe scaling operations.

Summary. This paper makes the following contributions:

- Eventually stable reconciliation (ESR), a general specification for controller correctness as a liveness property;
- Anvil, a framework for developing practical controllers and formally verifying that the controller implementations satisfy correctness properties such as ESR;
- three representative and practical Kubernetes controllers verified using Anvil; and
- an evaluation of the end-to-end correctness and performance of the three verified controllers.

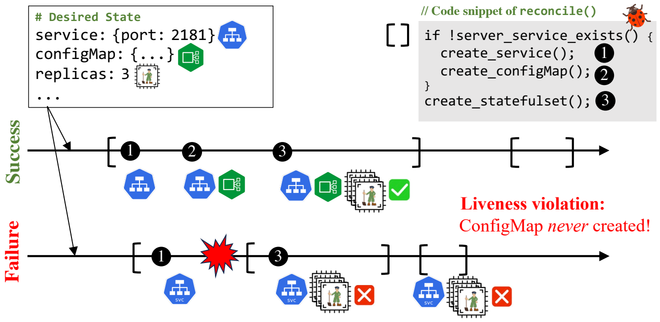
Anvil and the verified controllers are available at `https://github.com/vmware-research/verifiable-controllers`.

2 Implementing Controllers

Controllers follow the *state reconciliation* principle: each controller runs a control loop that continuously reconciles the cluster's current state to the desired state [4, 8]. At each loop iteration, a *reconciliation* procedure checks whether the current cluster state matches the desired state; if not, it performs corrective operations to move the cluster towards the desired state (e.g., launching new replicas in an ensemble of servers when existing replicas fail). The operations query or update the cluster state, represented by shared data objects. These state objects are exposed by REST-based API servers and are stored in a logically centralized data store like etcd [1]. The desired cluster state is described declaratively and can be dynamically updated during the lifecycle of a running controller. The reconciliation procedure is typically implemented in a `reconcile()` function, which is invoked whenever the desired state description (or its relevant cluster states) is changed.

Figure 1 exemplifies the reconciliation process of a Kubernetes controller for managing ZooKeeper. To create a ZooKeeper cluster, the controller takes three steps to create: ❶ a networked service (a Kubernetes service object [17]), ❷ a ZooKeeper configuration (a config map object [14]), and ❸ a stateful application (a stateful set object [18]) with three replicas. Each step is performed by creating a new state object of the corresponding resources via the Kubernetes API, which then triggers Kubernetes built-in controllers, e.g., the StatefulSet controller will create three sets of pods and volumes to run containerized ZooKeeper nodes. In the end, the cluster state matches the desired state. Later, if the desired state changes (e.g., its `replicas` is increased), the ZooKeeper controller will start a new iteration of reconciliation that updates the stateful set object to scale up the ZooKeeper cluster.

Correctness challenges. A bug in a controller's reconciliation can result in the controller *never* being able to match the desired state, even when `reconcile()` is called repeatedly. Controllers are expected to be level-triggered [53]: `reconcile()` can be called from any current cluster state to match any given desired state, with no guarantee that the controller has seen the entire history of cluster state changes [86]. In addition, controllers must tolerate unexpected failures and asynchrony while running `reconcile()`, which leads to a state-space explosion that makes testing controllers difficult. Figure 1 shows one of many bug patterns



```
# Desired State
service: {port: 2181}
configMap: {...}
replicas: 3
...
```

// Code snippet of reconcile()

```
if !server_service_exists() {
  create_service();   ❶
  create_configMap(); ❷
}
create_statefulset(); ❸
```

Figure 1: **An example of state reconciliation of an unverified ZooKeeper controller.** A liveness bug is triggered by a crash during reconciliation. The bug pattern is common in real-world Kubernetes controllers (known as intermediate-state bugs [85]).

```
pub trait Controller {
  type D; // desired cluster state description
  type S; // local state in the state machine

  /// Returns the initial local state (in the state
  /// machine) of every reconcile()
  fn initial_state() -> S;

  /// Returns S: next local state in state machine
  /// Req: external request (e.g. to Kubernetes)
  /// # Arguments
  /// * d: the desired cluster-state description
  /// * r: response to the request from last step
  /// * s: current local state in state machine
  fn step(d: &D, r: Resp, s: S) -> (S, Req);

  /// Returns true if all steps are done
  fn done(s: &S) -> bool;

  /// Returns true for error states
  fn error(s: &S) -> bool;
} // other advanced APIs are omitted
```

Figure 2: **Anvil's basic Controller API.** To implement a controller, developers implement the Controller trait.

```
pub fn reconcile<C>(d: C::D) -> Result<Action, Error>
  where C: Controller {
  let mut s = C::initial_state();
  let mut resp = None;
  loop { // exercise the state machine
    if C::error(&s) {
      return Err(ErrorNeedsRequeue);
    } else if C::done(&s) {
      return Ok(requeue(timeout));
    }
    let (next_s, req) = C::step(&d, resp, s);
    resp = send_external_request::<C>(req);
    s = next_s;
  }
} // details like validity checks are omitted
```

Figure 3: **Anvil code that assembles `reconcile()` using the Controller API in Figure 2.**

```
fn step(d: &ZKD, r: Resp, s: ZKS) -> (ZKS, Req) {
  match s {
    CheckService => { // if the service exists
      let service_get_req = KubeGet { ... }
      return (ReconcileService, service_get_req);
    }
    ReconcileService => {
      /// create/update the service based on response r
      if r.is_ok() {
        let service_update_req = ...;
        return (CheckConfigMap, service_update_req);
      } else if r.is_not_found() {
        let service_create_req = ...;
        return (CheckConfigMap, service_create_req);
      } else {
        return (Error, Noop); // restart reconcile()
      }
    }
    CheckConfigMap => { ... }
    ReconcileConfigMap => { ... }
    CheckStatefulSet => { ... }
    ReconcileStatefulSet => { ... }
    ...
  } // more step branches are omitted
}
```

Figure 4: **A simplified implementation of `step()` using Anvil for creating a ZooKeeper cluster.** Proof-related code is omitted.

of controllers [35, 44, 54, 64, 85]. If the controller crashes between steps ❶ and ❷ during an execution of `reconcile()`, Kubernetes will reboot the controller. The freshly invoked `reconcile()` call now faces the intermediate state created by the previous failed execution (❶). However, in this case, the controller would *never* perform ❷ due to a buggy predicate, which only checks whether the networked service exists, but not whether the config map also exists. As a result, the cluster state would never match the desired state—a liveness violation. Such liveness violations are notoriously hard to detect by testing or model checking [55].

Implementing controllers with Anvil. In Anvil, developers implement a controller using a state machine; this style is common practice in unverified controllers as well [2, 6], and in Anvil it enables TLA-style verification. Figure 2 shows a snippet of the Anvil Controller API specified using a Rust trait: it involves defining the initial state and the transitions of a state machine. Anvil's `reconcile()` uses the state machine as shown in Figure 3: it starts from the initial state and invokes `step()` iteratively until all steps are done or if any step encounters an error. Each iteration of `step()` returns the next state in the state machine, together with an external request. The external request is typically a REST call to Kubernetes APIs, but can also be extended to non-Kubernetes APIs (§6.1). The response to the external request is passed as an argument to the next iteration of `step()`. Note that the API enforces no more than one external request per `step()`, making the state-machine transition atomic with respect to cluster-state changes. Anvil's `reconcile()` interfaces a trusted Kubernetes client library (kube-rs [11]) which invokes `reconcile()` upon changes, handles its output, and requeues the next invocation.

Figure 4 shows the `step()` implementation of a ZooKeeper controller (Figure 1). The `step()` function takes the desired state description of the ZooKeeper cluster (`d`), the response (`r`) to the request from last step (if any), and the current local state (`s`), and deterministically returns the next local state and the external request. The state machine starts from the `CheckService` state, where it returns a request to read the service object [17] from the Kubernetes API (`service_get_req`) and the next state to transition to `ReconcileService`. The `reconcile` method (Figure 3) fetches the service object using the Kubernetes API, and moves on to the next iteration of `step()`, bringing the state machine to `ReconcileService` branch. The controller proceeds to create or update the service based on the response of `service_get_req`. In this way, the controller progressively reconciles each cluster-state object and eventually matches the desired state declared by `ZKD`.

Next, we present a general controller correctness specification, termed eventually stable reconciliation, in §3, and then explain how to verify it using Anvil in §4 and §5.

3 Eventually Stable Reconciliation (ESR)

Controllers reconcile the cluster state to match the desired state. While the details vary between controllers, and some controllers may have additional correctness guarantees, we formalize a general property called *eventually stable reconciliation (ESR)* that captures this ubiquitous pattern.

ESR captures two key properties of any controller's state reconciliation behavior: (1) *progress*: given a desired state description, the controller must eventually make the cluster state match that desired state (unless the desired state changes), and (2) *stability*: if the controller successfully brought the cluster to the desired state, it must keep the cluster in that state (unless the desired state changes).

To make our specification general, we do not wish to commit to any particular bound on the time or number of operations the controller takes to bring the cluster to the desired state. So, we want to talk about guaranteed *eventualities*. Such unbounded eventualities are naturally described using *temporal logics* [80]. We use TLA (temporal logic of actions) [58], a linear-time temporal logic well-suited to our needs. TLA is designed for reasoning about a system described as a state machine. The behavior of the state machine is captured by its set of traces, infinite sequences of system states where the first state is a valid initial state and each subsequent state is obtained via a valid transition from the previous state.

We formalize ESR as a TLA formula that should hold for *all* traces of the system's execution, where the system includes both the controller and its environment, under all possibilities for asynchrony, concurrency, and faults (e.g., controller crashes). We use d to denote a state description, $\mathtt{desire}(d)$ to denote whether d is the current description of the desired state, $\mathtt{match}(d)$ to denote whether the current cluster state matches the description d. Our definition of ESR is given by the following formula:

$$\forall d. \square \big(\square \mathtt{desire}(d) \Rightarrow \Diamond \square \mathtt{match}(d) \big). \qquad (1)$$

Informally, ESR asserts that if at some point the desired state stops changing, then the cluster will eventually reach a state that matches it, and stay that way forever. The temporal operators $\Diamond$ (eventually) and $\square$ (always) are used in temporal logics to reason about the future of an execution trace. If a predicate P talks about the current state, then $\square P$ says that P holds in the current state and all future states, while $\Diamond P$ says that P holds in the current or some future state. Temporal logics such as TLA also allow nesting of temporal operators; for example, $\Diamond \square P$ means that eventually we get to a point such that from that point onwards, P always holds.

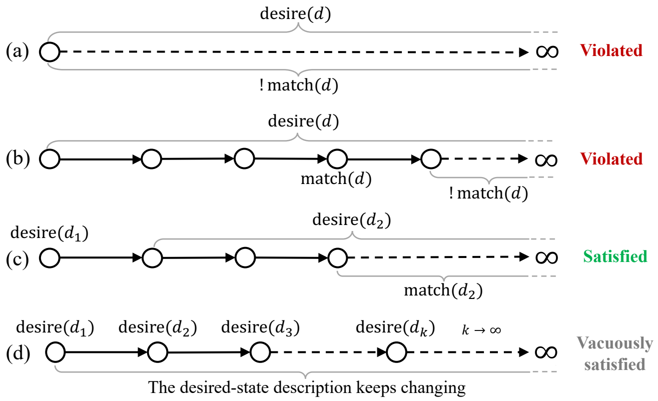


Figure 5: **Executions that violate or satisfy ESR.**

The formalization of ESR is a key contribution of this paper in that it captures the key correctness properties shared by virtually all controllers: progress and stability. We elaborate on this with a detailed dissection of eq. (1).

The innermost conclusion of the formula is $\Diamond \square \mathtt{match}(d)$, which states that eventually ($\Diamond$) the controller matches the desired state (progress), and from then on, it always ($\square$) keeps the cluster state at the desired state (stability). In front of this expression, $\square \mathtt{desire}(d)$ is a realistic and necessary premise for the controller to match the desired state—if the desired state description keeps changing forever, the controller will keep chasing a moving target forever, and nothing can be guaranteed as we do not wish to assume a bound on how long state reconciliation takes. The outer $\square$ in eq. (1) says that $\square \mathtt{desire}(d) \Rightarrow \Diamond \square \mathtt{match}(d)$ always holds, meaning that the controller continuously reconciles the cluster state *regardless of its past execution*. Finally, the $\forall d$ states that the controller reconciles all desired state descriptions.

Figure 5 illustrates the ESR definition in some examples, some that satisfy the definition and others that do not: (a) violates progress because the cluster state never matches d, (b) violates stability because the cluster state first matches d but then deviates from d, (c) satisfies ESR because the cluster state eventually matches and always matches d_2, and (d) vacuously satisfies ESR because the desired state never stops changing, so $\square \mathtt{desire}(d)$ does not hold for any fixed d.

The verification goal for each controller is to prove that the controller satisfies ESR—*all* possible executions of the controller satisfy ESR. We use `model` to describe all possible executions of the controller that runs in an environment with asynchrony, concurrency and faults. We use $\leadsto$ (leads-to) notation to simplify the presentation of the ESR property, where $P \leadsto Q$ means $\square(P \Rightarrow \Diamond Q)$. Then the statement that the controller satisfies ESR is formalized as:

$$\mathtt{model} \models \forall d. \square \mathtt{desire}(d) \leadsto \square \mathtt{match}(d). \qquad (2)$$

The power of ESR. Strictly speaking, ESR (eq. (1)) only guarantees one successful state reconciliation—the one that happens after the desired state stops changing forever. However, in practice the controller has no way of knowing if the desired state will change in the future or not. Therefore, we can expect that a controller that satisfies ESR will bring the cluster to match the desired state (and keep it like that) for any desired state that remains unchanged for *long enough*. ESR achieves this without getting into the gory details of defining exactly how long is long enough. Note further that because of the outermost □ in eq. (1), a controller that satisfies ESR will deliver *multiple* successful state reconciliations, assuming that the desired state goes through a series of slow changes.

Our analysis shows that ESR can ensure the absence of a broad range of controller bugs [44, 64, 85]. For example, recent testing tools [44,85] detected 70 bugs across 16 popular controllers that the controller never matches the desired state due to improper handling of corner-case state descriptions, inopportune failures and concurrency issues, which consist of 69% of all the detected bugs. All such bugs are precluded by ESR. Prior work [64] also reported failure patterns where the cluster state, after matching a desired state, then deviates due to conflicting interactions with other controllers. Such bugs, as stability violations, are also precluded by ESR.

4 Anvil

Anvil is a framework for developing controllers and mechanically proving that they implement correctness specifications like ESR. Anvil is built on top of Verus [61], an SMT-based deductive verification tool for Rust backed by Z3 [39], in similar spirit to Dafny [62]; it offers a Hoare-logic [52] framework for reasoning modularly about imperative code in Rust.

Figure 6 shows the workflow of using Anvil to verify a controller. The developer first provides 🅐 a *controller model* (an abstract state machine) and then proves two theorems: 🅑 the Controller trait implementation (Figure 4) conforms to the controller model and 🅒 the controller model, together with a model of the environment (e.g., the network, other controllers, faults), satisfies specifications like ESR (eq. (2)).

Writing the controller model and verifying the implementation conforms to the model are straightforward. The controller model is an abstract state machine with the same structure as the implementation state machine. To prove conformance, developers prove that each step in the implementation corresponds to exactly one step in the model using standard Floyd-Hoare style reasoning (§4.1). Note: the controller model is written in Verus' specification language to enable verification.

Verifying the model entails ESR is more challenging: developers need to apply temporal logic reasoning on the interaction between the controller and its environment (including faults) at the model level to prove ESR. To reduce developers' burden on specification and proof, Anvil provides (1) a TLA embedding (§4.2) that defines temporal logic operators on top of first-order logic to enable specification and proof in temporal logic (Verus does not support temporal logic), (2) a model of the controller environment (§4.3), including components that a controller interacts with, faults that a controller must tolerate, and reasonable assumptions on fair scheduling and faults that controller liveness depends on, and (3) reusable lemmas (§4.4) that encode temporal proof rules and liveness and safety properties of the interactions between a controller and the environment; these lemmas can be directly assembled into developers' ESR proofs.

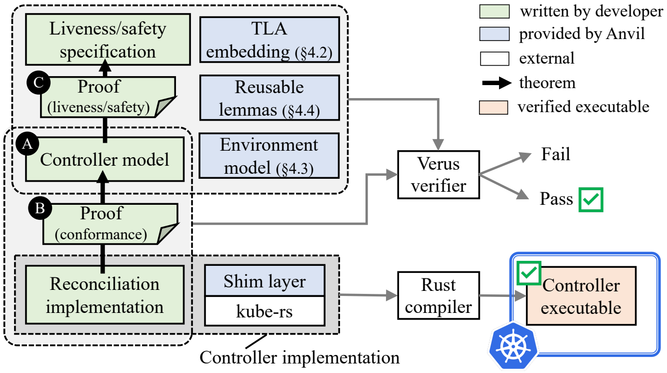

Figure 6: **An overview of Anvil's workflow.**

In this section, we explain how Anvil supports the verification of controllers and then present a general, effective strategy for developing proofs to verify ESR in §5.

Assumptions. Anvil relies on the following assumptions: (1) The TLA embedding correctly defines TLA concepts [58]. (2) The controller environment model correctly describes the interactions between the controller and its environment. (3) The specification of the unverified APIs for querying and updating the cluster state correctly describes the behavior of these APIs. (4) The verifier (Verus and Z3), the Rust compiler, and the underlying operating system are correct.

4.1 Controller Model

To verify controller correctness, developers first write a controller model and prove the controller implementation conforms to this model, similar to prior work [49, 51]. The controller model is a mathematical, state-machine representation of the imperative controller implementation, which abstracts the data types in the implementation and enables TLA-style verification. Given the proof of implementation-model conformance, the model is not assumed to be correct in Anvil's overall verification guarantee.

Anvil provides an API for developers to write the controller model, shown in Figure 7. This API defines a state machine and is similar to the Controller API in Figure 2, except that all the methods and variables are written in *ghost code* [61, 62]. Ghost code is auxiliary code that describes properties of programs and is used for verification only—the code is erased before compilation and thus poses no runtime overhead. Concretely, in the controller model, all the methods are Verus' `spec` functions which are purely functional, and all the variables are ghost types that represent an abstract view of the variables in the implementation, e.g., a heap-allocated Rust `Vec` is represented as a mathematical sequence (Verus' `Seq`).

```
pub trait ControllerModel {
  type DV; // view of the desired state description
  type SV; // view of local state in the state machine
  spec fn m_initial_state() -> SV;
  spec fn m_step(d: DV, r: RespV, s: SV) -> (SV, ReqV);
  spec fn m_done(s: SV) -> bool;
  spec fn m_error(s: SV) -> bool;
} // other advanced APIs are omitted
```

Figure 7: **Anvil's ControllerModel API.** Developers use the API to write the controller model (an abstract state machine). It mirrors the implementation trait (Figure 2) but is written in ghost code.

Given a controller implementation, writing the controller model is straightforward. Given a `step()` implementation in the Controller API (Figure 2), developers write a corresponding `m_step()` using the ControllerModel API (Figure 7). If the implementation's `step()` returns a Kubernetes-API request, the model's `m_step()` correspondingly returns a ghost-type request (`ReqV`) that queries the Kubernetes API model (§4.3.1). The other trait methods are largely identical to their counterparts in the implementation except for the data types.

For each implementation data type defined by developers, such as the types for the desired state description and the state machine's local state (e.g., `D` and `S` in Figure 2), developers need to define a corresponding ghost type (e.g., `DV` and `SV`), typically by replacing implementation data types with corresponding ghost types. For example, if `D` has a field of Rust `Vec` type, `DV` will have a field of Verus `Seq` type. Developers also need to define a `view()` function that converts an implementation object to the corresponding ghost-type object.

Implementation-model conformance. Developers need to prove that the implementation state machine has the same initial state, transitions and termination conditions as the model state machine through `view()`. Figure 8 shows the theorem to prove conformance for the ZooKeeper controller's `step()` in Figure 4. This theorem states that the model's `m_step()` produces the same output (in ghost types), given the same input (in ghost types) of the implementation's `step()`.

```
fn step(d: &ZKD, r: Resp, s: ZKS) -> (res: (ZKS, Req))
  ensures res@ == ZKControllerModel::m_step(d@, r@, s@)
{ ... } // implementation body is omitted
```

Figure 8: **The conformance theorem written as a postcondition of `step`.** The `step` function is executable (part of the controller implementation). The symbol `@` is a shorthand for `.view()` in Verus, which converts an implementation type into a ghost type.

The key challenge in enabling and automating the conformance proof is to reason about data types defined in external, unverified libraries. For example, the controller implementation needs to use data types that define Kubernetes state objects from the kube-rs [11] library, but Verus cannot directly reason about definitions from unverified libraries. So, Anvil defines wrappers that translate every Kubernetes state-object type to its corresponding ghost type. These wrappers are straightforward to implement and are trusted; Anvil includes unit tests that cover *all* the trusted wrapper methods.

The controller implementation uses the wrapper types instead of raw types from kube-rs, and the model uses the corresponding ghost types. For verification, Verus automatically tracks the wrapper's view (`view()`) through the postconditions of the wrapper methods used in the controller implementation. Verus compares the object's view to the ghost object used in the controller model to check the conformance proof; e.g., to prove the theorem in Figure 8, Verus compares the returned request's view and its counterpart in the model.

With this design, the conformance proof is done by standard Floyd-Hoare style reasoning [52] and is largely automated by Verus. Most of the manual proof effort is the requirement to ask Verus to prove two objects are equal if they have the same properties, e.g., to prove a `Vec`'s view (in the implementation) and the corresponding `Seq` (in the model) are equal.

4.2 TLA Embedding

To enable liveness reasoning on top of Verus, Anvil develops a TLA embedding that models important concepts in TLA. Anvil follows IronFleet [51] and models three major concepts as follows: (1) *an execution* is an infinite sequence of system states encoded as a mapping from natural numbers to states, (2) *a temporal predicate* is a boolean predicate on executions, and (3) *a temporal operator* (e.g., $\Diamond$, $\Box$ and $\leadsto$) is a function that transforms one temporal predicate into another. Every temporal operator is defined using only first-order quantifiers on executions. Suppose `P` is a temporal predicate and `ex` is an execution, `eventually(P)` (resp. `always(P)`) is a temporal predicate that holds true of `ex` if `P` is true on some (resp. all) suffixes of `ex`, that is, at some (resp. all) future time.

With the TLA embedding, developers can specify the theorem that the controller satisfies ESR (eq. (2)) as in Figure 9. The definition of `desire` is typically reused among controllers but can also be extended if more premises are required for liveness. The definition of `match` varies across controllers; e.g., the `match(d)` for the ZooKeeper controller in Figure 4 checks if the service, config map and stateful set exist in the data store and match the desired state description `d` (Figure 10).

```
// model ⊨ ∀d. □desire(d) ⇝ □match(d)
model.entails(
  forall(|d: DV|
    always(desire(d)).leads_to(always(match(d)))
  ))
```

Figure 9: **The ESR theorem specified using the TLA embedding.**

In the style of specifying systems [59], Anvil diligently abstracts away executions: developers model components at the levels of state and action (transition between states), then complete liveness proofs with temporal operators. Essentially, Anvil encourages developers to express concepts as *state*

```
spec fn match(d: ZKDV) -> TemporalPredicate {
  lift(|s: ClusterState| { // lift a state predicate
    let store = s.state_object_data_store;
    store.contains(service_name(d))
    && store.contains(config_map_name(d))
    && store.contains(stateful_set_name(d))
    && store[stateful_set_name(d)].replicas == d.size
    && ... // more statements are omitted
  })
}
```

Figure 10: **The definition of the ZooKeeper controller's `match`.** The temporal predicate, when applied to an execution, checks the first state to see if the state objects exist in `store` and match `d`. `ZKDV` is the view of the ZooKeeper desired state description (`ZKD`).

predicates over individual states or *action predicates* over individual transitions. Developers can convert a state predicate to a temporal predicate using a `lift` function [59]: an execution satisfies the lifted predicate if its first state satisfies the state predicate; lifting an action predicate likewise applies the predicate to the first two states of an execution. For example, the temporal predicate `match(d)` is defined by lifting a state predicate as shown in Figure 10. In this way, developers focus on reasoning about individual states and actions when proving invariants and lift them to temporal predicates when applying temporal proof rules (§4.4.1). This differs from IronFleet which interacts directly with instantiated executions throughout the liveness proof. We present Anvil's temporal reasoning style in detail in §5.2.

4.3 Modeling Controller Environment

To reason about interactions between a controller and its environment, Anvil models the controller environment. The goal is to describe the external behavior of different components in the environment and capture the factors that affect a controller's correctness, including asynchrony, concurrency and faults. To this end, Anvil models the environment as a compound state machine, consisting of individual state machines that depict the behavior of different components, such as the network and the API server, as well as faults. The environment model also comes with reasonable assumptions on fair scheduling and faults that liveness depends on.

4.3.1 Modeling Environment Components

Anvil models the environment as a compound state machine with each inner individual state machine modeling one component that a controller interacts with, including:

- an asynchronous network that delivers messages among components with no ordering guarantees;
- the cluster-state data store and the API server; the cluster state is stored in the logically centralized data store (e.g., etcd [1]) and exposed by the API server which handles the controller's query or update requests;
- other controllers in the environment that might interact with the to-be-verified controller; and
- clients that request desired cluster states; clients can update the desired cluster state at any time.

Anvil embeds the controller model in the compound state machine to reason through the interaction between the controller and its environment. The compound state machine, in each step, chooses one individual state machine and invokes one step of that state machine. All the steps are atomic regarding how the cluster state advances (e.g., the API server only handles one request to update the cluster state in each step).

The compound state machine model naturally captures asynchrony and concurrency challenges for controllers. For example, time-of-check to time-of-use (TOCTOU) issues can happen when the cluster state has changed since the last time the controller queried it, but the controller issues an update based on its stale view of the cluster state.

A model of Kubernetes environment. Anvil models the Kubernetes cluster-state data store as a map that stores state objects. Anvil models Kubernetes API servers' mechanisms for validating and coordinating controller requests, including its multi-version concurrency control mechanism wherein each object is versioned. Requests from the controllers must be validated with a version check to take effect.

Anvil models Kubernetes built-in controllers that interact with other controllers, including (1) the garbage collector [16] which deletes a state object if all of its listed owners have been deleted, (2) the StatefulSet controller [18] which manages stateful applications, and (3) the DaemonSet controller [15] which manages daemons (e.g., for monitoring) on every node.

4.3.2 Modeling Faults

Anvil models common faults that happen in modern clusters as actions in the compound state machine; the compound state machine in each step chooses to either let one component take one step or let one fault happen. Anvil models two types of faults: (1) *controller crash*: the controller can crash and reboot an arbitrary number of times. Each crash makes the controller stay offline for an arbitrary number of steps before it is rebooted. After a crash, the controller loses its internal (in-memory) state and has to start over from the beginning of its reconciliation procedure. (2) *request failures*: any request sent by the controller can fail at any point due to network timeouts or the API server being busy.

4.3.3 Specifying Liveness Assumptions

Liveness verification needs careful assumptions. In a concurrent, asynchronous system, *fairness assumptions* are needed to prove that something eventually happens as it relies on the system and its environment getting a chance to take certain actions—a property that is expected to hold in practice but must be nonetheless explicitly incorporated in our formal assumptions. This problem is especially pronounced for controller liveness: a controller's reconciliation (1) relies on other components' actions to complete, and (2) can be interrupted by faults or conflicting actions from other controllers. Anvil makes assumptions that the environment eventually allows the controller to make progress.

Weak fairness assumptions on actions. Applying the *weak fairness* [58] assumption is effective to make the liveness property hold, without assuming any specific fair scheduling. A weak fairness assumption states that if an action A remains "enabled" (i.e., the action can possibly occur), the action eventually occurs: $\Box\texttt{enabled}(A) \leadsto A$. The predicate $\texttt{enabled}(A)$ is true, if for S (the first state of the execution), there *exists* a next state S' such that $A(S,S')$ is true; that is, it is possible for A to occur and transition to S'.

We include fairness assumptions in the model by assuming weak fairness on the actions of the controller and other components in the environment.

Assumptions on faults. Controller liveness also needs assumptions on faults. If the compound state machine chooses to reboot the controller in every step, the controller will never get a chance to finish reconciliation. However, overly strong assumptions like "the controller crashes only once" lead to weak correctness guarantees. To strike a balance, we assume that faults can happen an arbitrary number of times but eventually stop happening, in the spirit of partial synchrony [40].

To incorporate this assumption, we add a "disable-fault" action for each type of fault to the compound state machine. We then add the weak fairness assumption to disable-fault actions. That is, the disable-fault action eventually happens, after which the corresponding type of fault no longer happens.

Assumptions on other controllers. Controllers share the cluster state and thus can conflict with each other. A controller's liveness relies on conflicts being eventually resolved, which mandates assumptions on other controllers. In Kubernetes as an example, the built-in StatefulSet controller can compete with the target controller forever. Suppose the controller uses a stateful set to manage a stateful application and updates the stateful set to match the desired state description. At the same time, the StatefulSet controller continuously updates the stateful set to publish the current status of each running node. When the two controllers are updating the same object concurrently, only one can succeed [13]. Thus, the environment model can adversarially keep letting the target controller lose the race and never reach the desired state.

Anvil assumes that the StatefulSet controller eventually stops updating the stateful set *until* the target controller updates the stateful set again. Similar to the fault assumption, we add to our model an action (with weak fairness) that disables the built-in StatefulSet controller's updates on a stateful set; the target controller's successful update to this stateful set will enable the StatefulSet controller again. Anvil makes the same assumption on how the built-in DaemonSet controller updates daemon sets.

4.4 Reusable Lemmas

Proving ESR requires applying temporal proof rules to reason about the controller's interaction with the environment. This is challenging in two ways: (1) temporal reasoning does not have good automation because SMT solvers like Z3 lack decision procedures for temporal operators, and (2) the interaction between the controller and the environment is complex and is subject to asynchrony and faults. To reduce developers' proof effort, Anvil provides a library of reusable lemmas that encode (1) commonly used temporal proof rules and (2) generic reasoning patterns in the controller environment.

```
proof fn leads_to_transitive(
  model, P, Q, R: TemporalPredicate
)
  requires
    model.entails(P.leads_to(Q)),
    model.entails(Q.leads_to(R))
  ensures model.entails(P.leads_to(R))
{ ... } // proof body is omitted
```

Figure 11: **The leads-to transitivity lemma.**

4.4.1 Temporal Reasoning Lemmas

Anvil provides temporal reasoning lemmas that encode commonly used proof rules to improve temporal reasoning automation. These lemmas are useful for proving liveness for any controller. One example is the *leads-to transitivity* lemma (Figure 11). It shows that if $P \leadsto Q$ and $Q \leadsto R$, then $P \leadsto R$, all under the same assumption *model*. The proof of this lemma involves using the temporal logic definitions, reasoning about an arbitrary time in an execution where P holds, and showing there exists a corresponding time where R eventually holds (using an intermediate time when Q holds, as guaranteed by the preconditions). In return, the developer can easily invoke the lemma without reference to execution or specific indices (these are hidden in the temporal logic lemmas). The leads-to transitivity lemma is frequently used for chaining leads-to formulas to deduce ESR: in our controllers used as case studies, the lemma is used over 50 times. So far, Anvil includes statements and proofs of 70+ such temporal reasoning lemmas, representing a broad range of temporal reasoning patterns.

4.4.2 Environment Reasoning Lemmas

Environment reasoning lemmas prove liveness and safety properties of the interaction between a controller and the environment. We have developed 60 such lemmas. These lemmas are generic to all controllers, and developers can assemble the lemmas into their proofs. We present a representative lemma derived from Anvil's Kubernetes environment model.

Example lemma on the garbage collector (GC). Developers need to reason about their controller's interaction with the built-in GC (§4.3.1). The GC's job is to delete orphan objects whose owner [21] no longer exists: e.g., a stateful set owns a set of pods, thus deleting the stateful set orphans these pods. The GC can conflict with the controller: (1) after the controller updates the owner of an orphan object, the GC deletes the object due to its stale view [86], and (2) the controller attempts to update an object that was deleted by the GC.

To prove ESR, developers need to prove that eventually the GC stops racing with the controller on the object. To help developers prove that eventually the GC stops trying to delete an object x (as x has an existing owner), Anvil provides a lemma with the precondition that any request from the controller that tries to (re)create or update x sets x's owner to an existing object, and the postcondition that eventually if x exists, it has an existing owner (Figure 12). This lemma saves developers the trouble of reasoning about a long chain of the GC execution, including that the GC eventually sends a request to delete x (if it is an orphan), the network eventually delivers the request, and the API server eventually handles the deletion. This lemma takes 200+ lines of proof code and is used in verifying all of the controllers in §6.

```
proof fn eventually_always_has_an_existing_owner(
  model: TemporalPredicate, x: ObjectKey
)
  requires model.entails(
    always(each_req_sets_an_existing_owner(x))),
    ... // some preconditions on fairness are omitted
  ensures model.entails(
    eventually(always(has_an_existing_owner(x))))
{ ... } // proof body is omitted
```

Figure 12: **The garbage collector lemma.** If each request that tries to create or update x sets x's owner to an existing object, then eventually it is always true that if x exists, it has an existing owner.

5 Proving the ESR Theorem

Proving the ESR theorem requires developers to reason about how the controller makes progress starting from any cluster state towards any desired state. We leverage the opportunity that all controllers follow the state-reconciliation principle and develop a proof strategy for ESR. The proof strategy is realized by temporal reasoning using Anvil's TLA embedding and lemmas. We present the proof strategy for ESR and temporal reasoning with Anvil in detail.

5.1 Proof Strategy for ESR

The key idea of our proof strategy is to divide the proof into two main lemmas by separation of concerns: (1) proving that the environment eventually gets stable, and (2) proving that the controller, starting from *any* state (`any_state()`) resulted from arbitrary previous executions and faults, eventually achieves the desired state in this stable environment. Here an environment is stable if (1) the controller does not conflict with the other controllers, (2) faults do not happen, and (3) the desired state description remains unchanged. The ESR theorem is finally proved by combining the two lemmas using temporal proof rules (e.g., leads-to transitivity). Figure 13 shows the high-level proof structure.

5.1.1 Environment is Eventually Stable

Proving that the environment is eventually stable is straightforward and is largely automated by Anvil's lemmas. For example, developers can directly invoke Anvil's lemma which proves that faults eventually stop happening based on Anvil's assumption of faults (§4.3.3). However, proving that the controller eventually stops conflicting with the other controllers still requires certain controller-specific reasoning. Take the garbage collector (GC) as an example, developers can use Anvil's lemma on the GC (Figure 12) to prove that the GC eventually stops racing with the controller on any object, after they prove that the controller correctly sets the owner of the target objects (required by the GC lemma).

```
proof fn ESR_proof()
  ensures model.entails(forall(|d: DV|
    always(desire(d)).leads_to(always(match(d)))
  )) /* the ESR theorem */ {
  // (1) prove ∀d.model ⊨ □desire(d) ⇝ stable_model(d)
  env_is_eventually_stable();
  // (2) prove ∀d.stable_model(d) ⊨ any_state() ⇝ □match(d)
  liveness_in_stable_env();
  // (3) prove model ⊨ ∀d.□desire(d) ⇝ □match(d)
  ...
  leads_to_transitive(...);
}

proof fn env_is_eventually_stable() // lemma 1
  ensures forall |d| model.entails(
    always(desire(d)).leads_to(stable_model(d))) {...}

proof fn liveness_in_stable_env() // lemma 2
  ensures forall |d| stable_model(d).entails(
    any_state().leads_to(always(match(d)))) {...}
```

Figure 13: **High-level structure of the ESR proof.** `model` describes the original environment in §4.3. `stable_model`(d) describes the stable environment: faults and conflicts stop, and the desired state d is stable.

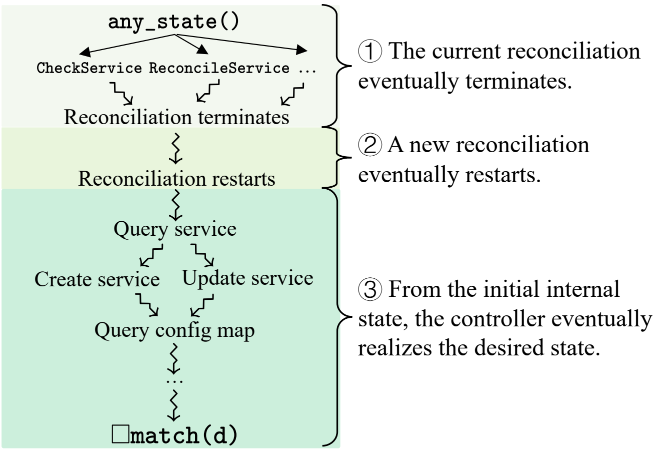
A notable corner case emerges due to asynchrony: even if the desired state description remains unchanged, the controller could still be affected by an older version of the desired state. Consider an execution where the controller crashes right after sending a request to match d_1, then the desired state description is updated to d_2 and remains unchanged from then, but the old request for d_1 is still pending in the network. After the restarted controller sends a new request to match d_2, the two requests will conflict with each other—the two requests try to make the cluster state match two different versions of the desired state. To address this problem, we prove that after the desired state description eventually stabilizes, any controller request for any previous version of the desired state will eventually leave the network.

5.1.2 Liveness in a Stable Environment

Within the stable environment, developers focus on proving that the controller reaches the desired state through each reconciliation step, without considering faults or conflicts.

The main challenge is to prove liveness starting from any possible state. The state here includes both the shared cluster state and the controller's internal state: the cluster state can result from any possible interleaving between the controller's previous execution and arbitrary faults, and the controller internally can be running any reconciliation step.

It is tedious to reason about different executions starting from every internal state. For the ZooKeeper controller in Figure 4, it would require reasoning about controller executions starting from `CheckService`, `ReconcileService` and all other branches in `step()`, respectively. To reduce proof burden, we organize the proof in three stages (Figure 14). First, we



any_state()
CheckService ReconcileService ...
Reconciliation terminates
Reconciliation restarts
Query service
Create service
Update service
Query config map
...
□match(d)
① The current reconciliation eventually terminates.
② A new reconciliation eventually restarts.
③ From the initial internal state, the controller eventually realizes the desired state.

Figure 14: **Proving liveness in a stable environment.**

prove a termination property: the controller's current reconciliation (the current invocation of `reconcile()` in Figure 3) eventually terminates regardless of its current internal state. This is done by reasoning about internal states backward, e.g., `CheckService` leads to termination if all its successor states lead to termination. Second, we prove that a new reconciliation eventually starts after the previous one terminates. This holds as Anvil requeues the next invocation of `reconcile()` when the current terminates (Figure 3). Lastly, we only need to reason about the controller execution starting from its initial internal state in the new reconciliation (e.g., `CheckService` in Figure 4) to prove that the controller eventually creates and updates all the state objects to match the desired state.

To reason about the controller execution starting from its initial internal state, we need to reason about how the controller manages each state object. We observe that controllers often employ similar workflow for managing different objects, which can be leveraged to develop general lemmas to further reduce proof burden. For example, the ZooKeeper controller in Figure 4 manages its service, config map and stateful set with a similar pattern: (1) querying the object and (2) creating or updating the object depending on the query result. We develop a lemma parameterized by state objects which proves that, from the step that the controller queries the object, eventually the object always exists and matches the desired state. The lemma internally reasons about how the controller creates or updates the object to match the desired state.

5.2 Temporal Reasoning with Anvil

The proof strategy for ESR is realized by temporal reasoning. With Anvil, developers perform temporal reasoning by focusing on reasoning about state and action predicates using Anvil's TLA embedding and lemmas. We use the example in Figure 15 to demonstrate temporal reasoning with Anvil.

Developers perform temporal reasoning to prove that *all* possible executions allowed by a model satisfy a property *Prop* (`model` $\models$ *Prop*). A model is defined as the initial state

```
1  // model ≜ init ∧ □next ∧ fairness(...)
2  let model = lift(init).and(always(lift(next))
3    .and(fairness(...)));
4
5  // (1) prove model ⊨ P ⤳ Q
6  // if P holds, P or Q will hold in the next state
7  assert forall |s, s'| P(s) && next(s, s')
8  implies P(s') || Q(s') by { ... }
9  // if P holds, running A makes Q hold in the next state
10 assert forall |s, s'| P(s) && next(s, s') && A(s, s')
11 implies Q(s') by { ... }
12 // if P holds, A is enabled (A can possibly occur)
13 assert forall |s| P(s) implies enabled(A)(s) by { ... }
14 wf1(model, next, A, P, Q);
15
16 // (2) prove model ⊨ Q ⤳ R
17 ...
18 wf1(model, next, A, Q, R);
19
20 // (3) prove model ⊨ P ⤳ R
21 leads_to_transitive(model, lift(P), lift(Q), lift(R));
22
23 // (4) prove model ⊨ P ⤳ □R
24 assert forall |s, s'| R(s) && next(s, s')
25 implies R(s') by { ... }
26 leads_to_stable(model, lift(next), lift(P), lift(R));
27
28 // (5) prove model ⊨ □Inv
29 assert forall |s| init(s) implies Inv(s) by { ... }
30 assert forall |s, s'| Inv(s) && next(s, s')
31 implies Inv(s') by { ... }
32 invariant_by_induction(model, init, next, Inv);
```

Figure 15: **Temporal reasoning with Anvil.** Developers focus on reasoning about states and actions and applying TLA proof rules.

(`init`), all possible next-state actions (`next`), and fairness assumptions (line 2-3). Fairness assumptions are only used for proving liveness properties such as ESR.

Proving ESR often involves proving that if condition P holds then eventually Q holds (i.e., $P \leadsto Q$). For example, if the controller sends a request, then eventually the request is received and handled by the API server. Proving $P \leadsto Q$ is typically done by applying the WF1 rule [58]. WF1 states that "Action A makes P lead to Q" with four requirements (1) running any action in a state satisfying P makes either P or Q hold in the next state, (2) running A in a state satisfying P makes Q hold in the next state, (3) P implies that A is enabled (i.e., A can possibly occur) and (4) A has the weak fairness assumption. To apply Anvil's `wf1` lemma (line 14), developers focus on proving (1)-(3) by reasoning about P, Q, A and all other actions allowed by the model (line 7-13), and (4) is automatically proved by the definition of the model.

Proving ESR requires reasoning about a sequence of actions. For example, the controller sends a request, the API server handles the request, and the controller receives the response and continues to send the next request. To prove that the controller makes progress through multiple actions, developers apply the `leads_to_transitive` lemma (line 21) to combine multiple leads-to properties into one ($P \leadsto R$).

To reason about stability (if $P \leadsto R$, then $P \leadsto \Box R$), developers need to demonstrate that R is preserved by all possible actions (if R holds, then it will hold in the next state) and apply the `leads_to_stable` lemma (line 24-26).

Proving ESR (or other properties) often requires invariant reasoning by induction (line 29-31). For example, to prove that a state object x always exists, developers need to prove an invariant that the controller *never* deletes x. Such invariants are often required when applying `wf1` and `leads_to_stable`.

6 Case Studies

We use Anvil to build three verified Kubernetes controllers for managing different applications and services (ZooKeeper, RabbitMQ, and FluentBit). For each controller, we use a mature, widely used controller as a reference (either the official Kubernetes controller of the applications or from companies that offer related products). We verify ESR for all three controllers, and a safety property of the RabbitMQ controller.

Feature parity. We aim to implement verified controllers that are feature rich with production quality. For the ZooKeeper and RabbitMQ controllers, we implement key features offered by the reference controllers [20, 23] including scaling, version upgrading, resource allocation, pod placement, and configurations, as well as network and storage management. For the FluentBit controller, we implement *all* the features offered by the reference controller [19]. We also implement important features missing in the reference controllers. For the ZooKeeper controller, we implement a feature that the controller automatically restarts each ZooKeeper server to load the new configuration once the configuration changes. For the FluentBit controller, we implement a feature that the controller allows users to customize how a load balancer discovers FluentBit daemons. All the verified controllers can readily be deployed in real-world Kubernetes platforms and manage their respective applications.

Experience. Anvil's Controller API (Figure 2) is expressive to implement all the features of the controllers. For verification, we spent around two person-months on verifying ESR for the ZooKeeper controller, during which we developed the proof strategy (§5). We took much less time (around two person-weeks) to verify the other two controllers using the same proof strategy and similar invariants. We find Anvil's ability to formally verify a controller's implementation invaluable. We discovered deep bugs via verification. Some of them also exist in the reference controllers but were not detected by testing [44, 85].

6.1 ZooKeeper Controller

We implement and verify a full-fledged ZooKeeper controller, using the controller [23] from Pravega [22] as the reference. Figure 4 is a simplified version of our ZooKeeper controller. We discuss two challenges of verifying the controller.

Supporting non-Kubernetes APIs. We extended Anvil to support non-Kubernetes APIs to implement features like scaling. To scale a ZooKeeper cluster, the controller needs to change ZooKeeper membership by invoking ZooKeeper APIs. We implement procedures to invoke ZooKeeper APIs as callbacks invoked by `reconcile()` (Figure 3); Anvil decides whether to invoke Kubernetes APIs or ZooKeeper APIs based on the request object returned by the controller `step()`.

Invoking ZooKeeper APIs needs new specifications beyond what Anvil supplies. Hence, we write a trusted model (an abstract state machine) of the ZooKeeper APIs used by our controller and register it with the extensible compound state machine. To prove liveness, we assume weak fairness on the ZooKeeper API model: if the controller sends a request to a deployed ZooKeeper cluster, it eventually receives a response.

Reasoning about dependencies between state objects. To prove ESR, we need to reason about *dependencies* between state objects—the desired state of one object depends on the current state of another object. For example, to support reconfiguration, our controller attaches the version number of the config map to the stateful set as an annotation [7]. To ensure the ZooKeeper servers managed by the stateful set use the updated configuration, the desired state of the stateful set should contain the current version number of the config map as an annotation. To verify the correctness of reconfiguration, in ESR, `match` asserts that each state object matches the desired state description (as in Figure 10), and the annotation in the stateful set matches the current version of the config map. We prove that the config map's version eventually becomes stable and thus the annotation eventually matches the version.

Bugs precluded. We found and fixed two liveness bugs when verifying our ZooKeeper controller. The first bug occurs when the controller crashes between the steps of scaling ZooKeeper and cannot continue reconciliation after restart, similar to Figure 1. This led us to find a similar bug in the reference controller we reported in [26]. Recent work [85] applied extensive fault-injection testing on this controller but failed to find this bug, because the bug only manifests in specific timing under specific workloads (not covered by tests).

The second bug was caused by the controller trying to update immutable fields in a stateful set. Kubernetes always rejects the update, so the controller never finishes its reconciliation. Our environment model captures how Kubernetes validates each request (§4.3), which helped us find this bug.

6.2 RabbitMQ Controller

We implement and verify a full-fledged controller for RabbitMQ, a widely used message broker [24]. We use the official RabbitMQ controller as the reference [20].

Verifying safety. Besides ESR, we verify a safety property for our controller. The official RabbitMQ controller disallows scaling down a RabbitMQ cluster by reducing the stateful set's `replicas` due to data loss concerns [25]. The recommended practice is to export the data, redeploy RabbitMQ with fewer replicas, and import the data back. So, our controller prevents reducing `replicas` count. We prove a safety property stating that the replica count *never* decreases using Anvil. The safety proof is done by standard inductive proof. For example, we first prove invariants like "no request in the network reduces replicas," and conclude the replicas in the data store never decreases using the invariants.

Bugs precluded. We found a safety bug and a liveness bug via verification. The safety bug was caused by a concurrency issue involving the RabbitMQ controller and the Kubernetes garbage collector (GC). Initially, we restricted that replicas never decreases in desired state descriptions using Kubernetes' validation rule [5]. However, safety can still be violated, because the GC may not immediately remove orphan stateful sets. If the stateful set updated by the controller was created by an old (already deleted) desired state description that set a larger replicas (r_1) than the current one (r_2), the controller would in fact decrease the stateful set's replicas ($r_1 \rightarrow r_2$). We fixed the bug by enforcing the controller to wait for the GC to delete orphan stateful sets.

The liveness bug was caused by a naming rule we inherited from the reference controller. The bug causes the controller to assign the same name for service objects from *different* RabbitMQ clusters. In this case, the desired state descriptions of two RabbitMQ clusters drive the controller to change each other's service object back and forth, thus neither can reach desired states stably. We caught this bug because the oscillation behavior prevented us from proving the cluster state eventually *always* matches the desired state description in the presence of another conflicting description. We fixed the bug by changing the naming schema. The same bug also exists in the reference controller.

6.3 FluentBit Controller

We implement and verify a controller for FluentBit, a popular logging and metrics service [9]. FluentBit is deployed as a group of daemons collecting and processing data on different nodes in a cluster. We use the official FluentBit controller as the reference [19] and implement *all* its features.

Incremental verification. To evaluate the efforts of maintaining an evolving controller, we first implemented and verified a basic version of the controller that deploys FluentBit daemons, and then added new features incrementally, including version upgrading, daemon placement, reconfiguration. We repaired the proof every time when a new feature was added. We find the efforts of evolving a verified controller manageable (§7.1).

7 Evaluation

We evaluate Anvil along the dimensions of verification effort (§7.1), controller correctness (§7.2) and performance (§7.3). Our evaluation shows that it is pragmatic to implement, verify and evolve practical Kubernetes controllers with Anvil.

7.1 Verification Effort

Table 1 shows the details of each verified controller we built using Anvil. Verifying each controller takes under 3 minutes in real time on a 6-core 16 GB laptop with 11 parallel threads.

	Trusted	**Exec**	**Proof**	**Time to Verify**

Table 1: **Code sizes and verification time of the controllers verified using Anvil.** Trusted includes the (verified) theorems, trusted assumptions and unverified implementation. Time in brackets is obtained by running the verifier in parallel (11 threads on 6 cores).

87% of proof functions verify in under ten CPU seconds, and the slowest of them takes 120 CPU seconds.

Implementing and verifying each controller takes around 2.5 person-months. The proof-to-code ratio ranges from 4.5 to 7.4 across three controllers. We attribute the relatively low ratio to Anvil's reusable lemmas (§4.4) and our proof strategy (§5). For example, the ESR proof of the RabbitMQ controller uses the same set of leads-to reasoning lemmas to prove nine different state objects eventually match the desired state.

The ESR proof mainly consists of proving invariants and applying temporal proof rules. Proving invariants takes about 40% of the proof, which can potentially benefit from research on inductive invariant inference [42,48,68,69,78,79,91,93]. All our temporal logic reasoning is done by applying Anvil's temporal logic lemmas without unfolding the definition of executions and temporal logic operators.

The verified controllers have a large portion of unverified (trusted) components: 67% of the trusted code is for defining wrapper types of Kubernetes custom objects (used for describing desired states) to integrate kube-rs, and their views to enable verification (§4.1). The ZooKeeper controller also relies on the trusted ZooKeeper API: 180 lines for specifying the ZooKeeper API and 138 lines for implementing the callbacks for Anvil to invoke the ZooKeeper API during runtime.

Controller	Functional testing		Crash testing	
	# Tests	# Bugs	# Tests	# Bugs
ZooKeeper	239	1	212	0
RabbitMQ	197	0	158	0
FluentBit	557	0	484	0

Table 2: **Testing results of the three verified controllers.** The tests cover all the features of the controller under test.

Evolving controllers with Anvil. We measure the efforts to evolve the FluentBit controller with Anvil by incrementally adding features and updating its proof. We first implemented and verified a basic FluentBit controller for deploying FluentBit daemons, then added 28 new features including version upgrading, daemon placement, and various configurations. On average, implementing a feature took less than a day and 47 lines of changes, including 19 lines in the proof. Among them, implementing `metrics_port` required the most changes (403 lines in total and 211 in the proof); it added a new service that routes traffic to the metrics port of each daemon, and we proved the service eventually matches the desired state.

Effort to build Anvil. As a reference, the Anvil framework consists of 5353 lines of reusable lemmas and 7817 lines of trusted code, including the TLA embedding (85 lines), the environment model (1846 lines) and the integration with Kubernetes (5886 lines); 89% of the integration is for defining wrapper types and views of Kubernetes built-in objects (§4.1). All the lemmas are verified in under one minute.

7.2 Controller Correctness

We run extensive end-to-end functional tests on the verified controllers using Acto [44]. Acto generates different desired state descriptions to exercise controller reconciliation under various scenarios. We also run extensive crash tests to check if the verified controllers can recover from random crashes during their reconciliation. The crashes are injected using an implementation of Sieve [85] for Rust controllers.

Table 2 shows the testing results. The crash tests did not find any bug—the verified controllers correctly recovered from all the injected crashes and successfully reconciled the cluster to the desired state. The functional tests found a bug in the ZooKeeper controller (no bug found in other controllers).

The bug is caused by an incomplete specification of a trusted ZooKeeper API that did not cover ZooKeeper misconfigurations. If a misconfiguration results in partial failures (ZooKeeper is still running but cannot serve write requests [67]), the controller fails to update the membership and thus blocks the subsequent reconciliation steps. We fixed this bug by adding configuration validation in the implementation, enhancing the specification, and updating the proofs.

7.3 Controller Performance

The verified controllers have comparable performance to the reference controllers. We use Acto [44] to generate many different desired state descriptions, triggering a sequence of reconciliations. For each desired state, we measure (1) execution times for the target controllers' `reconcile()` methods (Figure 1), and (2) the time it takes for the system to be fully reconciled (e.g., after the controller issues a rolling update). The experiments are run on CloudLab Clemson c6420 machines with dual Intel Xeon Gold 6142 processors, 384GB DRAM, and a 6Gb/s HDD running Ubuntu 20.04 LTS.

Controller	Verified (Anvil)		Reference (unverified)	
	Mean (ms)	Max (ms)	Mean (ms)	Max (ms)
ZooKeeper	439	696	212	413
RabbitMQ	439	725	690	1531
FluentBit	195	303	221	464

Table 3: **Comparison of `reconcile()` execution time (in milliseconds) between the verified controllers and their references.**

Table 3 shows that the verified and reference controllers have comparable execution times. The verified ZooKeeper controller's execution time is about twice that of the reference which implements optimizations to conditionally skip state updates. None of the controllers are latency critical. On average, `reconcile()`'s execution time takes less than 1% of the overall system reconciliation time, most of which is out of the control of the controller (e.g., container restart time).

We also evaluate if the verified controllers introduce more load on the data store which is often the bottleneck for Kubernetes scalability [28, 87]. We measure the disk I/O of etcd and the verified controllers do not cause noticeably more loads—the verified FluentBit controller causes only 0.44% load increase compared to the reference; the other two verified controllers do not cause load increase.

8 Related Work

Anvil is the first effort for building formally verified cluster management controllers. We discuss related work in controller correctness, systems verification and liveness verification.

Controller correctness. Liu et al. [65] use model checking to find if controllers in a specific deployment have conflicting interactions that violate user-supplied policies at the model level (not executables). In contrast, Anvil verifies controller *implementations* against ESR, a *general* controller-correctness specification. Automated testing techniques [44, 85] have found bugs in controller implementations. Anvil precludes such bugs by verifying that the controller implementation satisfies ESR for all executions. It has also revealed bugs that were missed by these automated testing techniques (§6).

Systems verification. Despite the rich literature, most systems verification efforts so far focus on safety rather than liveness [31–34, 36, 37, 49, 50, 56, 63, 66, 75, 82, 83, 88, 90, 94]. A notable exception is IronFleet [51], which also verifies liveness of system implementations.

Anvil differs from IronFleet in the objective and proof technique. Regarding objective, IronFleet verifies a Paxos-based replicated state machine and a sharded key-value store, with system-specific specification (e.g., "if the network is fair then the reliable-transmission component eventually delivers each message"). Differently, Anvil formalizes ESR as a general specification that captures the essence of state reconciliation and verifies multiple controllers against ESR. Anvil shares IronFleet's methodology of using TLA embedding on first-order logic. Different from many IronFleet's liveness proof statements that interact directly with instantiated executions by indexing (Figure 16), Anvil abstracts away executions to let developers model components, at the level of state and action, and complete liveness proofs exclusively with temporal operators (Figure 15).

```
lemma Lemma_PacketSentEventuallyReceivedAndNotDiscarded
  (b:Behavior<LSHT_State>, send_step:int, ...)
  returns (received_step:int, ...)
  requires 0 <= send_step;
  requires SendSingleValid(b[send_step], ...);
  requires ... // other preconditions are omitted
  ensures send_step <= received_step;
  ensures b[received_step].hosts[dst_idx].host.
    receivedPacket == Some(Packet(msg, ...));
{ ... } // proof body is omitted
```

Figure 16: **A representative liveness lemma example from IronFleet (written in Dafny) [10].** The lemma counts steps in one instantiated execution (`Behavior`) to prove that if the packet is sent at `b[send_step]`, it will be received at `b[received_step]`. This lemma, if written in Anvil, will have a postcondition in the form of `model.entails(sent.leads_to(received))` without taking or returning any execution instances or indices.

Liveness verification. Ivy [72, 78] incorporates a technique for proving liveness of distributed protocols using first-order logic [76,77]. Compared to Anvil, Ivy obtains a higher degree of proof automation at the expense of a more restricted modeling logic; we are exploring the potential to leverage some of Ivy's techniques in Anvil. LVR [92] proves liveness of distributed protocols by automatically synthesizing ranking functions with limited manual guidance. LVR is complementary to Anvil and might be able to synthesize ESR proofs for controller implementations. The Alloy analyzer has recently been extended to support linear temporal logic [3, 29, 70], which enables modeling liveness properties of protocols and system abstractions; but only finite instances can be checked and the analyzed abstractions are not formally linked to executable code. More broadly, the rich literature on liveness verification includes program termination [38] and liveness of concurrent programs [27, 41, 43]. These techniques target other systems and their liveness specifications, whereas Anvil's contribution specifically targets controller correctness and connects liveness proofs to an executable implementation.

9 Discussion and Future Work

The correctness of controllers verified by Anvil is not absolute. Anvil relies on trusted components, including the model of the environment, the shim layer, trusted external APIs, and the verifier, compiler, and OS. We indeed found a bug caused by an incomplete trusted assumption (§7.2). We believe that the bug does not diminish the value of Anvil. Anvil formally verifies reconciliation – the core of a controller – and reduces the code one needs to look for bugs in to the trusted assumptions.

Note that ESR does not preclude all possible controller bugs. For example, ESR may not rule out all potential safety violations. Unlike ESR as a *general* correctness specification, safety properties are often controller-specific; e.g., the safety property we verified in §6.2 that the replicas number never decreases is specific to the RabbitMQ controller.

We choose to focus on verifying ESR because ESR is a general, reusable property that precludes a broad range of bugs, and it is straightforward for developers to specify ESR. Some bugs precluded by ESR may be precluded by some safety properties as well, but these safety properties may be more difficult for developers to specify. For example, the bug in Figure 1 could be precluded by a safety property saying "irrecoverable intermediate states never happen." However, specifying such safety properties requires knowledge of the nature of the bugs (e.g., what kind of intermediate states the controller cannot recover from?) [55]. In contrast, specifying ESR only requires knowledge of desired states.

We expect verified controllers to be deployed on real-world Kubernetes platforms, running alongside unverified controllers. If the unverified controllers are custom controllers not modeled in Anvil (§4.3.1), Anvil cannot reason about their interactions with verified controllers, and hence cannot rule out bugs caused by conflicting interactions.

In future work, we aim to gradually replace existing (unverified) controllers with verified controllers using Anvil, including both custom and built-in ones. We plan to extend Anvil to admit multiple verified controllers and verify the interactions among them in a modular way. We also plan to ensure the quality of the trusted model of the environment, the shim layer, and external APIs using lightweight formal methods.

10 Concluding Remarks

This paper presents Anvil, a framework for developing and verifying cluster-management controllers, and ESR, a general specification for controller correctness. We have implemented and verified three Kubernetes controllers using Anvil. Our work shows that it is not only feasible but also pragmatic to implement, verify, and maintain practical Kubernetes controllers. We hope that Anvil and ESR lead to a practical path towards provably correct cloud infrastructures.

Acknowledgement

We thank the anonymous reviewers for their insightful comments on the paper. We thank Jay Lorch, Owolabi Legunsen, Ramnatthan Alagappan, and Yongle Zhang for their valuable feedback and discussions that helped shape this work. Abstract

Data centers increasingly host mutually distrustful users on shared infrastructure. A powerful tool to safeguard such users are digital signatures. Digital signatures have revolutionized Internet-scale applications, but current signatures are too slow for the growing genre of microsecond-scale systems in modern data centers. We propose DSig, the first digital signature system to achieve single-digit microsecond latency to sign, transmit, and verify signatures in data center systems. DSig is based on the observation that, in many data center applications, the signer of a message knows most of the time who will verify its signature. We introduce a new hybrid signature scheme that combines cheap single-use hash-based signatures verified in the foreground with traditional signatures pre-verified in the background. Compared to prior state-of-the-art signatures, DSig reduces signing time from 18.9 to 0.7 µs and verification time from 35.6 to 5.1 µs, while keeping signature transmission time below 2.5 µs. Moreover, DSig achieves 2.5× higher signing throughput and 6.9× higher verification throughput than the state of the art. We use DSig to (a) bring auditability to two key-value stores (HERD and Redis) and a financial trading system (based on Liquibook) for 86% lower added latency than the state of the art, and (b) replace signatures in BFT broadcast and BFT replication, reducing their latency by 73% and 69%, respectively.

1 Introduction

Digital signatures are used in many distributed protocols that have revolutionized the Internet through many use cases, such as enabling digital certificates [83], bootstrapping authentication protocols [30, 89], securing and auditing transactions [22, 71], tolerating Byzantine failures [4, 6, 18], and verifying software authenticity [28, 57]. Signatures are irrefutable proofs that someone produced a message, and these proofs can be verified by third parties. This property distinguishes signatures from message authentication codes (MACs) and authenticated symmetric encryption (e.g., SSL/TLS) [54]. Today's signatures are however too expensive for the growing genre of microsecond-scale systems in data centers. Even the fastest signature scheme, EdDSA [17, 50], accounts for 79–95.6% of the latency of applications such as auditable key-value stores, BFT broadcast, and BFT replication (Figure 1).

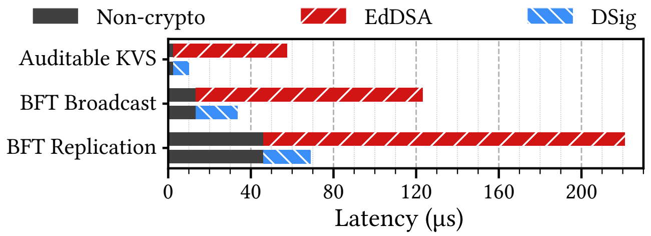

Figure 1: Median latency breakdown of an auditable key-value store (based on HERD [51], §6), a BFT broadcast primitive (CTB [3], §6), and a BFT replication system (uBFT [3], §6) when processing small requests using either EdDSA [50] (state of the art) or DSig. DSig reduces the cryptographic overhead by 86%, 82%, and 87%, respectively, and reduces the overall latency by 83%, 73%, and 69%, respectively.

We propose DSig, the first digital signature system to achieve single-digit microsecond performance for data centers. A key insight underlying the design of DSig is that, in many data center applications, signatures are issued and verified by parties known a priori in the common case, so signers and verifiers can exchange useful information beforehand and do part of the computation before knowing the messages to be signed, thereby reducing the latency of subsequent signature generation and verification. We use this observation to introduce a new hybrid online-offline signature system [37]. Hybrid schemes combine a traditional signature scheme that is slow but can sign many messages, with a hash-based signature scheme (HBSS) that is fast but can sign only one or a few messages. The traditional signature is used to validate a batch of HBSS key pairs, each of which signs one or a few messages. Hybrid signatures have been studied extensively in theory, but practical work has focused only on improving throughput for low-compute devices with limited bandwidth,

Table 1: Comparison of EdDSA and DSig in terms of latency to sign, transmit (tx) and verify; per-core sign and verify throughput; signature size; and background network traffic per signature with a single verifier.

	Latency (µs)			**Tput (Kops)**		**Sig size**	**Bg Net**
	Sign	Tx	Verify	Sign	Verify	**(B)**	**(B/Sig)**
EdDSA	18.9	1.1	35.6	53	28	64	0
DSig	0.7	2.0	5.1	131	193	1,584	33

on low-security signatures, or on tiny messages (§9).

Using hybrid signatures to achieve low latency and high throughput in data centers poses a number of challenges. First, the traditional part of hybrid signatures is compute-heavy and can impact latency. Second, hybrid signatures involve frequent key pair generation, which can exhaust compute resources and impact throughput. Third, the actual performance of hybrid signatures deviates from their theoretical models, as real performance requires careful consideration of microarchitectural effects (e.g., caching, prefetching) rather than simply the amount of computation. Fourth, to perform well, hybrid signatures need to be configured with an appropriate HBSS whose thousands of parameter combinations provide complex trade-offs between number of hash computations, signature size, and frequency of key pair generation; most parameter choices exceed our performance goals, the available network bandwidth, the computational resources, or all of the above.

We address these challenges as follows. First, we use hints about who will verify a message in the common case to preprocess the compute-heavy traditional signatures. Second, we use traditional signatures to sign and verify batches of HBSS public keys, thus amortizing the cost of their authentication, while hiding the latency introduced by batching from the critical path. Third, we study the real performance of HBSSs to determine the best schemes to use, and we discover non-intuitive cases where fewer hash computations actually harm performance. Fourth, we identify two promising HBSSs to use in DSig, W-OTS$^+$ [46] and HORS [84], and we explore their parameters in depth to understand how they affect latency, throughput, and resource usage; we give a recommended configuration of DSig that strikes a good trade-off.

We integrate DSig with five applications: two key-value stores (HERD [51] and Redis [87]), a financial trading system (based on Liquibook [73]), a BFT broadcast primitive (CTB [3]), and a BFT replication system (uBFT [3]). We use DSig to provide auditability through a signed security log in HERD, Redis, and Liquibook; and to replace the signatures used in CTB and uBFT to thwart Byzantine behavior.

We evaluate DSig and its applications. We find that DSig can sign, transmit, and verify a signature in 7.7 µs total, which is 7.2× faster than EdDSA [50], the fastest traditional signature scheme [17] (Table 1). DSig achieves 2.5× and 6.9× higher throughput than EdDSA for signing and verifying. DSig benefits applications significantly. In HERD, Redis, and Liquibook, DSig brings auditability with an added latency of less than 8 µs per operation, a reduction of 86% in overhead compared to EdDSA. In CTB, DSig reduces the broadcast latency by 73%, from 123 µs to 34 µs. In uBFT, DSig reduces the replication latency by 69%, from 221 µs to 69 µs.

The price for using DSig is as follows. First, to get the best performance, DSig needs a priori knowledge of where and when signatures are verified (DSig still works without such knowledge, but it is slower). Second, DSig requires extra bandwidth and space to transmit and store its larger ≈1.5 KiB signatures. This is a small cost in data-center systems, which have low-latency high-bandwidth networks and abundant storage, but DSig could be ill-suited for other settings, such as some wide-area systems.

In summary, our contributions are the following:

- We propose DSig, a new digital signature system targeted at microsecond-scale applications in data centers. DSig combines hash-based signatures, traditional signatures, and novel techniques to reduce latency in the critical path while achieving high throughput.
- We analyze and evaluate DSig's large parameter space for low latency at high throughput, and identify a configuration that best fits most scenarios.
- We implement DSig and integrate it into several applications: two key-value stores, a financial trading system, BFT broadcast, and a BFT replication system.
- We evaluate DSig and its applications. DSig significantly improves signature performance compared to EdDSA, the state of the art. These enhancements directly benefit the applications by providing better end-to-end latency and throughput, and by bringing auditability to the microsecond scale.

DSig is open source, available at `https://github.com/LPD-EPFL/dsig`.

2 Setting and Goals

Setting. We target microsecond-scale applications [2, 3, 11, 19, 31, 41, 76, 80–82] with a few tens of servers within the same data center—a scale that addresses the computing needs of many enterprises. These systems have a network with low latency (≈1 µs) and high bandwidth (100s of Gbps or even Tbps [74]).

Goals. Our goal is to achieve faster digital signatures to broaden their usability. We do not seek general-purpose signatures for all settings (wide area networks, mobile networks, embedded systems), but rather seek schemes that provide the right trade-offs in modern data centers. We seek signatures that provide the industry-standard level of security (128 bits).

Digital signatures are important because they are *transferable*: if Alice signs a message to Bob, Bob can prove to Carol that Alice indeed signed it (§3). This property makes signatures more powerful than mechanisms such as SSL/TLS or MACs, which provide only symmetric authenticated channels between Alice and Bob [54], which do not suffice for the applications we consider (§6). Signatures help tackle distrustful parties in distributed protocols for a wide variety of use cases: securing transactions, enabling digital certificates, bootstrapping authentication of users and services [30, 89], verifying software authenticity [28, 57], providing integrity of audit logs [22, 71], tolerating Byzantine failures [4, 6, 18], etc. Many of these use cases apply to microsecond-scale applications, as such systems increasingly bring together mutually distrustful users on shared infrastructure [48, 88]. For example, microservices can benefit from Byzantine fault tolerance [3]; signed transactions can provide auditability in high-frequency trading systems; and signed logs can provide a legal trail in high-stakes settings.

Threat model. Our threat model is standard for digital signatures [54]. Malicious entities can intercept, store, inject, delay, and alter messages. We assume the security of standard cryptography building blocks: traditional digital signature schemes (Ed25519 [50]), hash-based signature schemes (W-OTS$^+$ [46] and HORS [84]), and cryptographic hashes (SHA256 [77], Haraka (v2) [55], and BLAKE3 [75]).

3 Background

3.1 Digital Signature Schemes

A digital signature scheme (DSS) has a key pair consisting of a public key *PK* and a secret key *SK*. A signer *s* uses *SK* to sign a message *m*, producing a signature σ for *m*. The signature σ allows a party who knows *PK* (and knows that *PK* belongs to *s*) to verify that *m* was signed by *s*.

DSSs provide *authenticity*, *integrity*, *public verifiability* and *non-repudiation* of messages [54]. Authenticity means that a party with a message and its signature can verify the identity of the message's signer. Integrity means that the party can verify that the message matches the message that was signed. Public verifiability means that only *m*, σ, and *PK* are needed to verify the authenticity and integrity of *m*. Signatures are transferable: a party can use σ and *m* to convince anyone who knows *PK* that *m* is authentic (and typically *PK* is published, so everyone knows *PK*). This property differentiates digital signatures from other mechanisms, such as message authentication codes (MACs), vectors of MACs, authenticated channels (e.g., SSL/TLS), and symmetric encryption (e.g., AES). Non-repudiation means that *s* cannot deny the signing of *m* once its signature σ is known. Non-repudiation implies that signatures are non-forgeable: without knowing *SK*, it is computationally infeasible to produce a signature σ which passes verification with *PK*.

3.2 The Cryptographic Barrier

After DSSs were proposed [33], many schemes followed: RSA [85], ECDSA [49], EdDSA [50], etc. These schemes rely on the hardness of certain problems (factoring, discrete logarithms) under sophisticated arithmetic (e.g., modular on elliptic curves). They seek to provide strong security and small time to sign and verify. For example, the state-of-the-art 128-bit-secure EdDSA takes 19 µs to sign and 36 µs to verify a small message on modern CPUs (Table 1).

State-of-the-art DSSs are too slow for modern data centers: even the fastest schemes are an order of magnitude slower than network latencies [17] due to the use of sophisticated arithmetic, which consumes CPU and cannot be parallelized. This slowness makes traditional DSSs prohibitive for distributed protocols, microservices, and applications that run at the microsecond scale, which need to check the signatures of messages before acting upon them. For example, signature-based BFT protocols must check signatures before taking safety-critical steps such as computing a quorum intersection, voting, vouching for a message, deciding on a majority value, etc; similarly, auditable applications must check signatures before executing requests to provide auditability (§6).

Signing or verifying messages in batches can improve the throughput of DSSs, but batching further increases latency and is thus ill-suited for latency-critical applications.

3.3 Hash-Based and Hybrid Signatures

Hash-based signature schemes (HBSSs) were proposed by Lamport [59]. They are DSSs that avoid advanced arithmetic by using only cryptographic hashes. Hashes are advantageous because they can be computed quickly: modern algorithms (e.g., Haraka [55] and BLAKE3 [75]) can hash a small message in less than 100 ns on modern CPUs. In some HBSSs (e.g., HORS [84], W-OTS$^+$ [46]), signature generation and verification execute at the microsecond scale, as they require few hash computations.

To explain HBSSs, we overview the HORS scheme (Figure 2), which, whilst simple, illustrates the key ideas of HBSSs. The secret key *SK* for signing is an array of *t* random secrets (*t* is a parameter), while the public key *PK* for verify-

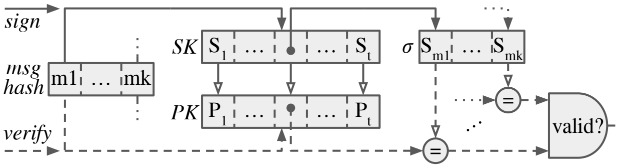

Figure 2: The HORS hash-based signature scheme. Solid lines convey the path taken to sign a message, while dashed lines convey the path to verify a signature. Hollow arrows indicate cryptographic hashes.

ing is the concatenation of the hash of each secret in SK. To sign a message, the signer hashes it with a salt into a string m, splits m into k substrings (k is a parameter), treats each substring as an index into SK, and concatenates the indexed secrets to obtain the signature σ. A verifier hashes the message with the salt and uses the substrings to index into PK. Then, the verifier hashes each secret in σ and checks that they match the indexed elements of PK. This scheme is secure because it is hard to (1) find messages that index the same secrets or (2) reveal secrets without being the signer. Other fast HBSSs, such as W-OTS$^+$ [46], are similar to HORS in that they sign by revealing a subset of the private key; as a result, they are limited to signing one or a few messages.

To overcome this limitation and sign an unlimited number of messages, hybrid signature schemes [37] combine HBSSs with traditional schemes. To sign a message m, a hybrid scheme concatenates an HBSS signature on m with the HBSS public key signed using a traditional signature. To verify a signature, the scheme verifies the HBSS signature of m and the traditional signature of the HBSS public key.

3.4 Challenges

Hybrid signatures were studied extensively in theory, but their application focused either on improving throughput in low-compute low-bandwidth devices, or on low-security signatures, or on tiny messages with only a few bits (§9). To use them in a high-performance data center setting, we must tackle several challenges.

Efficient signature verification. To verify a hybrid signature, we must check both its HBSS signature and its traditional signature. Traditional signatures, however, have high verification latency. We need new mechanisms to avoid the traditional signature verification in the critical path.

Frequent key generation. Because an HBSS key pair can be used only once or a few times, hybrid schemes need to frequently generate and sign new HBSS key pairs. This can become a bottleneck as it impairs signature throughput and, ultimately, its latency. We need new techniques to improve throughput while minimizing latency on the critical path.

Practical performance. We evaluate the performance of hybrid schemes and find that it does not match their theoretical analysis. The latter is based on simple metrics, namely the size of signatures and the number of hash calculations in the critical path. However, due to microarchitectural effects (e.g., CPU cache size, prefetching), optimal configurations in theory perform suboptimally in practice, and optimizations that target solely the theoretical metrics sometimes do not work.

Large parameter space. Hybrid signature schemes have many configuration options: the choice of the traditional scheme, choice of the HBSS, and their respective parameters. As a result, we are faced with thousands of options that provide different trade-offs in network bandwidth, computational resources, throughput, and latency characteristics.

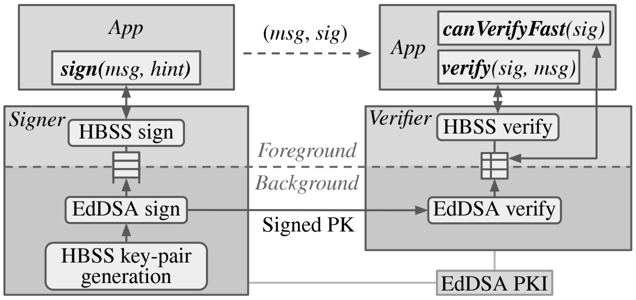

Figure 3: Architecture of DSig.

4 Design of DSig

We present the architecture of DSig (short for "Data center Signatures"), highlighting its extended interface and computing planes (§4.1). We then describe DSig's hybrid signature scheme (§4.2), its security (§4.3), and throughput optimizations (§4.4).

4.1 Architecture

Figure 3 depicts the architecture of DSig. Each process has a public-private key pair of a traditional signature scheme, where the public key is made available to other parties via a public key infrastructure (PKI). For the traditional signature scheme, we choose EdDSA [50] because it is the fastest such scheme [17]. The PKI can be as simple as an administrator pre-installing the keys, or it can be a full-fledged system.

DSig augments the interface of digital signatures (*sign* and *verify* functions) in two ways. First, *sign* takes a hint with the set of processes that will likely verify the signature. The hint is optional: if omitted, it defaults to all known processes. The hint does not restrict who can verify a signature—parties not indicated in the hint can still verify the signature, albeit at a lower performance. Second, a new *canVerifyFast* function returns whether verification of a given signature will be fast. This function can mitigate denial-of-service attacks by letting applications prioritize the handling of fast signatures (§6).

Internally, DSig has two planes: *foreground* and *background*. The foreground plane provides the user library with a synchronous API to sign and verify messages, while the background plane asynchronously pre-generates and propagates new HBSS keys to be used by the foreground plane. DSig's general design can be used with a wide range of HBSSs (e.g., Lamport's [59], HORS [84], W-OTS [34], W-OTS$^+$ [46]). We provide a specific recommendation based on an extensive performance study (§5).

Foreground plane. To sign a message, the signer uses a fresh HBSS key pair and returns to the application a DSig signature, which includes the resulting HBSS signature and the

Algorithm 1: Signers' Pseudocode

```
1  # Signer's setup
2  verifier_groups = { ... } # Provided
3  for group in verifier_groups:
4    signed_keypairs[group] = Queue()

6  # Signer's background plane
7  whenever $\exists$ group | signed_keypairs[group].size < $S$:
8    sk, pk = hbss.generate_keypair()
9    pk$_\sigma$ = {pk: pk, sig: eddsa.sign(pk)}
10   multicast <HBSS_PUBKEY, pk$_\sigma$> to group
11   signed_keypairs[group].push((sk, pk$_\sigma$))

13 # Signer's foreground plane
14 def sign(msg, hint):
15   group = smallest group containing hint
16   sk, pk$_\sigma$ = signed_keypairs[group].pop()
17   hbss_sig = hbss.sign(msg, sk)
18   return <SIG, hbss_sig, pk$_\sigma$>
```

Algorithm 2: Verifiers' Pseudocode

```
19 # Verifier's setup
20 verified_pks = Cache()

22 # Verifier's background plane
23 upon deliver <HBSS_PUBKEY, pk$_\sigma$> from process p:
24   if eddsa.verify(pk$_\sigma$, eddsa_pk_of(p)):
25     verified_pks.add((pk$_\sigma$, p))

27 # Verifier's foreground plane
28 def verify(msg, <SIG, hbss_sig, pk$_\sigma$>, p):
29   if (pk$_\sigma$, p) not in verified_pks:
30     if not eddsa.verify(pk$_\sigma$, eddsa_pk_of(p)): # Slow
31       return false
32   return hbss.verify(msg, hbss_sig, pk$_\sigma$.pk)

34 def canVerifyFast(<SIG, _, pk$_\sigma$>, p):
35   return (pk$_\sigma$, p) in verified_pks
```

corresponding HBSS public key signed with EdDSA. Signing with EdDSA is slow, so the HBSS public key is pre-signed in the background plane. On the other side, the verifier checks the authenticity of the message using the HBSS signature and the included HBSS public key. The authenticity of the HBSS public key is checked by the background plane.

Background plane. The signer generates HBSS key pairs and EdDSA-signs them before forwarding them to the foreground plane. It also sends the EdDSA-signed HBSS public keys to the background plane of the likely verifiers. The latter verifies the authenticity of the HBSS public keys.

The background plane hides the latency of two slow steps: (1) HBSS key pair generation, and (2) EdDSA-signing and EdDSA-verifying the HBSS public keys.

Note that DSig preserves the transferability of signatures irrespective of the background plane. Because DSig hybrid signatures are self-standing (as they include the EdDSA-signed HBSS public key), the only requirement for signature verification is knowledge of the signer's EdDSA public key. The background plane merely boosts performance when a hint is correct, by letting a verifier pre-check an HBSS public key before it receives a signature that includes it.

4.2 Signing and Verifying in DSig

The logic of a DSig signer is shown in Algorithm 1. Each signer is configured with a list of *verifier groups*—groups of processes that are likely to verify the same signatures on their critical path (line 2). This list has a default group that contains all the processes in the system, but is otherwise application-dependent. In the applications we examined (§6), the list was small and obvious (e.g., individual groups containing one process each). Each verifier group is associated with a key-pair queue (lines 3–4).

In the background plane, whenever a group's queue size is below a threshold S (line 7), the signer generates a new HBSS key pair (line 8), and signs the public key using EdDSA (line 9). Empirically, we found that S=512 works well while consuming only 3 MiB of memory per group. Then, the signer multicasts the signed public key to the processes in the group (line 10). The signer next appends the private key with the EdDSA-signed public key to the queue for consumption in the foreground plane (line 11).

To sign a message, the signer chooses the verifier group that matches the hint; if no group matches the hint, the signer picks the smallest group containing the hint (line 15). Then, it gets a new HBSS key pair from this group's queue (line 16). Next, the signer computes an HBSS signature of the message using the private key obtained from the queue (line 17). The DSig signature comprises the HBSS signature of the message together with its EdDSA-signed HBSS public key (line 18).

The logic of a DSig verifier is shown in Algorithm 2. In the background plane, the verifier receives EdDSA-signed HBSS public keys (line 23), which it verifies (line 24) and stores in a cache (line 25). In our applications, we found that having the cache store the latest $2{\times}S{=}1024$ HBSS public keys from each signer worked well while consuming only 100 KiB of memory per signer. In the foreground plane, the verifier first consults its cache to see if it has a verified entry for the HBSS public key (line 29). If so, the verifier proceeds with checking the HBSS signature using the HBSS public key. In this code path, the verifier checks signatures as fast as the underlying HBSS verify (line 32), which is fast. Otherwise, the verifier also checks the EdDSA signature of the HBSS public key (line 30), so the verifier can operate even without the background plane. The verifier's *canVerifyFast* function (§4.1) simply checks whether a signed HBSS public key has already been verified (lines 34–35).

As with other signature schemes, DSig can support key revocation through revocation lists that applications check prior to signing or verifying messages [54].

4.3 Security

For preciseness of argument, we show the security of our recommended DSig configuration, which uses W-OTS$^+$ [46] as its underlying HBSS (§5). Specifically, we show that this configuration of DSig is Existentially Unforgeable under Chosen-Message Attacks (EUF-CMA) [39] and that it provides 128-bit security, which is safe by today's standards [7].

EUF-CMA security. We consider Chosen-Message Attacks (CMA) in which the attacker can query the target to sign arbitrary messages. More precisely, we consider *adaptive* CMA in which the attacker can query the target based on public key(s) and previously obtained signatures. We consider Existential Unforgeability (EUF), which means it should be computationally infeasible for an attacker to forge a signature on any message, except for messages that have already been signed by the target.

DSig is as secure as its parts. To forge a signature in DSig, an attacker must find a combination of message (not previously signed), W-OTS$^+$ public key, EdDSA signature, and W-OTS$^+$ signature that passes the `verify` function (Algorithm 2). We assume that EdDSA provides EUF-CMA security, as proved by Brendel *et al.* [20], and show how DSig's security reduces to the security of W-OTS$^+$:

1. The verifier's background plane caches only correctly EdDSA-signed public keys (Alg. 2 lines 23–25). From the EUF-CMA security of EdDSA, and since a correct signer EdDSA-signs only its own public keys, (Alg. 1 lines 8–9), for any correct signer s, the verifier caches only the W-OTS$^+$ public keys s generates.

2. If a public key is not cached, the verifier EdDSA-verifies it on the critical path (Alg. 2 lines 29–31). As in (1) above, for any correct signer s, this verification only succeeds for public keys s generates. Thus, for any correct signer s, `verify` cannot return *true* for public keys s does not generate.

3. Since, for any correct signer s, an attacker can only use a W-OTS$^+$ public key generated by s, forging a DSig signature reduces to forging a W-OTS$^+$ signature.

W-OTS$^+$ with Haraka and BLAKE3. Hülsing proved that W-OTS$^+$ is EUF-CMA-secure when using a hash-function family that is second-preimage resistant, undetectable, and one-way [46]. Like SPHINCS+ [16], we pick the Haraka [55] hash-function family which satisfies those properties and relies on the battle-tested AES round function. Similarly to SPHINCS+, we reduce the signed messages to 128-bit digests by hashing them salted with the W-OTS$^+$ public key and a random nonce. We do so using the well-established BLAKE3 [75] hashes. Finally, we tune W-OTS$^+$'s parameters to provide 128 bits of security when signing said 128-bit digests. More precisely, we set the size of secrets and public key elements to 144 bits, which, together with a W-OTS$^+$ depth of 4 (§5), provides a security level of 133.9 bits [46].

DSig's security level. Breaking DSig can be reduced to breaking either EdDSA, W-OTS$^+$, Haraka, or BLAKE3. The EdDSA signature scheme Ed25519 provides 128-bit security under practical attacks [14], and our configuration of W-OTS$^+$ provides 133-bit security. The security of both Haraka and BLAKE3 relies on well-studied components [7, 55] and to date, no attack has compromised their security.

4.4 Optimizing Throughput

DSig has a few throughput optimizations that do not significantly impact latency.

Speeding up key pair generation. Generating an HBSS key pair requires producing hundreds to thousands of secrets for the private key, and then hashing each secret for the public key. To produce secrets quickly, DSig collects entropy from the hardware at startup to get a truly random 256-bit seed, which DSig then salts with the key index and hashes using BLAKE3 to generate a digest with the size of the private key. To produce the public key quickly, DSig hashes the secrets using Haraka, which has a high-throughput implementation that optimizes instruction pipelining to compute multiple hashes efficiently.

Amortizing the cost of EdDSA signatures. EdDSA-signing every HBSS public key is slow and becomes a throughput bottleneck as each EdDSA sign-verify computation takes ≈55 µs [17]. DSig EdDSA-signs batches of HBSS public keys [86]. However, batching naively would increase the size of signatures, since the entire batch of HBSS public keys should be included in every DSig signature to make their EdDSA signature self-standing. DSig addresses this issue by arranging the batch of HBSS public keys into a Merkle tree [67] and EdDSA-signing its root. As a result, a DSig signature is composed of an HBSS signature, an HBSS public key, a Merkle inclusion proof, and the EdDSA signature of the Merkle root. The Merkle proof is a space-efficient way of proving that the included HBSS public key is part of the EdDSA-signed batch. As Merkle proofs require collision-resistant hashes, we use (the efficient) BLAKE3. The space efficiency of Merkle proofs comes at the computational cost of generating and verifying them. DSig moves most of this cost to the background plane of both signers and verifiers, which precompute and cache the full Merkle tree associated with a batch. Then, on the critical path, signing a key merely requires copying the subset of the tree that constitutes the Merkle proof, while verifying the Merkle proof consists of simple string comparisons. The efficiency of this scheme depends on the batch size, which we determine in §8.7.

Speeding up bulk verification. Verifying many signatures with no assistance from the background plane (e.g., when checking an audit log) requires checking the same EdDSA signatures many times. To speed up this process, EdDSA signatures verified in the foreground plane are cached. A cache entry takes only ≈33 bytes, a tiny overhead, but saves ≈36 µs of computation on our hardware (Table 3).

Reducing background bandwidth. Sending signed public keys both ahead of time and within signatures consumes significant networking bandwidth. To nearly halve the bandwidth usage, DSig batches, EdDSA-signs, and sends only BLAKE3 digests of the public keys in the background plane. This optimization requires computing the public key digest during signature verification, which adds only ≈1.3 µs of latency.

5 Choice of HBSS

DSig can be used with many HBSSs, but its performance heavily depends on the actual HBSS used and how this HBSS is configured. In this section, we explain which HBSS we choose for DSig and how we configure it.

5.1 HBSS Requirements

Our choice of HBSS is guided by the following requirements.

Security. To provide 128-bit security, DSig needs an HBSS with the same or stronger security.

Low sign and verify latency. DSig executes HBSS *sign* and *verify* operations on the critical path. These operations must have microsecond-scale latency. This latency depends on the choice of the hash function, on the number of hashes they involve, and on microarchitectural effects.

Short signatures. At the microsecond scale, signatures cannot exceed a few KiB in length, as larger signatures incur significant transmission latency: we experimentally find that when sending small messages each extra KiB takes approximately an extra microsecond on a 100 Gbps network. Furthermore, large signatures significantly increase the bandwidth consumption when applications send small messages.

Compressible public keys. Recall that DSig signatures must include an HBSS public key in order to be self-standing (§4.2). However, the combination of an HBSS signature and its public key can be in the KiB range, which is undesirable. We thus seek HBSSs for which this combination can be compressed, leading to smaller DSig signatures.

Lightweight key generation. HBSS key generation mainly involves hash computations, the number of which depends on the HBSS and can bottleneck DSig's throughput. HBSS that use few hashes for key generation are thus desirable.

5.2 Analysis

HBSSs can be grouped in two classes: HBSSs with keys that can sign only one or a few messages [34, 46, 59, 84], and HBSSs with keys that can sign many messages [9, 15, 16, 21, 47, 58]. Only the first class provides low latency (the second focuses on quantum resistance). Within that class, we focus on the fastest HBSSs: HORS [84] and W-OTS$^+$ [46].

HORS. Recall that a HORS signature reveals a subset of its private key secrets determined by the message being signed (§3.3). Verifying a signature requires hashing the revealed secrets, checking that they match the public key, and checking that all the secrets mandated by the signed message were revealed. HORS has two parameters: the number k of secrets revealed in a signature and the number of times r that a key pair can be used. The size of HORS keys is proportional to r, so picking $r \geq 2$ presents no benefits and we set $r=1$. Smaller values of k, however, lead to fewer hash computations, and thus to lower latency in theory, but they require larger HORS public keys for the same security level. Large HORS public keys require compression to fit our signature size budget. We thus devise two compression techniques, described next.

The first technique shortens the embedded HORS public key by removing the elements that can be deduced from the HORS signature (top of Figure 4). We analyze this approach in the first part of Table 2, which shows that configurations with few hashes ($k<32$) have large signatures (tens of KiB) that exceed our budget.

To use HORS signatures with small k while staying within our signature size budget, we devise another compression technique inspired by SPHINCS [15]. This technique is based on the observation that verifying a HORS signature merely requires checking that the few revealed secrets match the public key; knowledge of the full public key is unnecessary. We enable such checks using Merkle inclusion proofs: we arrange all public key elements in a Merkle forest, and EdDSA-sign its roots. Such DSig signatures replace their HORS public

Table 2: Analytical comparison of a DSig signature using either HORS or W-OTS$^+$ as its HBSS for various configurations with EdDSA batches of 128 public keys.

Conf	# Critical Hashes	Signature Size (B)	# BG Hashes	BG Traffic (B/Verifier)
Using HORS with factorized PKs				
k=8	8	8Mi	512Ki	33
k=16	16	64Ki	4Ki	33
k=32	32	8,552	512	33
k=64	64	4,456	256	33
Using HORS with merklified PKs				
k=8	8	4,712	1Mi	8Mi
k=16	16	4,968	8Ki	64Ki
k=32	32	5,480	1Ki	8Ki
k=64	64	6,504	510	4Ki
Using W-OTS$^+$				
d=2	≈68	2,808	136	33
d=4	≈102	1,584	204	33
d=8	≈161	1,188	322	33
d=16	≈263	990	525	33
d=32	≈434	864	868	33

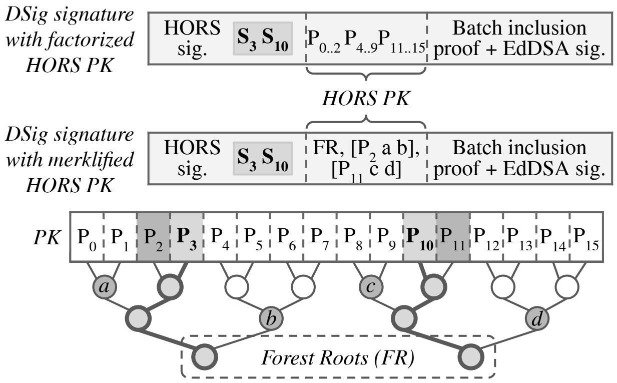

Figure 4: DSig signatures when using HORS with either factorized or merklified public keys. For illustration purposes, we depict a toy configuration of HORS with 2-secret signatures and 16-element keys.

Figure 5: Layout of DSig signatures when using W-OTS$^+$.

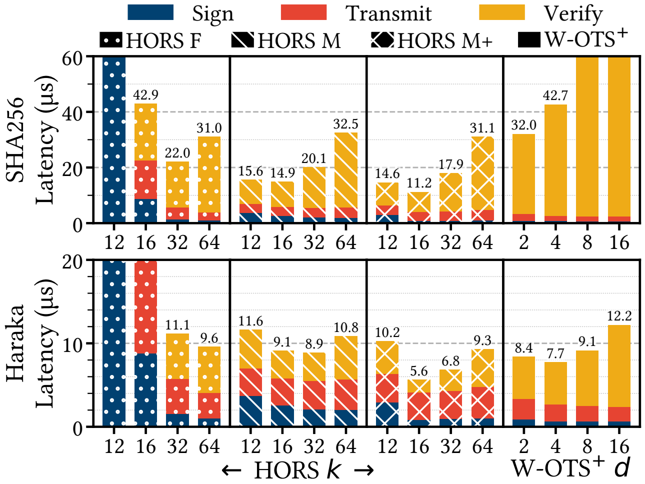

Figure 6: Sign-transmit-verify latency of DSig for 8 B messages using different hashing schemes (SHA256 (top) and Haraka (bottom)), and different HBSS configurations: HORS with factorized PK (HORS F), HORS with merklified PK (HORS M) and prefetched keys (HORS M+), and W-OTS$^+$.

key with the forest roots and the inclusion proofs of the revealed secrets (bottom of Figure 4). To avoid the overhead of checking Merkle proofs (i.e., computing around a hundred BLAKE3 hashes) on the critical path, we use a latency-hiding technique similar to the one in §4.4: signers send their complete public keys ahead of time to verifiers (by disabling background bandwidth reduction (§4.4)); verifiers precompute Merkle forests in their background plane, so Merkle proof verification on the critical path becomes mere string comparisons. We analyze this approach in the second part of Table 2, which shows that configurations with very few hashes ($k\leq16$) have tractable signature sizes, but come at the expense of significant background traffic and many background hashes.

W-OTS$^+$. W-OTS$^+$ differs from HORS in two main ways. First, W-OTS$^+$ secrets are hashed $d-1$ times to obtain the public key, where d is a depth parameter. Second, to sign, each secret is hashed a different number of times, as determined by the message to be signed, before being included in the signature. We lower sign latency by caching these hashes upon computation of the public key so that signing reduces to string copying. To verify a signature, we hash each element the required number of times to get to depth d, as determined by the signed message, and verify that the obtained results match the public key. Note that W-OTS$^+$ does not require embedding the public key in the DSig signature (Figure 5). A downside of W-OTS$^+$ versus HORS is that W-OTS$^+$ needs many more hashes on the critical path.

We analyze W-OTS$^+$ within DSig in the last part of Table 2, which shows that W-OTS$^+$ configurations with small d satisfy our requirements regarding signature size, background processing, and bandwidth consumption. Moreover, although they all require more hashes than HORS on the critical path, their signatures are smaller than the smallest HORS ones. Note that as d gets bigger, the gain in signature size is outweighed by the drastic increase in hash computations.

Conclusion. Our analysis points to three general configurations for further experimental evaluation: (1) HORS with factorized PK and k close to 64, (2) HORS with merklified PK and k close to 16, and (3) W-OTS$^+$ with d close to 4.

5.3 Evaluation

We measure the latency of signing an 8 B message, transmitting it along with its DSig signature, and verifying the signature for the sensible HBSS configurations presented in §5.2. Our experimental setup is detailed in §8. We consider three hash functions: SHA256 [77] (the slowest), BLAKE3 [75], and Haraka [55] (the fastest). Figure 6 shows the results for SHA256 and Haraka (BLAKE3 stands in between).

When using Haraka (bottom of Figure 6), HORS with factorized public keys (denoted *HORS F*) achieves its best end-to-end latency for k=64. For k<64, its latency increases in spite of having fewer hashes on the critical path due to the transmission time of larger signatures.

Surprisingly, HORS with merklified public keys (*HORS M*) signs and verifies only marginally faster despite its far lower number of hashes. This disappointing performance is a microarchitectural effect of the size of the Merkle forests. Indeed, for the assembly and verification of precomputed Merkle proofs to be fast, the relevant elements of their associated Merkle forest should be present in local cache (L1/L2).

However, CPU prefetching is inefficient due to the inherent randomness of Merkle proofs.

To demonstrate the benefit of having the Merkle proofs in the local cache, we modify DSig to prefetch public and private keys into the processor cache right before signing and verifying. The modified system (*HORS M+*) achieves an end-to-end latency of as little as 5.6 µs (signing in 0.9 µs, verifying in 1.5 µs and transmitting in 3.3 µs) for k=16. For smaller k, the keys do not entirely fit in the local cache, hence the performance degradation.

W-OTS$^+$ achieves its best latency of 7.7 µs for d=4 (signing in 0.7 µs, verifying in 5.1 µs and transmitting in 2.0 µs) where it strikes a good balance between few hashes (low d) and short signatures (high d). We omit prefetching W-OTS$^+$ keys, as it has negligible latency benefit (not shown).

When using SHA256 (a slower hash function, top of Figure 6), HORS with factorized public keys (HORS F) sees its verification time vastly increase for large k, while small k still has long transmission time. HORS with merklified public keys (HORS M) has better latency for smaller k, which differs from HORS M with Haraka. Indeed, it is preferable to have fewer SHA256 computations (small k) than smaller Merkle forests (large k) since SHA256 is considerably more expensive than cache misses, which is not the case of Haraka. Finally, the large number of hashes (68 in expectation) of W-OTS$^+$ makes it perform worse than the best configuration of each presented HORS variant.

5.4 Recommended Configuration

From our analytical (§5.2) and experimental (§5.3) studies, we recommend using W-OTS$^+$ with d=4 and Haraka. This configuration offers single-digit sign-transmit-verify latency, tractable 1,584 B signatures, and requires little background computation and networking. Although HORS with merklified keys can achieve lower latency, it is too costly (in compute, bandwidth, and CPU cache pollution) and its superior performance requires modifying applications to prefetch keys into the processor cache, which can be impractical. Note, however, that the choice of HBSS depends on the relative performance of hardware and software: in the future, if cache misses become cheaper and hashing becomes relatively more expensive, low-k HORS configurations could be appealing.

6 Applications

We apply DSig to key-value stores, a financial trading system, BFT broadcast, and BFT replication.

Key-value stores (HERD [51] and Redis [87]). State-of-the-art key-value stores provide microsecond-level performance and form the backbone of many data center applications, microservices, and cloud services. Key-value stores are used to keep security-sensitive information such as service configuration, session management data, cached queries, access control data, chat sessions, etc. Yet, most key-value stores lack *auditability*—the ability for a third-party to check a log of all operations (reads and writes) executed on the key-value store. More precisely, in an auditable key-value store, the server keeps a log of executed operation such that, for any operation *op* in the log, the server can prove to a third party that *op*'s client requested its execution. For example, the third party may be a forensics specialist or a prosecutor, who wants proof that a client requested access or modification to some data. The threat model is that clients may wish to bypass the audit (i.e., execute an operation undetected), while the server is honest. The proofs provided by the server are operations signed by clients and the key-value store must ensure that (a) if an operation signed by client C is in the audit log, then it was executed by the key-value store for client C, and (b) if an operation is executed by the key-value store for client C, then it appears in the audit log as an operation signed by C.

To provide auditability, a key-value store requires all requests to be signed by clients and logged by the server. The server must check the client signature before executing a request (otherwise a client could send a request with a bogus signature, which the server would execute without later being able to prove it), so traditional digital signatures significantly increase the latency of microsecond-scale key-value stores.

We use DSig to add auditability to two key-value stores: HERD and Redis. HERD is highly optimized for the RDMA networks present in data centers, while Redis is popular among web application developers. HERD provides simple `GET` and `PUT` operations on key-value pairs, while Redis also provides higher-level operations on common data structures, such as lists, maps, sets, etc. We modify both systems so that clients use DSig to sign all operations, and servers log and verify the signed operations before executing them. This logging requires 1.5 KiB of storage per operation due to DSig's signatures. Key-value stores have predictable signing and verifying processes: clients simply set their signatures hints to the server process. Logs can be persisted at the microsecond scale using persistent memory. This is not currently implemented due to lack of hardware, but data from Yang *et al.* [91] indicate that persistence would take less than 4 µs, and this latency can be masked by storing in parallel with signature verification. Vanilla HERD takes ≈2.5 µs to `GET` or `PUT` a key-value pair, while vanilla Redis takes ≈12 µs.

Financial trading system (Liquibook [73]). Liquibook provides an order-matching engine for financial trading—it matches buy and sell limit orders from clients. We consider a trading system built using Liquibook and RDMA for fast client-server communication. We use DSig to enhance the system and provide auditability, as we did for key-value stores. Signature hints are identical to key-value stores. Without auditability, the trading system takes ≈3.6 µs to process orders, of which ≈2 µs are spent on communication.

BFT broadcast (CTB [3]). Byzantine Fault Tolerance (BFT) is becoming more relevant in data centers, due to the need

Table 3: Configuration details of machines.

CPU	2× 8c/16t Intel Xeon Gold 6244 @ 3.60GHz
NIC/Switch	Mlnx CX-6 MT28908 / MSB7700 EDR 100 Gbps
Software	Linux 5.4.0-167-generic / Mlnx OFED 5.3-1.0.0.1

to tolerate failures beyond simple crashes [42, 44, 45, 69, 70]. Consistent broadcast is a core BFT primitive that prevents equivocation [23] and has many uses, as in money transfer [27, 40], consensus [1, 13, 25], multi-party computation [10] and decentralized learning [35, 38] protocols. We consider uBFT's state-of-the-art implementation of Consistent Tail Broadcast (CTB) and replace its signatures with DSig's to improve performance. Signing hints are simple, as each signature is verified by all processes running the protocol.

BFT replication (uBFT [3]). State machine replication (SMR) is the standard approach for fault-tolerance [2, 18, 66]. We consider uBFT, a microsecond-scale BFT SMR system for data centers. BFT SMR protocols, including uBFT, often employ signed messages to guard against Byzantine replicas. uBFT recognizes the high cost of digital signatures and follows a fast/slow path approach. The fast path avoids signatures and has a latency of 5 µs. The slow path uses signatures, with a latency of ≈220 µs. The slow path is triggered even without Byzantine behavior (e.g., due to process slowness), leading to latency fluctuations between its two modes of operation. We use DSig to replace the digital signatures in uBFT and improve its performance. Signing hints are simple, as each signature is verified by all processes running the protocol. Moreover, we use DSig's DoS-mitigation mechanism (§4) to prevent a malicious attack from triggering superfluous EdDSA verifications. More precisely, because uBFT is a quorum system, it can make progress with $n-f$ responses (n is the number of replicas, f is the maximum number that can be Byzantine). We make a small modification to uBFT to use the *canVerifyFast* function to prioritize handling of messages that do not incur the EdDSA signature check. As a process gets at least $n-f$ messages from non-Byzantine processes, it ignores the slow-to-check messages from Byzantine players.

7 Implementation

Our implementation of DSig has 3,019 lines of C++17 (CLOC [32]). We use our own implementation of HORS [84] and W-OTS$^+$ [46], the official implementations of BLAKE3 [75] and Haraka [55], and Dalek's implementation of EdDSA (Ed25519 [65]). BLAKE3 and Dalek's EdDSA use AVX2 for high performance. We use uBFT's framework [3], which provides fast point-to-point communication.

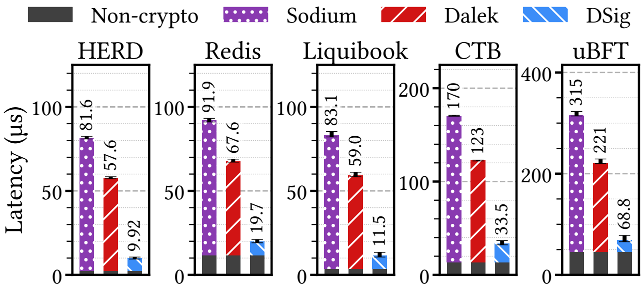

Figure 7: End-to-end latency of different applications using Sodium, Dalek or DSig for signatures. Printed values show the median latency; whiskers show the 10th and 90th %-iles.

8 Evaluation

We evaluate the performance of DSig and verify its suitability as a microsecond-scale signature system. We aim to answer the following:

- How do microsecond-scale applications that use signatures benefit from DSig's low latency (§8.1)?
- How does DSig's signing and verification latency compare to traditional signatures (§8.2, §8.3)?
- What is the throughput of DSig (§8.4)?
- How do DSig's higher bandwidth requirements impact its scalability (§8.5, §8.6)?
- How do we set DSig's EdDSA batch size (§8.7)?

Testbed. Our testbed is a cluster with 4 servers configured as shown in Table 3. The dual-socket machines have an RDMA NIC attached to the first socket. Our experiments execute on cores of the first socket using local NUMA memory. We accurately measure time using the TSC [43] via `clock_gettime` with the `CLOCK_MONOTONIC` parameter.

DSig configuration. We configure DSig per §5: in all experiments, we use W-OTS$^+$ with a depth d=4 as its HBSS. We dedicate a single core to DSig's background plane, which provides a high-enough throughput for our applications (§8.4). Unless specified otherwise, we use an EdDSA batch size of 128 (§8.7) and provide correct verifier hints when signing.

Baselines. We compare DSig against two well-known signature libraries: Sodium [8] (written in C) and Dalek [65] (written in Rust). Both implement the EdDSA signature scheme Ed25519—the fastest traditional scheme to date [17].

8.1 Application Latency

We configure applications with different signature schemes (Sodium, Dalek, DSig) and measure their latency. For the key-value stores, we use 16 B keys and 32 B values, 20% of `PUT` requests and 80% of `GET`s, where 90% of `GET`s return a value. For Liquibook, 50% of the requests are `SELL`s and 50% are `BUY`s. For CTB, we broadcast 8 B messages. Finally, for

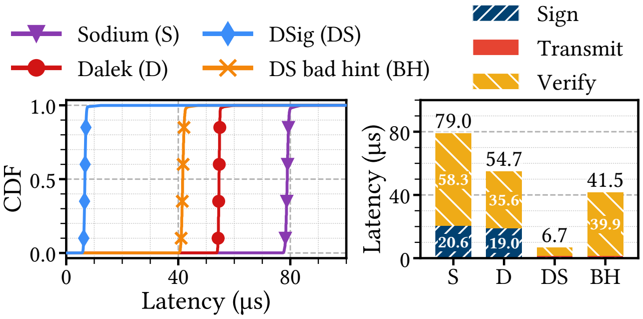

Figure 8: (Left) CDF of latency when signing, transmitting, and verifying the signature of 8 B messages using Sodium, Dalek and DSig with/without correct hints. (Right) Median latency breakdown. Transmission overhead is barely visible.

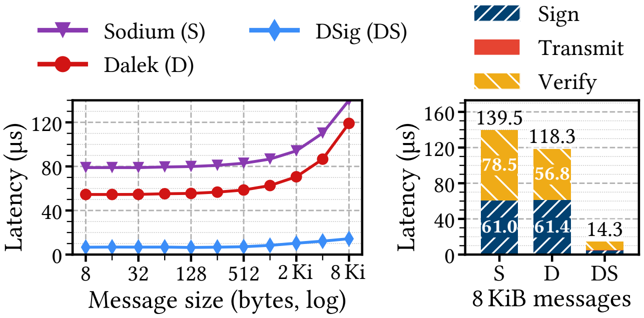

Figure 9: (Left) Latency to sign, transmit, and verify the signature of various-size messages using Sodium, Dalek and DSig with correct hints. (Right) Median latency breakdown for 8 KiB messages. Transmission overhead is invisible.

uBFT, we consider SMR operations of 8 B. We issue 10,000 requests one at a time to each application, measure the end-to-end latency, and report the 10th-, 50th-, and 90th-percentiles.

Figure 7 shows the results. For the three applications on the left, DSig provides auditability for a small cost: an increase of less than 7.9 µs in end-to-end latency. Sodium and Dalek add ≈79 µs and ≈55 µs, respectively, which is 10× and 7.0× DSig's overhead. In CTB, replacing Sodium (resp. Dalek) with DSig reduces the median cryptographic overhead by 87% (resp. 82%), and reduces the median end-to-end latency by 80% (resp. 73%). In uBFT, DSig reduces the median cryptographic overhead by 91% (resp. 87%), and reduces the median end-to-end latency by 78% (resp. 69%) compared to Sodium (resp. Dalek). DSig provides similar latency gains at the 90th percentile. In summary, across the tested applications, DSig significantly reduces cryptographic overheads and improves latency over the state of the art.

8.2 Latency of DSig

We study the latency to sign a message, transmit a signature, and verify a signature using DSig. We also consider the latency of incorrectly hinted DSig signatures for which EdDSA signatures are verified on the critical path. This represents the worst-case scenario for DSig. In each experiment, a process signs an 8 B message and transmits the signed message to a second process, which verifies the signature. We run each experiment 10,000 times for each signature scheme. The signature transmission latency is the incremental cost of adding the signature to a message, computed as the difference between transmitting a message with and without a signature. We estimate message transmission time as half of the round-trip time for ping-ponging the message.

Figure 8 shows the results. All signature schemes have stable latency up to the 99.9th percentile. Sodium and Dalek have similar signing median latency of 20.6 µs and 18.9 µs, respectively. While Sodium verifies in 58.3 µs, Dalek verifies in only 35.6 µs (39% faster) thanks to the use of AVX2 instructions. The (incremental) network latency is less than 100 ns for both since their signatures are merely 64 B. With correct hints, DSig takes 0.7 µs to sign and 5.1 µs to verify. This is 27× and 7.0× faster than Dalek, respectively. Interestingly, even though DSig's larger signatures lead to a 1.0 µs transmission overhead (more than 10× Dalek's), it has limited impact on its latency which is dominated by verification. Overall, DSig is 8.2× faster than Dalek. With incorrect hints, DSig's signature verification requires verifying both HBSS and EdDSA signatures, so verification latency increases to 39.9 µs (4.3 µs more than Dalek's). Signature generation, however, is not impacted as signers still benefit from background EdDSA precomputation and the total latency, although rising to 41.5 µs, is still 24% lower than Dalek's. Even with incorrect hints, DSig has much lower combined sign-transmit-verify latency than the state of the art.

8.3 Effect of Message Size on Latency

We study the effect of message size on the latency of DSig by running the experiments of §8.2 with varying message sizes.

Figure 9 (left) shows the results. With larger messages, DSig's total latency increases gradually but remains below 15 µs. Sodium's and Dalek's latencies are much higher. They also increase faster because they use a slower hash function than DSig (SHA256).[1] Figure 9 (right) shows the latency breakdown for the largest size (the breakdown for the smallest size is in §8.2). In all schemes, the split is about half-half to sign and verify, with negligible transmission time.

8.4 Throughput

We study DSig's throughput. In an experiment, a process signs small 8 B messages repeatedly with either a constant or

[1] Most signature schemes hash the input to operate on a fixed-size string.

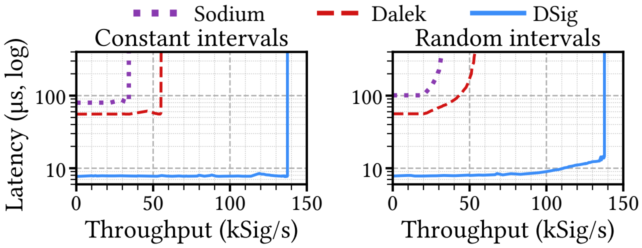

Figure 10: Latency-throughput graphs for Sodium, Dalek and DSig. Signatures are issued at constant or exponentially distributed intervals. All three use two cores on both sides; DSig dedicates one of them to its background plane.

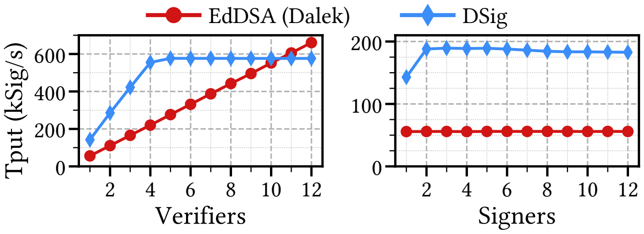

Figure 11: (Left) DSig's throughput with a signer sending the same signature to multiple verifiers. (Right) DSig's throughput with a verifier receiving different signatures from multiple signers. The NICs' bandwidth is limited to 10 Gbps.

an exponentially distributed random interval between signatures. The signer transmits the signature over the network to the verifier, which verifies it. We measure the total latency (sign plus transmit plus verify) and throughput of DSig, and compare it against Sodium's and Dalek's. In all experiments, the signer and the verifier use two cores each. DSig dedicates one core to each of its planes so that background events minimally impact foreground operations, while Sodium and Dalek use all cores to handle multiple messages in parallel.

Figure 10 shows the results as latency-throughput graphs with median latency and average throughput. With constant signature interval, all three systems exhibit stable latency until reaching maximum throughput. Sodium maintains a latency of ≈80 µs up to a throughput of 34 kSig/s where it is bottlenecked by verification time (58 µs). Dalek maintains a latency of ≈56 µs up to a throughput of 56 kSig/s where it is also bottlenecked by verification time (36 µs). DSig maintains a latency of ≈7.8 µs up to a throughput of 137 kSig/s where it is bottlenecked by the signer's background plane, which takes 7.4 µs to generate a new public key. We separately measured the verifier's background plane; it achieves a throughput of 3.6 MSig/s, so it is not a bottleneck. With a random signing interval, queuing occurs gradually, so the respective bottlenecks are less abrupt, causing a smoother latency degradation.

We run another experiment to measure the per-core throughput of DSig by running both of its planes on one core, and compare it to the per-core throughput of Dalek. While Dalek achieves 53 kSig/s signature generations (resp. 28 kSig/s verifications) per core, DSig achieves 131 kSig/s signature generations (resp. 193 kSig/s verifications) per core.

In summary, DSig sustains significantly higher throughput at much lower latency than EdDSA-based systems.

8.5 One-to-Many, Many-to-One Performance

We now study DSig's scalability and bottlenecks in one-to-many and many-to-one scenarios. In *one-to-many*, one signer signs a message and sends the signature to many verifiers; this pattern is common in distributed protocols. In *many-to-one*, many signers sign different messages and send them to the same verifier; this pattern is common in client-server applications. We run experiments where the signer(s) and verifier(s) use one foreground and one background core to work as fast as possible. We measure the aggregate verification throughput, and report the average. We consider a scenario where most of the network bandwidth (≈90%) is consumed by other activities, by limiting our NICs' bandwidth to 10 Gbps. This of course makes it harder for DSig to operate since it consumes more network bandwidth than other schemes. We compare the scalability of DSig to a two-core system based on Dalek.

Figure 11 shows the results. In one-to-many (left of figure), DSig's throughput increases until 577 kSig/s with 5 verifiers; at this point, the signer saturates its link to the verifiers, with the 1,584 B signatures and their 33 B background data accounting for ≈7 Gbps. Dalek scales more slowly than DSig with the number of verifiers, but it is not affected by bandwidth, as it continues to scale beyond 11 verifiers, at which point it surpasses DSig's throughput with 603 kSig/s using merely ≈300 Mbps to transmit 64 B signatures.

In many-to-one (right of figure), two signers are enough to achieve DSig's maximum throughput of 190 kSig/s as they saturate the verifier's foreground plane, which we set to run on a single core. As signing with Dalek is faster than verifying, Dalek does not scale beyond 1 verifier and achieves a maximum throughput of 53 kSig/s.

Overall, DSig's main scalability bottleneck compared to Dalek is its larger signatures.

8.6 Effect of Larger Signatures

We study how DSig's larger signatures affect application performance. In each experiment, we run a synthetic application where a server receives signed requests of a given size, checks their signature, spends some given processing time, and sends a 16 B unsigned reply. Similarly to §8.5, we limit the NICs' bandwidth to 10 Gbps, and compare the same application when using DSig or EdDSA. For fairness, EdDSA uses Dalek and pre-hashes messages with BLAKE3. In addition, we run an experiment with signatures disabled. The application runs with 4 cores: DSig uses 1 core for the background plane and

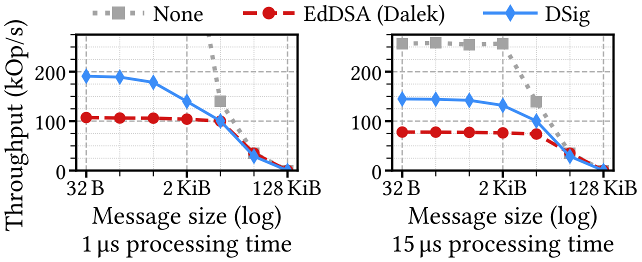

Figure 12: Request throughput of an application using signatures when NICs' bandwidth is constrained to 10 Gbps, for different request sizes and request processing times.

3 cores to handle requests, while the others use 4 cores to handle requests. We run enough clients to saturate the server. We consider 7 request sizes (32 B, 128 B, 512 B, 2 KiB, 8 KiB, 32 KiB and 128 KiB) and 2 processing times (1 µs and 15 µs).

Figure 12 shows the results. For both processing times, DSig outperforms EdDSA up to 8 KiB, after which it performs similarly to EdDSA. For small messages (32 B–512 B), the limited bandwidth has no impact on either scheme, so DSig significantly outperforms EdDSA thanks to its lower computational cost. With 2 KiB messages and 1 µs processing time, bandwidth impacts DSig while EdDSA is almost unaffected. Relative to 512 B messages, DSig's throughput decreases by 22%, while EdDSA's decreases by only 1.9%. Higher processing time offsets DSig's bandwidth bottleneck closer to 8 KiB messages. Beyond these points, the throughput of both DSig and EdDSA converges to that of the application that does not use signatures, as network bandwidth bottlenecks all three systems, making the overhead of signatures negligible.

In summary, DSig's higher per-core throughput lets applications reach higher throughput than with EdDSA even with limited network bandwidth, up to moderate-size messages.

8.7 EdDSA Batch Size

To set the size of EdDSA-signed key batches (§4.4), we run the same experiment as in §8.2 for different batch sizes, and we measure the latency and the per-core throughput. To take into account the impact of larger batches on low-end networks, we limit our NICs' bandwidth to 10 Gbps, as in §8.5 and §8.6.

Figure 13 shows the results, where a batch size of 1 means no batching. We see that batch sizes do not affect latency much (left of figure).[2] Throughput is different (right of figure): initially, batching improves throughput a lot for both signing and verifying. The gain dwindles when the amortized EdDSA cost per signature becomes a diminishing fraction of the overall computation as batches get larger. The best signing throughput is 135 kSig/s for batches of 32 keys, while the best verifying throughput is 206 kSig/s for batches of 4,096 keys. We pick a batch size of 128 as a balance.

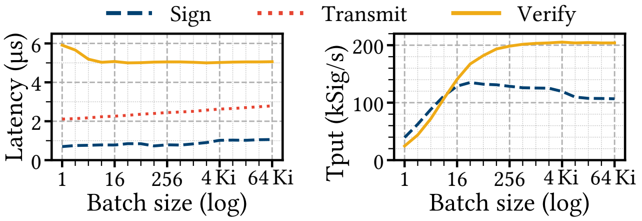

Figure 13: (Left) Median latency to sign, transmit, and verify a signature on an 8 B message with DSig for different EdDSA batch sizes. (Right) Single-core throughput of signing and verifying for different EdDSA batch sizes.

9 Related Work

HBSSs. HBSSs are well studied and prior work has proposed different implementations of them, many of which are variants of HORS [60,63,72,90]. Li *et al.* [63] proposed a variant targeted at smart grids with limited storage that reduces key and signature size but increases computation costs. Wang *et al.* [90] proposed a scheme with small signatures and microsecond performance, but it is limited to providing low ≈ 50-bit security. HORSE [72] reduces the cost of few-time signatures by repeatedly hashing the private key secrets, creating a matrix whose last row is the public key; however, it restricts the order in which applications can reveal public keys. W-OTS$^+$ [46] was proposed by Hülsing as a variant of W-OTS [34] with reduced signature and key sizes.

Online/offline signature schemes. The concept of online/offline digital signatures, in which heavy computation is done prior to knowing the message to sign, was first introduced by Even *et al.* [37]. So far, practical applications of the theoretical concept (including hybrid signature schemes) have targeted low-compute devices and/or wide area networks, with a focus on improving signature throughput or reducing bandwidth [53,62,64,78,92,93]. Recently, Esiner *et al.* [36] also recognized the importance of low-latency signatures, yet their solution is tailored for industrial control systems with tiny messages (25 bits), and does not provide self-standing signatures. No prior work addresses hybrid signatures in data centers with microsecond-scale performance.

Merkle-based signatures. Prior work proposes schemes that rely exclusively on HBSSs to sign (virtually) infinitely many messages, with the goal of attaining quantum resistance. Most of this work is based on XMSS [21], such as SPHINCS [15] and variants [16,47,58]. Instead of distributing keys regularly, these schemes efficiently pack an infinitude of one-time public keys using Merkle inclusion proofs [68]. These proofs need to be checked during signature verification, thus making the performance of such schemes be in the milliseconds.

Signature-like schemes. The cost of signatures has fueled alternatives for different scenarios. Message authentication codes (MACs) provide authentication and integrity of mes-

[2] The transmission latency differs from §8.2 due to the 10 Gbps NIC limit.

sages, but lack transferability, as parties use a shared secret to communicate. While MACs are widely used in networked systems to provide authenticated channels between two parties, they are not substitutes for signatures, as they provide weaker properties, they are harder to use, and they are more susceptible to protocol mistakes. In particular, using MAC-based mechanisms in BFT protocols has several drawbacks: (1) These mechanisms are ad-hoc and highly dependent on the protocol: some require MAC vectors [24] others require MAC matrices [5]; others explicitly prefer or mandate signatures over MACs for critical messages [3,4,26]. (2) These mechanisms add complexity to the BFT protocols, e.g., by requiring a fast-slow path approach where the fast path avoids signatures but the slow path (or view change) still uses them [3,4,24,26,29,56]; this added complexity increases their attack surface [26]. (3) These mechanisms often add messages and roundtrips to the protocols [5,29,79], and/or lower their resilience to failures [5,79].

Some systems make extra assumptions to provide MAC with some form of transferability. TESLA [79] assumes clock synchrony and has time windows during which MACs are generated and transmitted; afterward, the MAC secrets are revealed to check previously seen MACs. This idea provides only a limited form of transferability and increases the latency of verification. Using trusted hardware [12, 52, 61], such as trusted execution environments (TEEs), one can provide MACs with transferability by hiding the secret and computing the MACs in the TEE so that every TEE owner can verify the MACs but only a designated TEE can create them.

10 Conclusion

DSig is the first digital signature system for microsecond-scale applications. DSig achieves single-digit microsecond latency for signing and verifying messages—27× and 7× faster than the prior state of the art—while achieving higher throughput. To achieve that, DSig introduces a new hybrid signature scheme that uses knowledge of where signatures are issued and verified in the common case. DSig can bring auditability to latency-critical applications with a small latency overhead, or replace other signature schemes in applications that use them. Ultimately, we believe that DSig makes digital signatures fast enough to broaden their use in data centers as a powerful security building block.

Acknowledgments

We thank the anonymous reviewers and our shepherd Steve Hand for their valuable comments, as well as the anonymous artifact evaluators for reviewing our implementation. We also thank Dariia Kharytonova, Ed Bugnion, Jean-Philippe Aumasson, Khashayar Barooti, Phillip Gajland, Pierre-Louis Roman, and Serge Vaudenay for their feedback.

Abstract

In this paper, we focus on building a ransomware detection and recovery system for cloud block stores. We start by discussing the possibility of directly using existing methods or porting one to our scenario with modifications. These attempts, though failed, led us to identify the unique IO characteristics of ransomware, and further drove us to build `DeftPunk`, a block-level ransomware detection and recovery system. `DeftPunk` uses a two-layer classifier for fast and accurate detection, creates pre-/post-attack snapshots to avoid data loss, and leverages log-structured support for low overhead recovery. Our large-scale benchmark shows that `DeftPunk` can achieve nearly 100% recall across 13 types of ransomware and low runtime overhead.

1 Introduction

Ransomware has become increasingly prevalent in recent years, posing a major threat to data security. Recent reports show that ransomware attacks have caused billions of dollars in losses to individuals and organizations [27, 29]. Typically, attackers exploit system vulnerabilities to access and encrypt users' data for ransom.

Cloud services are also facing increasingly aggressive ransomware threats. In ALIBABA cloud, our cloud block store (a.k.a., Elastic Block Storage, or EBS) has been under constant attacks. In Q3 of 2022 alone, we have received nearly one thousand reports from our EBS Virtual Disk (VD) users, yielding a 118% increase over the entire year of 2021.

To combat ransomware, practitioners have proposed various detection and recovery methods. At the application layer, users can use antivirus software and firewalls [21, 24, 31] to identify suspicious behaviors by monitoring file access and checking malware signatures. At the OS layer, recent works have demonstrated their ability to detect ransomware activities via behavioral analysis [33, 41, 45, 57]. Third, at the hardware layer, prior works have shown that, with hardware-assistance from customizable devices, the log-structured design of SSDs can be leveraged to detect and roll back ransomware activities [34, 35, 43].

Unfortunately, these traditional methods cannot be directly applied for our EBS. First, the application/OS layer methods require strong user cooperation. As a cloud vendor, we are unable to enforce our users to use specific software and/or OS. In addition, field statistics suggest that tenants may not always keep the software up to date, leaving potential vulnerabilities. Second, cloud providers usually use commodity hardware for cost efficiency and portability. Thus, it is impractical for us to build protection that only works on specialized devices. Third, certain vendors, including us, have already provided (periodical) VD snapshot for data recovery. Simply relying on such mechanisms may not be favorable for users, as they may lose the data between two snapshots due the hour-level interval and high CapEx led by the extra storage space

Existing solutions, while failing to work directly, inspire us to use the IO characteristics of ransomware (e.g., excessive Write-After-Read access) for detection, and leverage the garbage collection (GC) of log-structured design for recovery. This is because the block store service, by default, can monitor and analyze the block-level IO traffic. Moreover, our EBS is built on an append-only distributed file system (DFS), and thus supports similar mechanism to roll back data that have not been reclaimed by GC (such as SSD). The benefits of such design are two-fold. First, it does not rely on certain software or hardware support. Second, it can be easily deployed with little extra overhead imposed.

Therefore, we started exploring the possibility of building this solution. However, real world data show that such a preliminary attempt fails to deliver satisfactory accuracy in detection. We assume the main reason is that the existing detection algorithms—bounded by their prerequisites (e.g., need to use SSD's weak SoC) and lack of real-world access/analysis—can not effectively and efficiently distinguish ransomware traffic from normal IOs. Additionally, we find that the existing recovery methods can not always guarantee lossless data recovery due to the limited time of multi-version support.

In this paper, we propose `DeftPunk`, a block-level ransomware detection and recovery system for the cloud. Based on extensive comparisons between ransomware and normal workloads, `DeftPunk` constructs a rich set of features and uses a two-layer classifier for fast and accurate ransomware detection. To avoid data loss, `DeftPunk` creates pre- and post-attack snapshots to "lock in" the effects of the attack, and persists all modifications in between. For recovery, `DeftPunk` follows a "undo-redo" strategy to roll back the data to the pre-attack state and only redo the users' writes.

[*] Equal contributions.
[†] Corresponding author.

Specifically, we first assemble a large-scale ransomware dataset by collecting more than 140 hours of block-level IO traces from 13 mainstream ransomware (e.g., Wannacry [30] and Mallox [18]) and 16 types of real-world workloads from our EBS. The comprehensive comparison shows that, apart from the well-known Write-After-Read (WAR) pattern, ransomware also exhibits other characteristics, such as read to write ratio, access offset distribution and frequent access on the system disk. These observations help us to extend the feature set of `DeftPunk` by including IO statistics, dependency, working set size, offset and certain LBA spatial access.

The above extended features help `DeftPunk` to achieve higher accuracy. But, for deployment efficiency under the sheer volume of VDs and their IOs, we also need to consider the runtime overhead. Therefore, `DeftPunk` adopts a two-layer model. The first layer, focusing on eliminating false positives (i.e., filtering normal IOs), uses a straightforward decision tree algorithm with simple features (only requiring O(1) computation). The positive cases classified by the first layer will be further sent to the second layer for a double check. The second layer emphasizes on exposing all ransomware cases, and thus uses a more sophisticated algorithm (i.e., XGBoost [38]) with the complete set of features.

Based on the output of the two-layer model, `DeftPunk` can create a pair of snapshots right before and after the attack. Moreover, with multi-version support by the EBS log-structured design and GC pausing, `DeftPunk` can persist all data modifications during the attack. For recovery, `DeftPunk` follows a "undo-redo" strategy to roll back the data to the pre-attack state, and, based on a rule-based model, only redo the writes made by the users.

Based on our assembled dataset, we benchmark `DeftPunk` with a set of state-of-the-art ransomware detection methods. The results show that `DeftPunk` can always achieve nearly 100% recall with 95.8% precision, outperforming all other peers. Moreover, `DeftPunk` only uses 7 vCPU cores for processing 1 million IOPS for detection and can recover valid data at 4.62 GB per second. We have deployed `DeftPunk` in our EBS service for a few invited users, and it has successfully prevented 2 attacks with data fully recovered.

The contributions of this paper are summarized as follows:

- We assemble and release a large-scale ransomware benchmark with real-world traces[1].
- We build `DeftPunk`, a practical ransomware detection and recovery system for the cloud EBS.
- We extensively evaluate `DeftPunk` and the results show that `DeftPunk` outperforms peers by up to 95.77% in precision and nearly 100% in recall.

The rest of the paper is organized as follows. §2 gives a brief overview of our EBS and background of ransomware. §3 discusses the existing solutions and related work. §4 identifies the goals and challenges. §5 presents the design of `DeftPunk` and §6 shows the evaluation of `DeftPunk` in depth. We end this paper with a discussion on `DeftPunk`'s limitations in §7 and a short conclusion in §8.

2 Background

2.1 EBS in ALIBABA Cloud

Elastic Block Storage (EBS) serves as a cornerstone in today's cloud. To provide virtual block devices to users with high flexibility and availability, our EBS, similar to other vendors' architecture [9–11, 17], follows a "compute-to-store" philosophy. With this setup, the storage clusters are physically disaggregated—interconnected by data center network—from the compute servers (and subsequently the virtual machines running on them).

Figure 1 illustrates an overview of the EBS architecture. On the compute end, each server can host multiple Virtual Disks (VDs) and also embeds a client within the hypervisor to forward VD's requests to backend storage clusters. Once the *Block Proxies* receive the VDs' requests, they will then persist/fetch the data to/from the corresponding file in the distributed file system (DFS).

Like Google [49], Azure [37], and Alibaba Cloud [48], we too adopt a log-structured distributed file system (DFS) as the storage backend. The Block Proxy employs a Log-Structured Block Device (LSBD) to transform VDs' IO to an appending-only DataFile provided by the underlying DFS. One key functionality is to register the mapping (i.e., from VD LBA to location in DataFile) in a per-VD IndexMap to track latest location of data in the DataFile. Also, this requires a garbage collection (GC) for reclaiming space from stale data. In addition, we also set up a Snapshot Worker to allow users to create snapshots of their VDs and store them as binaries.

2.2 Ransomware

Ransomware, such as WannaCry [30], has been rampantly spreading across the globe, leading to billions of dollars financial losses. The typical procedure of a ransomware attack has three steps: (1) the attacker infects the victim's machine via weak password and/or system vulnerabilities; (2) the ransomware encrypts the victim's data; (3) the victim is instructed to pay a certain amount of ransom (e.g., cryptocurrency) for decryption.

Both industry and academia have been working on ransomware detection and protection. In Table 1, we summarize the commonly used methods by layers. First, at the Application layer, users can install antivirus software and firewalls [21,24,31] to monitor the suspicious behaviors (e.g., frequent access to unauthorized files and encryption) or match the signatures in the viruses database. Second, by intercepting system calls and file access patterns within the OS, recent studies have also proposed to detect ransomware activities via behavioral analysis [33,41,45,57]. Third, users or vendors could ask the hypervisor to take snapshots of the whole runtime to directly recover the data. This method is widely available by major cloud service providers [3,4]. Finally, many prior works have shown that the log-structured design of SSDs can be leveraged to detect and rollback ransomware activities [34,35,43]. The key idea is that valid data which are overwritten and encrypted by the ransomware will be marked as stale. But, the Flash Translation Layer (FTL) usually would not immediately reclaim their space, providing an opportunity to recover users' data before garbage collection.

3 Motivation and Related Work

The cloud is no stranger to ransomware attacks, especially when an increasing number of users are migrating their sensitive data to the public cloud [5–7,13,14,26–29]. A recent report by Zscaler cloud [7] states that ransom attacks have increased by 38% from April 2022 to April 2023, and they predict that attackers are likely to develop new types of ransomware and campaigns optimized for targeting cloud services and workflows. Sophos report [27] also indicates that the average ransom has increased from $812,380 in 2022 to $1,542,333 in 2023, not to mention the cost of the data recovery process and the losses due to downtime. In our cloud, we have also been witnessing a growing number of ransomware attacks on users. In just one quarter (2022 Q3), our cloud has recorded nearly one thousand ransom incidents, leading to an increase of 118% compared to the previous year.

One might wonder, with all the protection approaches available (see Table 1) and vendors' high emphasis on data security, why ransomware attacks are still so prevalent in the cloud. Here, we summarize the key reasons and challenges based on our observations and statistics from the field.

Human mistakes. User awareness is the first, and often the weakest, line of defense against ransomware attacks. To be human is to err, so it is not uncommon for users to fall victims to phishing or malicious emails and other malware. A recent survey by Fortinet [28] reports that phishing remains the top ransom tactic (56%). Other ransomware reports, such as those from Sophos [27] and SpyCloud [29], have likewise emphasized the vulnerability of humans in ransomware defense. Similarly, in our cloud, we discover that nearly all ransomware attacks start with a negligence being exploited (e.g., outdated software and weak password).

Lack of protection in VM. Normally, with antivirus software properly installed and security patches regularly updated, VM should be able to operate safely even under the threats of ransomware. However, in the cloud, VMs, can often run in an under-protected environment due to the following reasons.

First, only a small fraction of VMs are under sufficient antivirus software protection. For instance, Zscaler [2] reports that 17% of organizations are running workloads on unprotected virtual machines which is consistent with our observations from the field. Even for ones who have, they can still be at risks of latest attacks as 28% of VMs attacked by ransomware are running with vulnerable outdated OS and software. Third, while we provide OS images with built-in security support and automatic updates, only 19.4% of users opt in. One main reason, after discussion with multiple users, is that they tend to reuse their own OS images for consistency and compatibility after migrating to cloud.

Snapshot protection is expensive and coarse-grained. Our EBS allows users to persist the Virtual Disk (VD) as a snapshot and later use it to restore to a certain point in time. By taking periodical snapshots, users can conveniently recover from a ransomware attack by simply restoring the VD to the most recent checkpoint before the attack. However, in practice, this is not the case. First, the snapshot-based protection can be expensive. Even with our latest incremental snapshot service, the cost incurred from snapshots can easily 2.5 times more than the monthly rental of the VD, assuming VD is under normal traffic and snapshots are taken on hourly basis. Moreover, even if users are willing to pay the price, recovery by periodical checkpoint is still coarse-grained in the cloud EBS. For example, the highest specification VD in our cloud can achieve a throughput of 4000 MB/s and 100M IOPS. In this case, even if we use minute-level periodic snapshots, it would still result in a significant amount of data loss.

Hardware-based protection is impractical. Academia have proposed multiple approaches for defending against ransomware attacks via hardware assistance [34, 35, 43, 53]. However, these attempts would fall short for large-scale cloud deployment, such as EBS. First, previous works are based on specialized and/or prototype hardware, such as Open-Channel SSDs [34] or FPGAs, yielding a small chance for large-scale deployment. In addition, even if manufacturers manage to produce such hardware, it is still impractical as ransomware evolves rapidly. At the same time, frequently updating the firmware or providing backward compatibility for legacy devices would be a huge challenge.

4 Goals, Opportunities and Challenges

To this end, we have shown that the existing ransomware protection mechanisms can not be shoehorned to cloud services such as EBS. In this section, we first list the design goals of an ideal ransomware protection mechanism for EBS. Then, we discuss the potential opportunities for a practical detection approach based on intrinsic properties of EBS and the ransomware attack patterns. Finally, we present the insights we gained and challenges we faced from building and exploring this preliminary design.

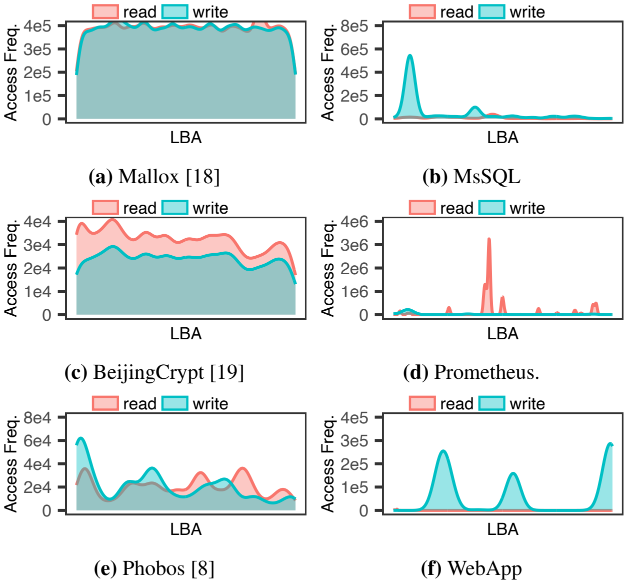
4.1 Design Goals

The role of a cloud vendor profoundly limits our ability and choices in applying existing techniques. Therefore, to develop a practical ransomware detection for EBS, we start by identifying the key requirements.

- *No data lost/tainted after recovery.* The most fundamental requirement for ransomware protection is to ensure that, once detected, no ransomed data is lost during recovery. In other words, all user issued IOs—before, during and after the attack—should be preserved and no tainted data left. On top of that, we need recover data in a timely manner with minimal effort from users.
- *Transparent to users.* The monitoring and detection should not rely on users' awareness or cooperation with the vendor, such as installing certain softwares, using specific OS, or updating patches under certain schedules. In addition, to obey privacy and security protocols, we also cannot directly control the VMs and/or insert (kernel) modules to proactively defend ransomware attacks.
- *Hardware independent to vendors.* As a cloud vendor, our solution should be based on commodity products, instead of depending on features only provided by specialized hardware (e.g., customizable Open-Channel SSDs) or prototype devices (e.g., FPGAs). Moreover, even for the commodity products, the ideal solution should provide backward compatibility, meaning that it can support legacy devices such as early models of SSDs or even HDDs.
- *Low runtime overhead.* The proposed solution should run with low resource consumption (e.g., CPU, memory, space, and network bandwidth). This is because, given the destructive impacts and the increasing prevalence of ransomware, the occurrence—compared to the massive volumes of VDs—is still rare in the wild. For example, on average, less than 0.001% of the VDs in our cloud are subjected to ransomware attacks on a daily basis. Hence, the high CapEx led by high resource consumption would not be acceptable to vendors or tenants.

4.2 Opportunities

While previous ransomware prevention techniques fail to work directly in EBS, we discover that the log-structured block device (LSBD) design bears great similarities with SSD internals. This motivates us to explore the possibility of borrowing ideas from the existing hardware-based methods. Next, we discuss the two similar opportunities our EBS shares with the hardware-based ransomware protection.



(a) Mallox [18] **(b)** MsSQL

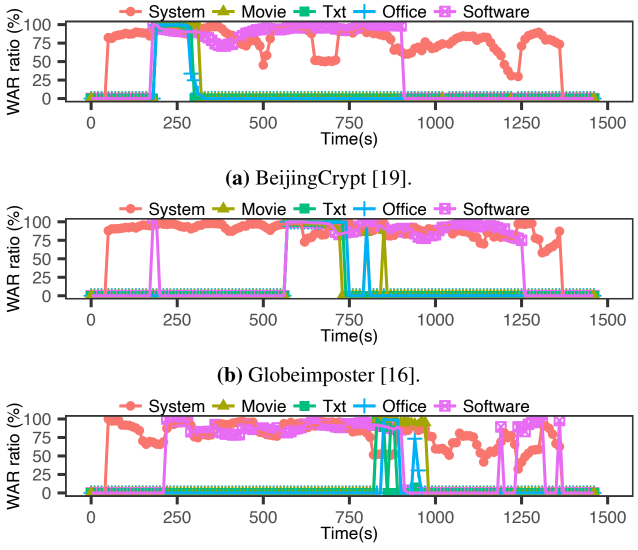
(c) BeijingCrypt [19] **(d)** Prometheus.

(e) Phobos [8] **(f)** WebApp

Figure 2: Comparation of LBA access frequency between ransomware and regular applications

Block-level ransomware access pattern. Ransomware usually follows a read-encrypt-write procedure on users' data. For example, a recent survey indicates that up to 76% of ransomware employed encryption-based attack mode [27]. Previous studies have shown that this access pattern holds across different ransomware families and can be caught at file system level (e.g., directory traversal, file type change, access frequency, etc [46, 54]) and device (i.e., SSD) level (e.g., statistics of erasure IO in [34, 35]). As Block Proxies handle VD requests in the format of Logical Block Address (LBA), we further explore the possibility of detecting ransomware attacks at the block level.

We start with the spatial and temporal patterns of typical ransomware. For the spatial pattern, Figure 2 (a)(c)(e) and



(a) BeijingCrypt [19].

(b) Globeimposter [16].

(c) Babuk [12].

Figure 3: Write-After-Read IO ratio by time on ransom attack

(b)(d)(f) respectively illustrate the LBA access patterns of a VD under ransom attacks and normal workloads. The x-axis represents the normalized LBA, and the y-axis shows the frequency of access within 10 minutes. By comparing the two, we can see an outstanding difference. The ransomware tends to have a similar amount of reads and writes to the same LBA. This is consistent with observations from previous studies [34, 35]. Namely, the "read, encrypt, and write back" pattern of ransomware is manifested as erasure IO (i.e., EIO) or Write-After-Read IO (i.e., WAR IO) at the block-level.

We then examine the temporal pattern of ransomware attack. Figure 3 shows the variations in the WAR ratio (i.e., the ratio of WAR IO to the total write requests) of three VMs (each with five VDs) under various ransomware attack. In each VM, the five VDs consist of one system drive and four data drives loaded with different types of data.

For example, Figure 3(a) illustrates the variations in the WAR ratio of the VM when it is under a BeijingCrypt attack. The WAR ratio of the system drive rapidly rises from 0 to 100% around 60s and maintains a relative high level until the attack ceases at 1370s, at which point the WAR ratio falls back to 0 rapidly. A similar pattern of “climb-maintain-drop” in the WAR ratio can be observed on other data drives, albeit with variations in the start or end time. Figure 3 (b) and (c) illustrate the WAR ratio dynamics for the VM during attacks by Globeimposter and Babuk, respectively, revealing patterns similar to those depicted in Figure 3(a). Hence, we can conclude that cloud-based ransomware also exhibit a distinct pattern of WAR IO at the block level, which is consistent with insights from ransomware detection on hardware level.

To sum up, we can conclude that ransomware attacks at the block level exhibit distinct patterns that can be detected by analyzing the LBA access records.

Method	Precision	Recall	F1-score
SSD-insider++	63.05%	87.53%	73.26%
RanSAP	84.83%	94.37%	89.23%
WaybackVisor	71.36%	93.06%	80.66%
Combine Model	90.74%	92.10%	91.42%

Table 2: Comparison of four ransomware detection algorithms.

Multi-version nature of LSBD. Recall that one key feature of EBS is adopting the log-structured block device (LSBD) in the Block Proxy (See §2.1). In this setup, all writes from the front-end VDs are appended to the end of the log, and the Block Proxy maintains a mapping table—called IndexMap—to track the latest metadata of data. Periodically, Block Proxy reclaims the space with garbage collection (GC).

This design is similar to the SSD’s append-only internal architecture, which serves as one of the prerequisites for hardware-based ransomware protection. The knack here is that, in both EBS and SSD, the stale data are usually *not immediately* reclaimed by GC and overwritten with new data. Instead, it can survive for a certain period of time which essentially enables multiple versions of data to co-exist. As a result, in the face of ransomware attacks, we can leverage this multi-version nature to conveniently roll back to early versions by altering the IndexMap.

4.3 A Preliminary Exploration

Based on the above two opportunities, a potential design for ransomware protection in EBS arises. In short, we can actively monitor all incoming IO from each VD and check whether the LBA access matches the ransomware patterns. If detected, we can conveniently roll back the data to a previous clean version. The benefits of this design are that: (1) it only relies on block-level IO records, thereby being transparent to users and hardware independent; (2) it can leverage the multi-version nature of LSBD, hence no extra storage space is required.

In this prototype, there are mainly three components. (1) *IO Trace Collector*: Collect the block-level IO records from Block Proxy including the operation code (read, write or trim), LBA, and length; (2) *Ransomware Monitor*: Periodically analyzing the IO records of all VDs to determine if any are targeted by ransomware attacks. The monitor essentially functions as a feature extractor combined with a classifier. The former extracts handcrafted features from IO records, while the latter is a machine learning-based classifier; (3) *Data Recovery*: Upon detection of an attack, the data recovery mechanism is activated, restoring the data to a pre-attack state by changing the IndexMap.

To validate the effectiveness, we test this prototype on our benchmark, which includes around 150 hours of Block IO traces from 13 common ransomware and 16 types of real-world workloads (see §6.1). In addition, we have implemented four variations by adopting three state-of-the-art detection methods from previous work including SSD-insider++ [35], RanSAP [40] and WayBackVisor [42], and a combined one (i.e., all features included). Table 2 demonstrates the precision, recall, and F1-score results of the four methods. From the results, we can observe that all four left room for improvement and combining features certainly help (i.e., highest F1-score).

Such solutions still do not meet our goals as they incur data loss or leave tainted data unhandled. First, false negatives is unacceptable as the valid copies of data may be lost during later GC. Second, having a less satisfied precision (i.e., identifying normal activity as ransomware) is also consequential as users' normal IO can be wrongly interrupted and rolled back.

4.4 Challenges

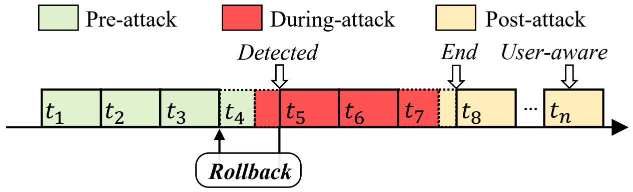


Figure 4: A typical process of ransomware attack, detection, and recovery.

Insufficient features. The straightforward design is based on the SSD and thus bounded by its limited on-chip resources (e.g., computational power and memory space). As a result, the feature extraction and classification algorithms become inherently straightforward (e.g., simple statistics of erasure IO in [35]), thereby yielding low accuracy. This also applies to the solutions based on kernel modules as they, too, need to be lightweight to avoid interfering with normal IO activities.

In EBS, the Block Proxies can have much more resources at hand. In addition, we can also set a standalone machine to run the detection module. Therefore, it is possible for our solution to include more features and adopt complex models for improvement. However, introducing features is helpful only when they reflect the unique characteristics of ransomware attacks, which requires careful analysis on the traces. Moreover, though EBS may have more computational power, spending too many resources on ransomware detection is still not economically acceptable due to the relatively low occurrence rate of ransomware attacks. In summary, we need to strike a balance between accuracy and overhead by identifying the unique characteristics and including them for feature construction.

Impermanent multi-version support vs. data loss. Even if we can achieve a high-accuracy model through the above endeavors, it is unlikely such a solution can always detect the exact timing of the ransomware attacks with no false positives/negatives. Hence, we may still run into data loss when rolling back is wrongly invoked.

Here, we use Figure 4 to illustrate a rundown on typical cases that might lead to data loss. In the figure, each rectangle represents a sample, and the background color indicates the three phases of the attack: pre-, during-, and post-attack. Assume that ransomware initiates an attack at the t_4 window (as indicated by the dashed line) and continues until t_7 window (also indicated by the dashed line). The detection model identifies the attack at t_5 and rolls back the data to t_4.

First, if the proposed solution fails to detect the attack at t_5 (i.e., false negatives), the user's data may become irretrievable if garbage collection (GC) has already kicked in. Note that data recovery can only issued by users but users may not be aware of the attack in time. Second, if the detection model wrongly labels normal IO as ransomware attack (i.e., false positives), it might cause user panic and even lead to incorrect data rollback. Third, even if the ransomware attack is alarmed, the user fails to stop normal IO until t_n which might be several hours after attack, the rollback-based recovery would result in greater data loss that all the user's normal IO during- and post-attack would be reverted.

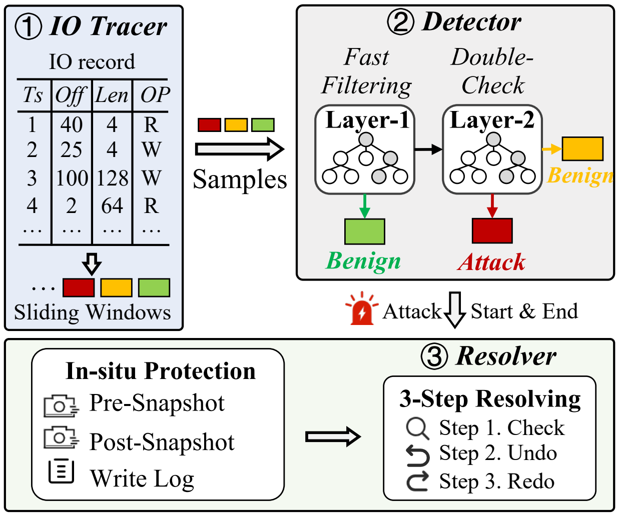
To solve above issues, the easiest way is to provide the multi-version support for all data modifications permanently. However, this is not feasible as it would quickly deplete the user's purchased disk space within months or even days due to the constant accumulation of data. The same reason also applies to vendors. Therefore, we need to find a solution that can efficiently persist all IO records from right before a ransomware attack until the end of it.

5 `DeftPunk` Design

We now introduce the design of `DeftPunk`, a practical ransomware detection and data recovery framework for cloud EBS. `DeftPunk` does not require users' cooperation, designated software support or customization on hardware in detection, and can guarantee no data loss during the recovery. The key to `DeftPunk` success is employing a two-layer machine learning model to efficiently detect attacks and create snapshots. Then, `DeftPunk` can notify the user and perform the subsequent data recovery. In this section, §5.1 presents an overview of the framework and workflow of `DeftPunk`, followed by a detailed discussion on the three main components: the feature engineering (§5.2), two-layer classifier (§5.3) and data recovery (§5.4).

5.1 Overview

Data preprocessing. Figure 5 demonstrates the high-level procedures and interactions between components in `DeftPunk`. First, the IO Tracer, embedded in the Block Proxies (BP), constantly monitors all incoming IO record (i.e., formatted as `<timestamp, offset, length, operation>`) and group them as IO records by VDs. Then, IO tracer generates samples with a sliding window of 10 seconds. For example, assume a BP that serves three VDs. For a minute



Ts	Off	Len	OP
1	40	4	R
2	25	4	W
3	100	128	W
4	2	64	R
…	…	…	…

Figure 5: Overview of `DeftPunk`.

of monitoring, IO Tracer would generate 6 samples of IO records for each VD.

Ransomware detection. Upon receiving the IO record samples, `DeftPunk` first uses the *Layer-1 Classifier*, based on simple features (e.g., IO count) and a decision tree, to perform fast scanning with an emphasis on high recall and low computational cost. If the sample fails to pass the first layer (i.e., suspicious of a ransom attack), it will be further checked by the *Layer-2 Classifier*. The second model uses a superset of Layer-1's features by including more complex ones, (e.g., statistics of entropy, Working Set Size, and IO offset), and employs a more sophisticated model (i.e., XGBoost), aiming at high precision. If the sample is again labeled as positive, `DeftPunk` would trigger snapshot generations.

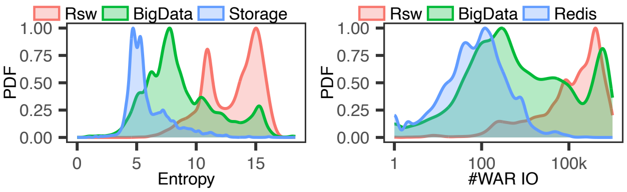
Creating snapshots. When a positive sample arrives, the snapshot worker would first create a Pre-attack Snapshot and a Post-attack Snapshot at the beginning and the end of it, respectively. As a ransom attack may span across multiple 10-second samples, the snapshot worker continues to create new Post-attack Snapshot to replace the previous one until the incoming sample becomes negative. Meanwhile, during the attack, `DeftPunk` would also pause the EBS garbage collection for this VD to prevent the accidental deletion of the valid data until the post-attack snapshot is finalized.

Data recovery. When the user has been notified of the attack (e.g., via our alert message or discovering certain data become inaccessible), one needs to issue a recovery request. `DeftPunk` would follow a three-step recovery process. (i) *checking*: `DeftPunk` first checks and lists all tainted LBAs (i.e., 4KB long each) during the attack. If a LBA is further modified (by the user) after the post-attack snapshot, then data in that LBA would not be recovered. (ii) *undo*: `DeftPunk` would revert all data in tainted LBAs to the version of the pre-attack snapshot. *redo*: `DeftPunk` would run another rule-based model to identify IOs made by the users and redo them.

5.2 Feature Engineering

In §4.4, we mentioned that one key reason for suboptimal performance of existing solutions is the insufficient feature engineering. To construct features for `DeftPunk`, we first conduct an extensive study on real-world VDs' IO traces to identify the fundamental differences between ransomware and normal user behaviors (§5.2.1). Based on the insights, we then devise the extended features for the two-layer model.

5.2.1 Characterizing IO Behavior



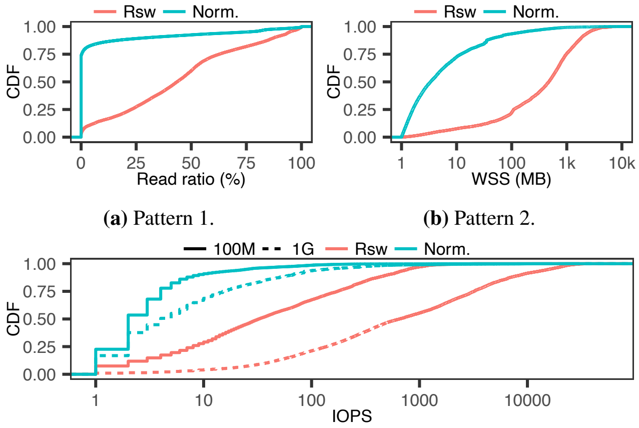
(a) Offset entropy **(b)** WAR IO count

Figure 6: Opportunities of detecting ransomware at block-level.

We first reason why typical features used in existing works, such as *offset entropy* in [40,42] and *WAR IO count* in [34,35], can be ineffective. In Figure 6(a), we present the probability density function (PDF) of the offset entropy for samples in our dataset. "Rsw" indicates the PDF of all ransomware samples. "BigData" and "Storage" represent two different types of common workloads. We can observe a distinct difference in the PDF of offset entropy between Rsw and Storage, while there exists large PDF overlap between BigData and Rsw. Figure 6 (b) exhibits a similar pattern on Bigdata and Rsw.

This comparison clearly shows that normal workloads can be easily mislabeled (or the other way around) if we solely rely on a selected few simple features. We believe that one major root cause is that previous work mostly focus on positive samples (i.e., ransom attack IOs) without noticing or studying the similarities they share with normal traffic. Hence, we study both the patterns of ransomware and normal I/O behaviors and propose three patterns for better feature engineering.

- **Pattern 1.** Ransomware typically exhibits nearly equal amounts of read and write in bytes, whereas the read-to-write ratio of normal IOs is often skewed. Figure 7(a) presents the cumulative probability density (CDF) of the read-ratio (i.e., the proportion of read requests to total requests). We can see a notable gap between the CDF of normal workloads (Norm.) and ransomware (Rsw), with the average value for Norm. being X and the average value for Rsw being Y.
- **Pattern 2.** The IO offsets of ransomware are distributed more broadly across the LBA space, and each offset is typically accessed only once. In contrast, the IO offsets under



(**a**) Pattern 1.

(**b**) Pattern 2.

(**c**) Pattern 3.

Figure 7: Three unique patterns that can distinguish between ransomware and normal workloads.

normal workloads tend to be concentrated. Figure 7(b) shows the CDF of the working set size (WSS) for the two categories of samples, and we can similarly observe a significant difference between Norm. and Rsw.

- **Pattern 3.** Ransomware displays obvious WAR on the system disk, particularly in the Master Boot Record (MBR) region at the beginning of the LBA, whereas such operations are rarely performed by normal users. Figure 7(c) displays the IOPS (Input/Output Operations Per Second) for the two categories of samples within the first 100MB and the first 1GB of the LBA.

5.2.2 `DeftPunk` Feature Engineering

Based on the findings above, we construct the following as `DeftPunk`'s enhanced feature engineering for ransomware detection. Table 3 presents the 43 features we employed along with their corresponding meanings. For ease of understanding, we categorize these features into 5 classes, which include:

- **IO Dependency**. This set of features characterizes the behavior of adjacent I/O operations in a temporal context. In addition to including Write-After-Read (WAR), which has been adopted by other works [34, 35], we also incorporate three other types of read-write sequences, such as Read-After-Write (RAW), Read-After-Read (RAW), and Write-After-Write (WAW).
- **IO Statistics.** This part constitutes the basic statistics of VD IO, including the IO count, total bytes, and IO size. Here, features are made separately for read (R), write (W), and the sum of read and write (RW). The design of this feature set is inspired by **Pattern 1.**
- **Working Set Size (WSS)**. Inspired by **Pattern 2**, we track the working set size (WSS) for 6 types of I/O. Here, WSS refers to the proportion of the LBA space that is accessed by a specific type of IO.
- **Offset Statistics**. Compared to WSS, this category of features characterizes the distribution of I/O across the LBA at a finer spatial granularity, such as the mean, variance, standard deviation, coefficient of variation (CoV) [32], and entropy [56] of the IO offset. The design of this type of feature is also inspired by **Pattern 2**.
- **Access on LBA Head Region**. As mentioned in **Pattern 3**, ransomware may tamper with data in the head region of the LBA. Bearing this in mind, we conduct statistics on IO that fall within the first 100MB and 1GB of the LBA, including the I/O count and total bytes.

In Table 3, we also list the computational complexity (in Big O notation) for each class. Note that the traditional definition of Write-After-Read (WAR) is to check whether there are sequential read and write requests accessing the same LBA offset. However, we extend the definition of WAR by relying on both the offset and the length to decide whether the LBA accessed by the sequential read and write requests are overlapped. Therefore, our check for WAR requires a time complexity of O(logn) rather than O(1). The reason to do this is that we find that ransomware can read a large volume of data and then writes it in smaller chunks, exhibiting the behavior of "read-write-...-write". According to the traditional definition of WAR, this behavior would be characterized as 1 WAR and 2 WAWs, which can be similar to normal user IO. However, our definition of WAR would describe this behavior as 3 WARs and 2 WAWs, thereby distinguishing it from the I/O behavior of normal users.

5.3 Two-layer Model

The enhanced feature engineering can improve the precision/recall of the detection. However, simply building a classifier based on the entire set of features would not be practical for production deployment. This is because certain features such as IO dependency, offset entropy, and WSS would have high computational complexity and thus yield a high overhead in detection. For example, given a VD with 1 million IO records, the processing time for IO dependency can be 14 seconds for one thread. In this case, blindly applying the entire set of features would consume nearly 56 virtual CPU cores for 1 million IOPS online only for feature calculation.

Therefore we propose a two-layer model to balance the trade-off between overhead and detection accuracy. First, we use a simple feature set in the first-layer model for fast filtering the majority of non-ransom activities. We apply the complex feature set with second classifier to scrutinize the suspected cases labeled by the first model. Specifically, the two-layer classifier is implemented as follows.

Layer-1: Fast and Broad Filtering. This layer aims to achieve a high recall and rapid initial scanning of ransomware using features with O(1) complexity. Hence, we evaluate the detection performance of three commonly-used simple classifiers, including k-Nearest Neighbors (kNN) [39], Logistic Regression (LR) [50], and Decision Trees (DT) [51], with

Type	Description	Complexity	#Features
IO Dependency on Block	**IO count / Bytes** of (RAW / WAR / RAR / WAW) IO	O(logn)	8
IO Statistics	**IO count / Bytes / Size / Bps** of (R / W / RW) IO	O(1)	11
Working Set Size (WSS)	**WSS** of (R / W / RAW / WAR / RAR / WAW) IO	O(logn)	6
IO Offset Statistics	**Var / CoV** of (RW) IO	O(1)	2
	Entropy of (R / W / RAW / WAR / RAR / WAW) IO	O(logn)	6
Access on LBA Head Region	**IO count / Bytes** on first (100M / 1G) of (R / W) IO	O(1)	8

Table 3: Feature engineering of `DeftPunk`. *In the second column "Description", the bold text separated by slashes ("/") represents different metrics, while the parts within parentheses separated by slashes represent different IO types. For example, the meaning of the first row is to calculate the IO count and Bytes for each of the four IO types: RAW (Read-After-Write), WAR, RAR, and WAW. Therefore, there are a total of* $2 \times 4 = 8$ *features. R, W and RW IO refers to read, write, and read-write, respectively..* **Var**: *variance*; **WSS**: *working set size*; **CoV**: *coefficient of variance*.

Layer	Model	Precsion	Recall	F1-score
Layer-1	KNN	73.1	82.5	77.5
	LR	32.7	91.1	48.1
	DT	**87.5**	**95.9**	**91.5**
Layer-2	RF	96.2	97.6	96.9
	lightGBM	95.1	97.1	96.1
	CatBoost	95.4	98.5	96.9
	XGBoost	**95.8**	**98.6**	**97.1**

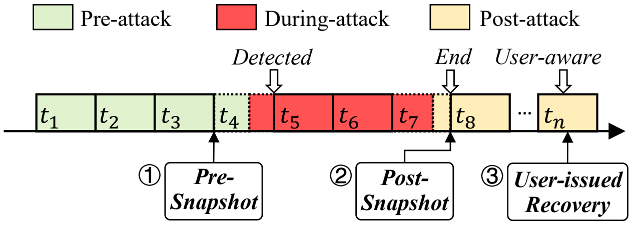

Figure 8: `DeftPunk`'s timeline for lossless data recovery.

the results depicted in Table 4. We choose the Decision Tree (DT) as the classifier for layer-1 as it achieves the highest recall (95.9%).

Layer-2: Accurate Double Check. Suspected cases from layer-1 are passed to the layer-2, which employs computationally expensive features that can better distinguish between ransomware and normal behavior. Here, we add all the features mentioned in Table 3 to the model, and similar to layer-1, we test the performance of four commonly-used complex classifiers, including Random Forest (RF) [36], LightGBM [44], CatBoost [52], and XGBoost [38], with the results presented in Table 4. The results indicate that XGBoost achieves the highest F1-score (97.1%) and thus is chosen as our layer-2 classifier. Our further experiments in §6.6 demonstrate that the two-layer model maintains the same detection performance as single-layer model but with much less computation needed.

5.4 Creating Snapshots

Once an attack is detected, `DeftPunk` generates a pair of snapshots, called pre-/post-attack snapshots. The goal is to "lock in" the effects of the ransomware to make sure all data modification during the period are recorded and recoverable. Then, inspired by the "undo-redo" mechanism in database, `DeftPunk` reverts all the LBAs modified by the ransomware. We also employ another rule-based model to identify the LBAs modified by the user and redo them.

Creating pre-attack snapshot. Once notified by the two-layer classifier, the snapshot worker checkpoints the IndexMap and data of the VD at the time of beginning of the labeled batch window. This is enabled by the multi-version nature of LSBD, which allows the snapshot worker work backwards as long as the previous changes have not been garbage collected. This is guaranteed by setting up the length of a sample to be 1 minute and configuring the GC to only collect stale data that are at least older than 30 minutes. Meanwhile, we also pause the GC on this VD.

Creating post-attack snapshot. Generating the post-attack snapshot is different. As a ransomware attack might be longer than a single sample, `DeftPunk` waits until the two-layer classifier labels an incoming as negative. Then, the snapshot worker creates a post-attack snapshot at the end of last labeled sample and resume GC. In addition, we also record all the writes, including data and LBA, between two snapshots as a write log. Note that the writes between pre-snapshot and detection time can be obtained due to the multi-version support. Plus, the modifications after the detection time can be recorded as we have paused the GC. Finally, we compare the IndexMaps between the two snapshots to only keep data pre-snapshot that are modified during the attack and drop others for space efficiency.

5.5 Data Recovery

To this end, we have acquired three pieces of data, including a pre-attack snapshot (i.e., data, LBA and versions at t_3 in Figure 8), a post-attack snapshot (i.e., LBA and versions at t_8), and a write log (i.e., data and LBA between t_1 and t_5). Now, `DeftPunk` follows three steps to recover the data.

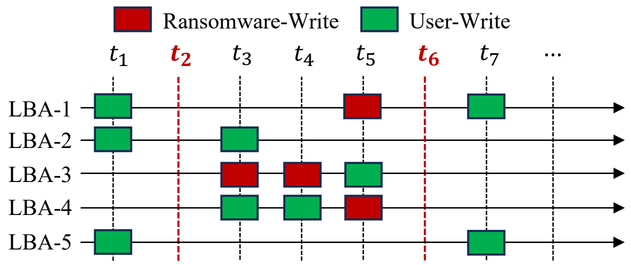

Figure 9: Five cases of LBA data recovery by `DeftPunk`.

Identifying the tainted LBAs. Once the user has been notified of the ransomware attack, they can initiate the request for data recovery. `DeftPunk` would first check if the LBAs listed in the post-attack snapshot are modified by the users after the attack. `DeftPunk` would not try to recover data from such LBAs as they are deemed valid by the users (i.e., LBA-1 and LBA-5 in Figure 9).

Undo. Executing undo is straightforward. `DeftPunk` would revert all involved LBAs (i.e., only modified during the attack but not after) to the version of the pre-attack snapshot.

Redo. Ransomware usually skips files that are already opened (e.g., LBA-2) for writes or kills the user's writing process (e.g., LBA-1) to ensure data integrity of the encrypted files. Still, it is possible that the user's IO exists in the tainted LBAs such as LBA-3 (i.e., user overwrites encrypted LBA block) and LBA-4 (i.e., user's writing is not immediately stopped).

To avoid data loss, `DeftPunk` needs to redo these users' IOs. First, `DeftPunk` employs a rule-based model, which checks the in-place write-after-read (WAR) patterns, to determine whether an IO is indeed modified by the ransomware. Note that, in this case, simply checking the WAR pattern can effectively single out the ransomware IOs because these LBAs have already been filtered by the two-layer model. In other words, the chance of a user's IO coincidentally matching the ransomware's IO pattern is extremely low. We further discuss how to handle such a corner case in §5.6. Then, `DeftPunk` would drop the tainted IOs and apply the normal ones in order.

5.6 Corner cases.

Missing the start/end. The ransomware might start or end right around the 10-second sliding window splitting. Hence, a few IOs made by the ransomware might evade the two-layer model checking and taint the users data. In this case, we further include IOs from one more sample before and after the labeled sample to the write log to avoid data loss.

Mislabeled writes. During the attack, the users might coincidentally write to the LBAs with the similar pattern as the ransomware, e.g., encrypting or rewrite the files. Consequently, the rule-based model may incorrectly mark the behaviors as ransomware and revert them. Note that experiencing this type of mislabeling is rather unlikely in practice. This is because all known ransomware would choose to terminate the user's writing process targeting the same LBAs or simply avoid these addresses (i.e., files) to ensure the integrity of ransomed data. So far, we have not observed any such cases in the field.

Nevertheless, we employ a manual checking process if the user is unsatisfied with the automatic undo and redo. We provide the users with a tool to associate files to LBAs. Then, for the files (and their corresponding LBAs) that are mistakenly reverted, the users can choose to drop/apply the writes on an individual basis. Note that simply using this tool and asking the users to manually check all the LBAs would be impractical given the sheer volume of IOs during runtime.

Data inconsistency. `DeftPunk` is a block-level solution and hence does not provide file/application-level consistency guarantees. It is possible that recovery process can lead to data inconsistency. For example, applying a user's overwrites on the encrypted data may result in a corrupted file (i.e., LBA-3). To resolve this, restoring to the pre-attack snapshot guarantees a clean start. In addition, users can again use our manual checking tool for a finer control of what IOs to apply or drop on tainted LBAs.

Multiple attacks. As the data recovery is only triggered by the user after the notification, it is rare but still possible that the same LBAs have been attacked multiple times. Now, we further discuss the case of two consecutive attacks. The analysis and solution shall apply to the case of multiple attacks (e.g., three or more). Depending on the distance between the two attacks, we can have the following cases:

- *One pair of snapshots.* When the the second attack closely follows the first one (i.e., within 2 samples), `DeftPunk` would treat the two as a single attack as the post-attack snapshot would include an extra sample (see corner case 1). Then, `DeftPunk` performs data recovery as usual. If there is a user's IO between the two attacks, `DeftPunk` can use the rule-base model to check and only redo user's IOs.
- *Two pairs of snapshots.* If the two attacks are far apart (e.g., one day away), `DeftPunk` creates a pair of snapshots for each attack. Then, `DeftPunk` performs data recovery on each attack separately in time order. In this case, the user's IOs between the two attacks would not be affected as the two are treated as independent attacks.

5.7 Runtime Modes

To avoid mislabeling, `DeftPunk` runs in a per-batch mode in the field. Specifically, a batch is 10-minute long and thus includes 60 10-second records. `DeftPunk` labels a batch as positive as long as one sample has been flagged.

Further, users can enable/disable Deftpunk on a Viritual Disk (VD) basis. For example, if a user has mounted multiple VDs, the user can choose to only protect important VDs (e.g., data drives) with Deftpunk but not ones for caching. In addition, we initially allowed system administrators to use only a part of the feature set or just Layer-1 of the two-

App.	#Batch	#IO($1e5$)	App.	#Batch	#IO($1e5$)

layer model to achieve lightweight detection. However, we later found that such a trade-off is not efficient as it leads to a significant drop in detection performance with minor reduction in overhead. We present an experiment on this in §6.6. We recommend that users enable the full feature set and adopt the complete two-layer model.

6 Evaluation

Our evaluations intend to answer the following questions:

- What is the composition of the benchmark? (§6.1)
- How does `DeftPunk` perform against other methods on a per-sample basis? (§6.2)
- How does `DeftPunk` perform in zero-shot scenario? (§6.3)
- How does `DeftPunk` perform in per-batch setup? (§6.4)
- Does the feature engineering work? (§6.5)
- What is `DeftPunk`'s runtime overhead? (§6.6)
- How is `DeftPunk` in deployment? (§6.7)

6.1 Ransomware Benchmark

The dataset is composed of two parts:

Negative samples (normal IO). Benign samples consist of I/O records from EBS virtual disks (VDs) running real-world workloads from the field. Table 5 shows the types of workloads, the number of batches, and the volume of IO records. Note that each batch refers a group of IO records of a VD within a 10-minute span. Each IO record is quadruple, formatted as `<timestamp, offset, length, operation>`. To generate negative samples, we reuse the sliding window mechanism. Therefore, a 10-minute batch can generate 55 1-minute long negative samples. In total, we have gathered nearly 2 million samples.

Postive samples (ransomed IO). We generate positive samples by simulating ransomware attacks atop the normal IOs. Specifically, we follow a "ransomware-OS-application" configuration to generate batches. For each configuration, as shown in Table 6 we mix and match the ransomware families (1 in 13), operating systems (1 in 6), and background applications (1 in 5). Each generated batch is around 10 minutes long and we use the same sliding window methodology to generate positive samples. Note that a ransomware attack can be shorter than 10 minutes. Therefore, we also discard samples that do not have any ransom activities (i.e., samples before/after the ransomware in the generated batch). In total, we have 52 thousands positive samples.

Metric. Ransomware detection is a typical binary classifier, determining whether a sample is positive (i.e., ransomed) or not. Therefore, we use *precision* (i.e., the proportion of positive identifications that are actually correct), *recall* (i.e., the proportion of actual positives that are correctly identified), and the *F1-score* (i.e., the harmonic mean of precision and recall) for measurement.

6.2 Per-Sample Test

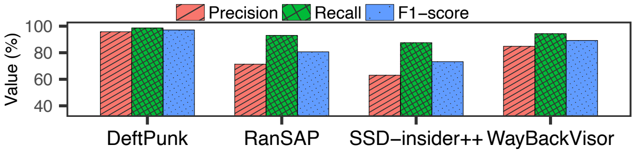

Figure 10: Overall performance of `DeftPunk`.

We compare `DeftPunk` with three other ransomware detection methods including SSD-insider++ [35], WaybackVisor [42] and RanSAP [40]. We split the dataset as 90% for training and 10% for testing. We use 10-fold cross-validation which means we train and test the models 10 times and each time with a different 10% as test set.

We calculate the average recall, precision, and F1-score of each candidate from the 10 tests. In Figure 10, we can observe that `DeftPunk` clearly outperforms all others with a 98.6% in recall, 95.8% in precision, and 97.1% in F1-score. This validates the effectiveness of `DeftPunk`'s feature engineering and two-layer model.

We further analyze the false positive/negative cases. First, it is possible `DeftPunk` incorrectly flags normal IOs as ransomware activities (i.e., precision is not 100%). Normally this is because users' IOs exhibit the same write-after-read patterns as ransomware activities, such as data encryption, in-place compression, and format conversion (e.g., changing a mp4 video file to a mkv one). `DeftPunk` alleviates this issue by leveraging multiple patterns instead of just write-and-read for detection. Still such coincidences may occur and lead to the mislabeling. Note that having a few false positives is acceptable. Recall that DeftPunk follows a detect-notify-rollback process. Therefore, if DeftPunk mislabels normal activities, the notified users can just ignore the alerts, and inform us to delete these snapshots. No rollback would be executed unless the users confirm an attack has occurred.

Second, it is possible DeftPunk misses some ransomware activities (i.e., recall is not 100%). In the per-sample test, the main reason is that the ransomware attack, which usually lasts several minutes, can span multiple samples. Certain samples (e.g., the very first or last one) may not contain enough ransomware activities to be successfully identified, thereby lowering the recall. Note that, in practice, DeftPunk is deployed in a per-batch manner (i.e., 10-minute window), where the recall is near 100% (see §6.4).

6.3 Zero-shot Detection Performance

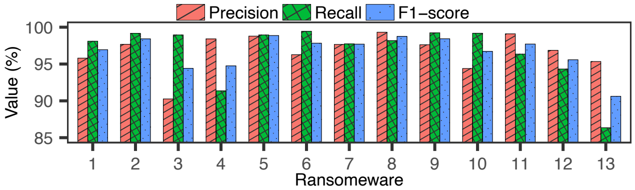

Figure 11: Zero-shot performance of DeftPunk.

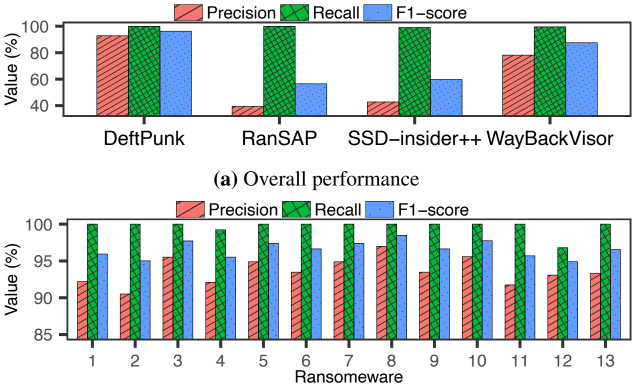
Given that ransomware can be fast evolving, we further measure DeftPunk's detection performance on "unseen" ransomware. Each time, we remove one type of the 13 ransomware families from the training dataset but still keep samples from that family in the testing set (i.e., zero-shot).

Figure 11 displays the results where each group of three bars show the performance of a specific ransomware family were removed from the training set. We can see that DeftPunk is capable of effectively detecting most unseen ransomware, maintaining at least 95% recall and 90% precision. This indicates that our feature engineering captures the common characteristics of ransomware.

The only exception is Wannacry. Further analysis suggests that Wannacry is intentionally slowing down its operation (e.g., CPU utilization is below 25%, and disk throughput is below 10%) to evade detection. Similar to the aforementioned discussion on false negatives, the lower recall is caused by the scant amount of ransomware activities in some samples due to the intentionally *diluted* IOs. Note that such an evasion strategy—while useful in the per-sample test—is not effective in our deployment scenario (i.e., per-batch experiment, see §6.4) for more details.

6.4 Per-Batch Experiment

Note that in the previous two experiments we calculate the performance on a per-sample basis. While they validate the overall designs of DeftPunk in a microbenchmark fashion, DeftPunk in practice is deployed on a per-batch checking basis (see §5.4). In other words, as long as one sample within a 10-minute batch is marked as positive, the entire batch is marked as positive. Note that per-batch testing is closer to real-world setup due to the streaming of IOs.



(a) Overall performance

(b) Zero-shot performance

Figure 12: Per-batch performance of DeftPunk.

In Figure 12, we rerun the experiments in §6.2 and §6.3 but with a per-batch basis. We can see that DeftPunk can always achieve near 100% recall across all situations with a minor (around 2% on average) decrease in precision. Surprisingly, with per-batch detection, DeftPunk can even successfully identify Wannacry ransomware in zero-shot experiment which intentionally dilutes its IO for evasion. On stark contrast, other methods while also have an increasing recall, can experience considerable precision loss, yielding low practicality (i.e., frequently issuing false alarms).

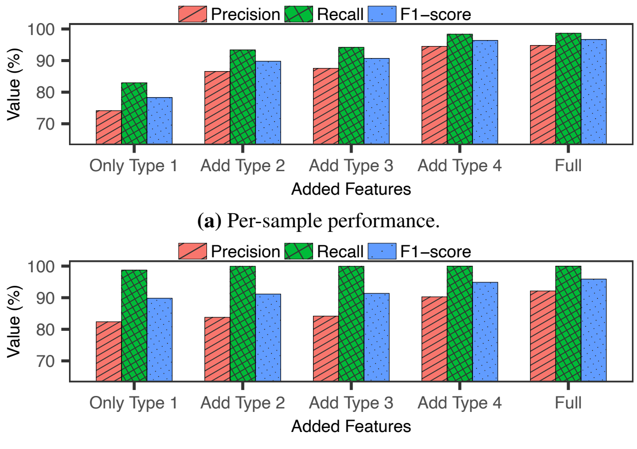
Obviously, compared to experiments in §6.2 and §6.3, the precision and recall in per-batch experiments are much higher. This is because the per-batch test reduces the chances of mislabeling by taking multiple samples (i.e., 1 batch = 55 samples) into consideration. Nevertheless, DeftPunk may still fail to identify certain ransomware activities. One representative case is the Babuk ransomware (i.e., the 12th in Figure 12(b) being undetected in a VD with mostly text files. Further analysis reveals that Babuk is designed to not encrypt text files, thus being latent (i.e., not encrypting files) and avoiding the detection.)

6.5 Effectiveness of Features

Now, we measure the effectiveness of DeftPunk's feature engineering. Specifically, from only one type of features, we add on another set of features and evaluate the overall performance of DeftPunk on both per-sample and per-batch basis. In Figure 13, we can see that DeftPunk's performance steadily increases with the addition of more features. This validates the effectiveness of DeftPunk's feature engineering.

6.6 Runtime Overhead

Monitoring and preprocessing in DeftPunk incur negligible overhead as the IO Tracer only checks and packs the quadru-



(a) Per-sample performance.

(b) Per-batch performance.

Figure 13: Ablation study of `DeftPunk`'s feature engineering. *In the figure, the Type 1 features corresponds to all features associated with the 1st row (IO Dependency on Block) in Table 3, with Type 2 through Type 4 following in a similar fashion.*

Model	Precision	Recall	F1-score	Time (s)
Layer-1 Only	87.3%	95.9%	91.5%	**3.72**
Layer-2 Only	94.9%	98.6%	96.7%	**56**
DeftPunk	95.8%	98.6%	97.1%	**4.85**

Table 7: Comparison of `DeftPunk` v.s. Layer-1/2 only.

ple metadata in an asynchronous fashion (i.e., non-blocking).

For detection, we evaluate the speedup made by the two-layer model by comparing it against the Layer-2 only model. Table 7 shows that, on processing 1 million IOs with one thread, the two-layer model only takes 4.85 seconds, yielding a 11.5× speedup over the Layer-2 only model. Including the overhead for detection, as well as data processing and transfer, we are able to process data at 140,000 IOPS using a 2.7GHz vCPU, which means that on processing 1 million IOs per second we need around 7 vCPUs.

We can enforce `DeftPunk` to run with only Layer-1 enabled for lower overhead. In Table 7, we can see that, with only first layer, `DeftPunk` can speed up 24.3% (i.e., from 4.85 to 3.72 seconds). However, both precision and recall decrease significantly (e.g., from 95.8% to 87.3% in precision). By weighing the trade-off between performance and speedup, we believe the two-layer model is the best choice for `DeftPunk`.

For recovery, `DeftPunk` introduces additional storage space because of the snapshots and write logs. For a typical 100GB VD under ransom attack, our experiments show that the storage overhead is around 150MB on average, much less than the periodical snapshots.

6.7 Deployment

Currently, we have deployed `DeftPunk` in our EBS service for limited internal users. For each internal EBS cluster (hosting more than 30K VDs), we deploy one machine (8 virtual CPU(2.7 GHz), 32 GiB Memory) to run `DeftPunk`'s detection and recovery components. `DeftPunk` has already successfully prevented two attacks with data fully recovered within 240 minutes after internal users issued reports. We expect to release `DeftPunk` for public review in the near future.

7 Potential Limitations

7.1 EBS-specific Solution

The success to `DeftPunk` is based on two properties of ALIBABA EBS, the log-structured design and block-level IO support. However, this does not mean `DeftPunk` can only be applied to ALIBABA EBS. First, the log-structured design is widely adopted in many cloud storage systems (e.g., HDFS [55]) and file systems (e.g., F2FS [47]). Practitioners can also leverage the multi-version support, snapshots and GC pausing to secure a full-copy of data modifications during attack. Second, block-level IO monitoring and analysis can be achievable for cloud vendors and system administrators. Moreover, with our open dataset and users' own traces, they can also train their own models to detect ransomware activities following our feature engineering practice.

7.2 Effectiveness on Unknown Ransomware

In this paper, `DeftPunk` shows its effectiveness on 13 types of well-known ransomware. There can be others that are not covered or even still under development. However, we believe this does not pose a great threat to `DeftPunk`'s validity. First, the zero-shot experiments show that the features of `DeftPunk` can generalize well to unseen types of ransomware. Second, `DeftPunk` can be quickly adapted to new ransomware by introducing new features and deployed to production systems as it is a pure software solution.

7.3 Threats of Mimicry Attacks

The features of `DeftPunk` arise from the three ransomware IO characteristics (i.e., Pattern 1-3 in §5.2.1). First, to encrypt, ransomware exhibit unique in-place write-after-read LBA patterns. Second, to quickly attack multiple files, ransomware would touch many files and encrypt a small proportion in each of them, yielding a wide range of sporadic LBA accessing. Third, to increase the impacts, ransomware would especially favor important areas (e.g., head region).

It is possible that future attackers may choose to evade `DeftPunk` detection by avoiding the above behaviors in their ransomware. However, we believe such efforts can be ineffective or even against the interests of ransomware (i.e., becoming less stealthy or unprofitable). First, using different access patterns (e.g., Wannacry slowdown) can still be caught by `DeftPunk` even under zero-shot setup (see §6.4). Moreover, further slowing down the IOs can backfire as it takes much longer time to finish file encryptions and can easily alert the users. Additionally, countermeasures for this slowdown attack in `DeftPunk` is straightforward—condensing the workloads (e.g., include a set of features to treat 10-minute workloads as 1-minute ones).

Second, we have seen "pseudo-ransomware" (e.g., wiperware [1]) choose not to encrypt but to directly destroy data (e.g., filling zeroes), thereby not showing write-after-read patterns (only writes, no read). But, they are no longer active as few victims would pay the ransom and current ransomware usually allows victims to decrypt a small proportion of data to show validity. In addition, we notice certain early ransomware (e.g., Gpcode.ak) do not follow in-place write-after-read but to delete original files and create new ones with encryption. However, they, too, soon have died out due to showing unusual patterns (i.e., frequent file deletion) and excessive IO traffic (creating a mass amount of files), which can be easily singled out and restored (e.g., PhotoRec for Gpcode.ak [23]).

Third, we can see that even if ransomware avoid Pattern 2 and 3 (i.e., "Only Type 1" in Figure 13), `DeftPunk` still shows high recall (98.8%). But, by doing this, ransomware would impact less files and/or target less important ones, thus being unattractive to the attackers.

In other words, Patterns 1-3 persist across all 13 families of ransomware are as a result of such patterns reflecting the fundamental nature of ransomware, especially after generations of evolutions. Admittedly, future attacks may evade detection in a different fashion or combine multiple strategies together. For example, ransomware can encrypt a selected set of important files with a more “diluted” pattern to minimize footprint.

To sum up, two lessons we have drawn from the above analysis are: (1) Closely monitoring the latest development. Propagation of new ransomware, while fast, still takes time to spread, which renders a window for us to analyze. (2) Building adaptive solutions. The security "arms race" is often inevitable and never-ending. One important advantage of `DeftPunk` is software-based and thus offers high flexibility, which further enables us to quickly adapt to emerging threats.

8 Conclusion

In this paper, we revisit a pressing problem in data security: defending against ransomware attacks. With a large-scale study on the IO characteristics of ransomware, we identify a rich set of features and leverages the log-structured multi-version properties to build `DeftPunk`, a block-level ransomware detection and recovery system. Our extensive evaluation shows that `DeftPunk` can achieve nearly 100% recall with 95.8% precision with minor overhead.

Acknowledgments

The authors would like to thank our shepherd Prof. George Amvrosiadis and anonymous reviewers for their meticulous reviews. We are also grateful for the support from the EBS team, and feedbacks by Amber Bi, Keely Xu, and Qingke X.F. on early drafts of this paper. Abstract

End-to-end encrypted messaging applications ensure that an attacker cannot read a user's message history without their decryption keys. While this provides strong privacy, it creates a usability problem: if a user loses their devices and cannot access their decryption keys, they can no longer access their message history. To solve this usability problem, users should be able to back up their decryption keys with the messaging provider. For privacy, the provider should not have access to users' decryption keys. To solve this problem, we present Secure Value Recovery 3 (SVR3), a secret key recovery system that distributes trust across different types of hardware enclaves run by different cloud providers in order to protect users' decryption keys. SVR3 is the first deployed secret key recovery system to split trust across heterogeneous enclaves managed by different cloud providers: this design ensures that a single type of enclave does not become a central point of attack. SVR3 protects decryption keys via rollback protection and fault tolerance techniques tailored to the enclaves' security guarantees. SVR3 costs $0.0025/user/year and takes 365ms for a user to recover their key, which is a rare operation. A part of SVR3 has been rolled out to millions of real users in a deployment with capacity for over 500 million users, demonstrating the ability to operate at scale.

1 Introduction

End-to-end encrypted messaging applications like Signal [85], WhatsApp [24], and Messenger [58] are used by hundreds of millions to billions of users. They provide end-to-end encryption: user devices (the "ends") encrypt user messages so application servers receive only encrypted messages without decryption keys. Only the users in a conversation can decrypt the messages locally on their devices. This paradigm protects user messages even if the application provider or cloud infrastructure is compromised.

To provide this guarantee, end-to-end encrypted messaging application providers must ensure that their users' secret keys are protected against a wide range of attacks by malicious employees, cloud provider administrators, or other privileged agents. Unfortunately, this creates a usability problem: if a user loses their secret keys, for example by losing their devices, the user loses access to their account and message history because these keys are necessary to decrypt the user's chat history and metadata (e.g., address book, social graph). The application provider cannot directly store user secret keys because it could then decrypt user messages, violating the core principle of end-to-end encryption. Therefore, users who lose their devices should be able to recover their secret keys without the provider getting access to their secret keys.

Shortcomings of many existing key recovery systems. A potential strawman is to allow the user to download their secret keys (e.g., print them on a piece of paper) and store them in a safe place [40, 46, 59], but this places extra burden on the user [76]. A more user-friendly approach to this problem is to allow a user to use a password or a PIN to encrypt their key [33]. Unfortunately, these are often vulnerable to brute-force dictionary attacks [82, 83]. Furthermore, standard safeguards (e.g., forcing the attack to be performed online) can easily be circumvented by the application provider.

Current deployed systems [4, 43, 51, 88, 96, 98] prevent brute-force attacks by using secure hardware to limit the number of PIN guesses. This approach provides a strong protection against service provider administrators and cloud providers. While these systems all represent significant advances in password-based key recovery, they rely on the security guarantees of a *single* type of secure hardware. Although secure hardware is a powerful tool for enhancing the security of systems, it can eventually be subverted—attackers have extracted user secrets from secure hardware in the past [12, 14, 31, 35, 62, 75, 79, 87, 90, 91, 94, 95]. In these systems, compromising just one type of secure hardware enables an attacker to recover many users' secret keys, which is a catastrophic scenario for any popular encrypted system.

[*] Equal contribution.

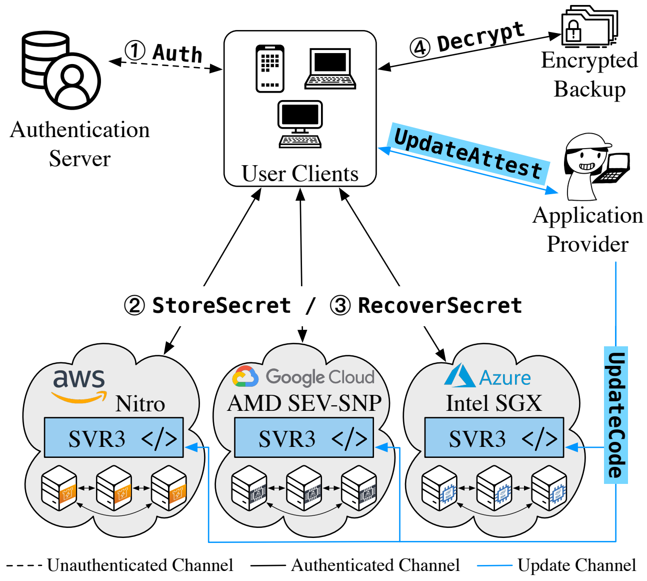

Figure 1: System architecture for $n = 3$ enclave clusters, with each cluster using a different type of hardware enclave.

Key recovery without a single point of security failure. In this paper, we contribute **S**ecure **V**alue **R**ecovery **3**[1], a PIN-based secret key recovery system that prevents any one type of enclave or cloud provider from becoming a central point of attack. Our security properties are informed by the observation that many vulnerabilities are quickly patched, and so it is challenging for an attacker to find vulnerabilities *simultaneously* on different enclave architectures. SVR3 proposes a layered architecture, illustrated in Figure 1, consisting of a tailored cryptographic multi-server key recovery protocol that distributes trust across three different enclaves from three distinct hardware vendors on three major clouds: Intel SGX in Microsoft Azure, AMD SEV-SNP in Google Cloud, and Nitro in AWS. SVR3 ensures that even if an attacker simultaneously compromises two of these enclave types and the respective clouds, the attacker cannot reconstruct the user's secrets due to the cryptographic protocol. The attacker needs to simultaneously compromise the security of all of the clouds and all of the enclave types to reach user secrets.

We implemented SVR3 as a production-ready system embedded in Signal Messenger [85], an end-to-end encrypted messaging application with tens of millions of users. We have already deployed an initial version of SVR3's implementation to millions of users globally, and the fully featured system is in the process of deployment at the time of publication. A third-party auditor, NCC Group, audited the deployment of Signal's SVR2, a predecessor system currently in production and using SVR3's consensus protocol on a single trust domain. SVR3 is open source [84] and can be used by any end-to-end encrypted system that needs secret key recovery (e.g., encrypted messaging [24, 85], email [72, 74], or storage [99]). To the best of our knowledge, SVR3 is the first deployed cross-enclave, cross-cloud secret key recovery system. The servers for SVR3 cost only \$0.0025/user/year and it takes 365ms for a user to recover their key, which is a rare operation.

Design decisions. Our design choices were guided by the goal of developing a real-world PIN-based key recovery system that prevents dictionary attacks, is easy and affordable to maintain, and provides security even if a particular enclave or cloud provider is vulnerable. We summarize the key decisions below.

A layered security architecture (§2–§3). We aim to protect users' secrets against three major classes of attackers: cloud attackers, an internal application provider attacker, and external hackers. To achieve this, one strawman is to distribute trust across multiple organizations. However, finding reliable and trustworthy such organizations is difficult and expensive [21, 50]. Instead, we introduce an architecture that layers cryptographic security on top of hardware security by using different types of enclaves in different clouds. The hardware enclaves enable creating three separate trust domains, and the cryptographic tools split secret keys across the trust domains.

PPSS to distribute trust (§4). Password Protected Secret Sharing (PPSS) [5] provides password-based key recovery while distributing trust across multiple backends and limiting attackers to online dictionary attacks. Different PPSS schemes have different deployment consequences, and we select the construction by Jarecki et al. [37] primarily because it requires no cross-trust domain communication and the server design enables clients to use different secret sharing schemes if they wish. We use this protocol to construct our one-round key recovery protocol, where the servers receive no information about whether the PIN guess was correct, and the servers unconditionally delete key material after a fixed number of PIN guesses (which can be refreshed by the clients). This is in contrast to existing works [85, 88, 98], which rely on password-based authentication and require multiple communication rounds.

Rollback protection through enclave memory and consensus (§5). Like Signal's original SVR1 system [85], SVR3 protects against *software* rollback attacks by keeping all data (e.g., guess counts) inside enclave memory. In order to prevent data loss, we replicate data across multiple enclaves in the same cloud. SVR1 uses the original Raft consensus protocol [66], which is not safe under *physical* rollback attacks. In principle, an attacker with physical access (e.g., a DIMM interposer [89]) to a single server in a vanilla Raft replica group could take control of the group and roll back log entries. To defend against such attacks, we develop a modified Raft [66] protocol, Raft$^{\circlearrowleft}$, that provides safety under physical rollback attacks, as specified in §3.2. We prove its safety under a formal TLA+ [45] model in the face of physical rollback attacks.

[1] This is the third generation of Signal's SVR service and succeeds SVR1 [51], which did not distribute trust across multiple types of secure hardware. (SVR2 was a transition system consisting of a partial SVR3 design.)

Secure code updates via auditing (§6). To enable code updates while providing strong security, we allow clients to audit the deployed code and explicitly disallow sharing of data between different (server) binary versions. Data migration between binary versions flows through the client, and clients can determine whether or not to store their secret value on each version of the binary.

Limitations. SVR3 relies on the underlying security guarantees of the enclaves it employs; supporting a new enclave or a new version of an existing enclave would require carefully reasoning about how it fits into the threat model. Splitting infrastructure across multiple cloud providers also incurs higher monetary costs than deploying on a single provider, but offers stronger security assurances. Finally, SVR3 does not support recovering the user PIN that is used in secret key recovery (i.e., if a user forgets their PIN, they cannot recover their key). We mitigate this in practice by periodically prompting the user to re-enter their PIN on the messaging client to prevent permanent lockout.

2 System overview

2.1 System architecture

Figure 1 shows the system architecture for an SVR3 deployment with three cloud providers, with the following entities:

Enclave clusters. The application owner deploys n enclave clusters (in our deployment, $n = 3$). To strengthen security, each enclave cluster should run on a different type of enclave in a different cloud environment (see §3). We will refer to each enclave cluster running on different hardware in a different cloud as a trust domain. Enclave clusters maintain replicated storage and respond to messages from clients. Each enclave cluster consists of a load balancer, a discovery service, and a geographically distributed replica group.

Authentication server. The authentication server establishes authenticated channels between clients and enclave clusters. The authentication server prevents malicious clients from exhausting PIN attempts for honest users because a client needs to authenticate to the authentication server (e.g., via an SMS code) before interacting with the enclave clusters.

Clients. Clients (e.g., mobile phones or laptops) interact with the authentication server and nodes in the enclave clusters in order to back up and recover their secret keys.

Application provider. The application provider will update the software and run monitoring and maintenance to ensure that the system is available and healthy.

2.2 System API

As shown in Figure 1, SVR3 exposes the following client API:

- Auth(client_id, client_cred) → auth_token: Establishes authenticated channel between client and server.

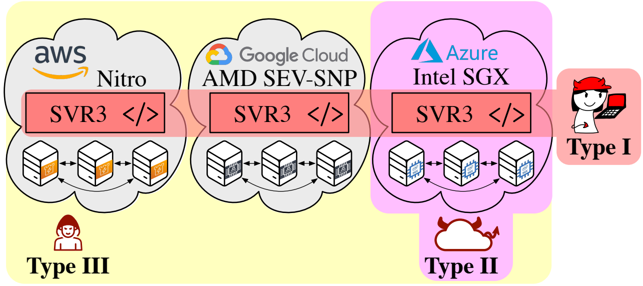

Figure 2: Types of attackers SVR3 protects against.

- StoreSecret(client_id, auth_token, val, pin): Backs up a value val for an authenticated client using a human-memorable PIN value pin and an authentication token auth_token.
- RecoverSecret(client_id, auth_token, pin) → {secret, ⊥}: Recovers the value secret for client if (and only if)
  - auth_token is valid for client_id,
  - pin matches the PIN provided at StoreSecret time for client_id, and
  - the number of unsuccessful RecoverSecret attempts for client_id does not exceed a set guess limit.

  Otherwise, outputs ⊥.

The client can use their recovered secret to locate, authorize access to, and decrypt their encrypted backup.

We describe how the developer updates SVR3 in §6.

3 Threat model and guarantees

SVR3's goal is to protect users's secrets. SVR3 provides different security guarantees against three types of server attackers, shown in Figure 2:

- **Type I (Internal).** This attacker compromises the organization deploying SVR3 (e.g., a malicious employee). This attacker does not have physical access to the cloud deployment, but can freely spin up and bring down machines and modify the software being run.
- **Type II (Cloud).** This attacker represents an entity with control over the physical infrastructure SVR3 is deployed on (e.g., a single cloud provider). While this attacker does not have the same degree of access to the entire multi-cloud system deployment, it can leverage physical access and tamper with the hardware running SVR3.
- **Type III (External).** This attacker is external to the deployment of SVR3 (e.g., a hacker), and attacks all parts of an organization's surface.

We express SVR3's security guarantees at two levels: (1) at the level of trust domains (§3.1), defining security in terms of which trust domains are not compromised, and (2) at the level of enclaves inside a trust domain (§3.2), specifying the conditions under which a trust domain is not compromised.

Like other end-to-end encrypted systems [72,74,98], if a user's device is compromised, SVR3 provides no guarantees to that user. For an uncompromised user device, we rely on the trustworthiness of client code released by Signal; we enable the community to scrutinize the client code and build trust in it by making it open-source [55–57].

SVR3 does not hide the identity of clients or the timing of backup and recovery requests.

3.1 Security across trust domains

SVR3 protects users' secret keys if at most t out of n trust domains are compromised. We assume that the odds of an attacker identifying and exploiting vulnerabilities *simultaneously* across $> t$ trust domains is low, which motivates our threat model. By simultaneous, we mean within the time period it takes to become aware of a vulnerability and replace the enclaves in the trust domain impacted by that vulnerability.

In our deployment of SVR3, we set $t = 2$ and $n = 3$, so we ensure security as long as at least one trust domain is not compromised. We limit PIN guesses by selecting a parameter u, a server *usage limit*.

Theorem 1 (Informal)**.** *In an SVR3 deployment configured with n trust domains, threshold t, and a usage limit u, assuming a password-protected secret sharing scheme (defined in §4.2), if an attacker compromises $\leq t$ trust domains, then SVR3 ensures that, for each secret key, the attacker only has $\lfloor \frac{nu}{t+1} \rfloor$ PIN attempts and, after that, cannot recover the secret key.*

We describe how SVR3 achieves Theorem 1 in §4.2.

3.2 Security within a trust domain

We now describe the threat model we consider when instantiating the trust domains assumed in §3.1. Recall that each trust domain consists of an enclave cluster and that each trust domain should use a different type of enclave.

3.2.1 Enclave threat model

SVR3's design is not tied to some specific enclave implementations. Different enclaves vary in design, so we abstract out the security properties that we require from the enclaves employed for SVR3's security guarantees (§3.2.2) to hold. An *uncompromised enclave* must provide:

(E1) *Application-level attestation*. The enclave can prove that certain code is running before other systems interact with it.

(E2) *Access control*. Enclave memory is encrypted, and access control is hardware-enforced to prevent all non-enclave access.

(E3) *Page-level rollback granularity*. The attacker can replace pages of data in the enclave's memory with older pages from the same physical location and can mix and match old and new pages, thus violating global memory integrity. We assume that an attacker cannot mount these attacks at a sub-page granularity (e.g., address level) either because the enclave protects this or other protection mechanisms are used in the enclave (see below).

Deviations from enclave threat model. We describe the properties of different enclaves and how they fit our threat model in §A of the full version [17]. Some recent enclaves use AES-XTS, which encrypts in 16B increments [15]. While our design currently targets enclaves that can only be rolled back at the page-level granularity (E3), we can implement atomic regions (regions that are guaranteed to run without interruption by an attacker) by utilizing the interrupt handler introduced by AEX-Notify [18]. We describe how to do so in §5.3. Given the changing landscape of enclave implementations and the possibility that enclaves may not adhere to (E1)–(E3) in the future, we assume that alternative mechanisms like AEX-Notify can be developed to address such discrepancies between real-world enclaves and our enclave threat model.

Attacks on enclaves. Enclaves are susceptible to attacks. We list four categories here and then discuss when SVR3 hardens a trust domain against them.

(A1) *Memory access pattern attacks*. Enclaves do not hide memory access patterns, enabling a large class of side-channel attacks, including but not limited to cache attacks [9,32,61,80], branch prediction [48], paging-based attacks [93, 100], and memory bus snooping [47].

(A2) *Software rollback attacks*. Enclaves are also susceptible to rollback attacks, also referred to as freshness or replay attacks [69]. Software rollback attacks occur from rolling back persisted state outside of the enclave's memory (**Type I** attacker).

(A3) *Hardware rollback attacks*. An attacker with physical access to the system bus can roll back enclave memory at the page level without detection (**Type II** attacker), for example, using a DIMM interposer [89].

(A4) *Other attacks*. Certain physical attacks allow an attacker to break guarantees (E1)–(E3) of enclaves (e.g., leakage due to power consumption [14, 62, 87] or denial-of-service attacks due to memory corruptions [31, 35]). Transient execution attacks [12,75,79,90,91,94,95] exploit speculative execution to leak secret data.

3.2.2 Security guarantees

SVR3 *hardens* a trust domain against a set of attacks, rendering the trust domain uncompromised despite those attacks. We describe the conditions below:

(H1) SVR3's memory-access patterns do not depend on user secret content, and hiding *which* user is recovering their key is a non-goal for SVR3, so it does not suffer from memory-access patterns side-channel attacks (A1).

(H2) SVR3 defends against software rollback attacks (A2).

(H3) SVR3 defends against hardware rollback attacks (A3) as long as $\leq s$ nodes in each cluster are simultaneously rolled back, where s is a fault-tolerance ("supermajority") parameter defined in §5.2.5. In our production deployment, we set $s = 2$.

(H4) Within a trust domain, SVR3 does not guarantee protection against other attacks (A4), which could render the trust domain compromised. In this case, SVR3 still offers the cross-trust domain security guarantees in §3.1.

3.3 Availability

Like other end-to-end encrypted systems [72, 98], Signal prioritizes security over availability of secret key recovery because users' secret keys are extremely sensitive and crucial to safeguard in an end-to-end encrypted system. Nevertheless, SVR3 provides availability to clients when at least $t+1$ trust domains are operating correctly. By correct operation, we mean that enclaves in the trust domain are online and none of the enclaves in the trust domain are under attack. Therefore, we expect the system to be available under normal operation.

SVR3 also does not defend against denial-of-service (DoS) attacks from a **Type I** attacker (since this is the organization that deploys SVR3 itself) or the authentication server.

SVR3 ensures that a malicious client cannot deny availability for an honest user (e.g., by exhausting the number of PIN attempts allowed) assuming that the attacker did not compromise the client credentials or the authentication server (used to Auth in Figure 1), and it did not otherwise compromise the servers beyond the availability threshold above.

It is important to consider what users would experience if trust domain(s) were to fail, leading to secret value loss. While this is a significant event when viewed from the perspective of the application provider, it will not lead to secret value loss for the majority of clients in practice: clients cache their SVR3-protected secret, and so clients can simply create a backup at the new deployment. Thus data loss is only a concern for users who lose their devices after the old deployment fails and before migration to the new deployment completes.

4 Secret key backup and recovery protocols

We now describe the cryptographic protocols in SVR3.

4.1 Establishing enclave sessions

To interact with the SVR3 servers, the client must first authenticate with the authentication server. If the user has lost their devices, then the authentication server sends the client an SMS code, and then the user enters the SMS code to receive a token. This process allows the authentication server to prevent malicious clients from denying service to honest users by exhausting all of their PIN attempts. Notably though, the authentication server does not have any information about user PINs. The client then uses this token to establish a secure channel with a replica in each trust domain. As part of the process of establishing a secure channel, the client runs remote attestation [16] with the enclaves to ensure that it is communicating with the expected enclaves.

4.2 PIN-protected secret sharing

In existing deployed PIN-based backup systems [43,51,96,98], a secure hardware device has access to users' secret keys and PINs or PIN-derived information in order to authenticate users. This design means that an attacker that compromises the secure hardware can, either directly or via a brute-force attack, learn user PINs. This property is particularly problematic when we consider the fact that many users re-use PINs across services.

As a result, when designing our cross-enclave cross-cloud solution, we cannot simply instantiate the above mechanism in each trust domain. Any one compromised trust domain would have access to the PIN, enabling the attacker to recover the user's secret key. Instead, we leverage the class of cryptographic protocols called *password-protected secret sharing (PPSS)* [5] protocols, which ensure that:

- An attacker that compromises $\leq t$ trust domains is still limited to an online dictionary attack.
- If an attacker fully compromises $> t$ trust domains, the attacker does not immediately learn client secrets. The attacker still must perform an offline dictionary attack on user PINs.

Identifying a suitable PPSS scheme for SVR3. Different PPSS schemes have different tradeoffs [1, 5, 36–38], so we worked to identify the most suitable scheme for SVR3 and then tailor it to our setting. Some prior work optimizes for metrics that are not important to our deployment, but sacrifices properties that are important to us.

For example, many of these works aim to reduce the number of exponentiations to improve efficiency [1, 36–38]. However, the number of exponentiations is not a bottleneck in our setting, especially because the number of trust domains (3) is small. The scheme with the fewest exponentiations [38] also requires coordinated server initialization and necessitates choosing secret sharing parameters at deployment time. Coordinated initialization could require us to redeploy all trust domains every time a single trust domain requires a security upgrade, and cross-trust-domain communication with security against **Type I** attackers is difficult. Choosing a secret sharing scheme at deployment time tightly couples PPSS parameters with clients and servers, removing the flexibility to modify client PPSS parameters without also changing the servers.

With these priorities in mind, we identified the PPSS from Jarecki et al. [37] as the most suitable because it is particularly simple: each backend generates a new secret key for a client when the client creates a new backup and then uses this key to evaluate an oblivious pseudorandom function (OPRF) [28] during secret reconstruction. Informally, a pseudorandom function (PRF) is a keyed function $F_k(\cdot)$ that, for a randomly chosen key k, appears to be random (indistinguishable from a function chosen uniformly at random from all functions with the same domain and range), even though it is deterministic and efficiently computable. An *oblivious* PRF is a two-party protocol where the server holds k and the client holds some input x. The protocol enables the client to learn $F_k(x)$ without the server learning anything about x or $F_k(x)$.

This PPSS scheme has several properties that are appealing for a real-world deployment:

- The protocol is one-round and concretely efficient.
- Different trust domains do not communicate with each other.
- Servers need minimal configuration. In particular they do not need any information about the threshold scheme being used, and different clients can use the same server with different threshold schemes.
- The protocol can use a standards-track OPRF with optional verifiability [23].

We note that the WhatsApp key recovery system uses a password-authenticated key agreement (PAKE) scheme [24, 98], and SVR3 does not. While PAKE protocols are a commonly cited application for PPSS schemes, we do not need to establish a session between our client and a server. We only need to recover a secret key, which is a simpler problem. Since branching while fetching secret shares is not sensitive, we do not need to layer oblivious data retrieval on top [22, 60].

Augmenting PPSS with usage limiting. Limiting attackers to a fixed number of password guesses is a core requirement for SVR3. While the application provider can use an authentication server for access control and rate limiting, this only restricts external users. SVR3 must limit powerful attackers with full administrative and physical access to the servers to the same finite number of guesses.

We solve this by leveraging our distributed-trust setting to enforce a *usage quota* on OPRF evaluations. A standard OPRF [28] allows a server with a PRF key to evaluate a PRF on a client input without learning the input. SVR3 allows the client to set a usage limit, u, at registration time, and each honest trust domain will delete that client's OPRF key after u OPRF evaluations. In order to instantiate an honest trust domain, we use enclaves to ensure that the server enforces the usage limit. Note that the security guarantees provided by PPSS and the heterogeneous enclaves are tightly coupled: the enclaves are critical for instantiating trust domains, and PPSS enables splitting a secret value across different trust domains.

In the below proposition, we bound the number of total OPRF evaluations based on the threshold t and trust domains n, providing the protection described in Theorem 1.

Proposition 1. *For a (t, n) instance of PPSS [37] with a usage-limited OPRF configured to allow u evaluations, an adversary has at most $\lfloor \frac{nu}{t+1} \rfloor$ PIN attempts before the secret cannot be recovered.*

Proof. Only nu OPRF evaluations are possible in the system. $t+1$ evaluations are needed to perform one PIN attempt. After $\lfloor \frac{nu}{t+1} \rfloor$ PIN attempts, $(t+1)\lfloor \frac{nu}{t+1} \rfloor$ OPRF evaluations have been used. Only $(t+1)\{nu/(t+1)\} < t+1$ more evaluations are possible, where $\{\}$ denotes the fractional part, that is, $\{x\} = x - \lfloor x \rfloor$. This is not enough to reconstruct the secret. □

5 Building a SVR3 backend

We now describe SVR3's system design within one trust domain. Per our threat model in §3, each uncompromised SVR3 trust domain consists of a cluster of machines, which we assume behave correctly except for possible physical rollback attacks and crash failures within a specified bound.

5.1 Design decisions

We first provide an overview of the design decisions behind SVR3's design to ensure fault tolerance and the security guarantees in §3.2.2.

Use of enclaves. In order to protect server secrets and allow clients to check the code that is processing their data, we run the core part of the service in an attested, confidential enclave.

In-memory database to avoid sealing. Data sealing is a mechanism whereby an enclave can encrypt internal state with a key that is unique to the platform and enclave, persist the encrypted data to disk, and then recover it if the enclave is torn down and restarted. As noted in prior work [26, 97], applications in commercially available enclaves that use data sealing to store state externally and recover from crashes are vulnerable to simple, software-based rollback attacks. Since a core function of SVR3 is to faithfully maintain a per-user OPRF evaluation count, rollback attacks would undermine the system and could allow an attacker unlimited online password guesses. To prevent this and achieve (H2), the enclave that stores the database of client secrets and usage counters is kept entirely in enclave-protected memory; it is *never* sealed and written to untrusted memory or disk. We show that the database fits entirely in memory without sharding users in §8.1.

Distributed consensus. Without a data persistence mechanism (e.g., data sealing), the servers cannot recover from crashes, and data in any failed server will be lost. To ensure that data is not lost, we build the service as a geographically distributed database. To ensure split-brain or other attacks do not allow excess PIN guesses, we use a distributed consensus protocol, modified from Raft [66]. We give a high-level overview of vanilla Raft in §5.2.1. Our modified Raft protocol, Raft$^{\circlearrowleft}$, which we describe in §5.2.3, hardens vanilla Raft against physical rollback attacks and ensures that client requests and usage count changes are committed before responding to client queries. We describe in §5.3 how we use Raft$^{\circlearrowleft}$ to achieve global integrity across the database when assuming page-level rollback granularity of enclaves (E3), achieving (H3).

5.2 Rollback-resistant consensus protocol

SVR3 already protects against the class of rollback attacks that arise from storing state outside of the enclave by keeping all state in memory. However, as discussed, machines can fail, and so in order to tolerate failures without losing data, we use Raft$^{\circlearrowleft}$, a modified version of vanilla Raft across enclaves from a cloud provider. A full TLA+ description of Raft$^{\circlearrowleft}$ is available in §E of the full version [17], and we provide a proof of safety based on the TLA+ specification in §D.

In this paper, we use n to refer to the number of trust domains and m to refer to the number of replica machines *within* a trust domain.

5.2.1 Vanilla Raft background

Raft [66] is a consensus algorithm that manages a replicated log across multiple nodes (replicas). It elects a single leader replica that receives and replicates log entries to the other follower replicas. The leader handles all client requests by appending new log entries and sending an AppendEntriesRequest to each follower for the duration of its *term*. Follower replicas respond to requests from the leader to replicate log entries. If the leader fails, a new leader is elected through a leader election process. Log entries are identified by `<index, term>`, where `index` is the log position and `term` is the current term number. There is at most one leader in any given term. A leader forces the followers' logs to duplicate its own: conflicting entries in follower logs (with some `term` t) will be overwritten with entries from the leader's log if the leader's term t' is $\geq t$. For f crash failures, Vanilla Raft requires $m \geq 2f+1$ replicas in order to provide safety and liveness.

5.2.2 The physical rollback problem

While keeping the database in memory protects against software rollback attacks, an attacker with physical access to the system bus could roll back enclave memory at the page level. Since such an attack is more expensive to perform than software-based rollback attacks, we can significantly improve security by requiring an attacker to perform these attacks simultaneously on multiple enclave replicas. With this context, we note that the vanilla Raft protocol [66], as specified, will allow an attacker who can roll back a Raft leader to make an unlimited number of PIN attempts: the Raft protocol does not look at log contents, so if a leader is rolled back and sends an AppendEntriesRequest for a new `<index, term>` log entry at an old log index, followers will accept it and allow the leader to commit.

Prior work [26, 97] has addressed a problem close to this one, but with important differences. First, they are designed for data-sealing rollbacks, which do not affect SVR3 because we do not use data sealing. Second, Raft$^{\circlearrowleft}$ also defends against physical rollback attacks, which prior works do not consider in their threat model. Physical rollback attacks are more difficult to detect than data-sealing rollback attacks: after a crash recovery, the new enclave has to execute code that decrypts the sealed data to rebuild the internal state and every data-sealing rollback needs to have the enclave go through this code path. The RR protocol [26] takes advantage of this process to detect data-sealing rollback attacks. Finally, existing protocols aim to ensure liveness in the face of rollback attacks, and this is an explicit non-goal for SVR3 as mentioned in §3.3.

5.2.3 Rollback prevention in Raft$^{\circlearrowleft}$

Together, the following additions to the Raft protocol enable us to prove safety of Raft$^{\circlearrowleft}$ in the presence of an attacker who can simultaneously mount physical rollback attacks against $\leq s$ nodes. For m Raft$^{\circlearrowleft}$ servers in a trust domain, s must be strictly smaller than m to ensure safety (§5.2.4). However, to ensure fault tolerance and liveness in the face of crash failures, s should be even smaller (§5.2.5).

Hash chain. Instead of using `<index, term>` to identify a log entry, as in Raft, we use `<index, term, hash`$_{\texttt{index}}$`>` where `hash`$_{\texttt{index}}$ = `Hash(entrydata, index, term, hash`$_{\texttt{index-1}}$`)`, `entrydata` is the contents of the log entry, and `Hash` is a cryptographic hash function. When a follower receives an AppendEntriesRequest, it computes the expected hash chain value and verifies that it matches the value in the request. If the values do not match, the follower rejects the request.

This prevents the simple rollback attack on Raft described in §5.2.1. However, it is still possible for an attacker who can roll back one server to gain unlimited password guesses by triggering an election with a quorum of servers that did not see the log entry for the first client request.

Supermajority. To ensure that an attacker capable of rolling back a single server cannot gain extra password guesses by triggering an election, we require quorums to have a supermajority of replicas so that the intersection of any two quorums contains more than s replicas, where s is a configurable parameter that is included in the server's attestation. This allows clients to be certain of the value of s used by the service and decide whether to accept it. We prove that an attacker must be able to roll back more than s enclaves to roll back a log entry that was committed by this Raft$^{\circlearrowleft}$. This supermajority parameter is comparable to PBFT's Byzantine nodes value [10].

Promise round. We add a *promise round* to the protocol. We discuss reasoning for why we add a promise round in the full version [17]. Once a quorum of servers acknowledges seeing a log entry, the leader will “promise" this entry by advancing its `promise_idx` to the index of this entry. A promised entry is not committed, but no replica will delete an entry that has been promised. This completes the first round.

The leader now sends its `promise_idx` to all followers in its next AppendEntriesRequest, and followers will update their own `promise_idx` to match the leader's when they process the message. From this point, these followers have promised the log entry and will not delete it. The followers send their current `promise_idx` with each AppendEntriesResponse. Once a quorum of replicas has promised an entry, it is committed.

5.2.4 Safety

In order to achieve safety, the number of machines in the enclave cluster must be larger than the number of rollback attacks we want to tolerate ($m > s$). As liveness under rollback attacks is a non-goal for SVR3 (an attacker with physical access can easily deny service), we decouple the constraints on m with respect to rollback attacks (s) and crash failures (f_c). We describe how s impacts liveness under crash failures in §5.2.5. We prove that Raft$^{\circlearrowleft}$ is safe under a bounded number (s) of physical rollback attacks within a trust domain.

Theorem 2 (Informal)**.** *Let M_R be the maximum number of machines in an enclave cluster that can be rolled back and s be our supermajority configuration parameter. If $M_R \leq s$, then under standard cryptographic assumptions, for every log entry <`index, term, hash`$_{index}$> that has been applied to the state machine of a server i, server i will never apply a different log entry at this index.*

Proof sketch. The argument follows the proof of safety in Ongaro [65] and relies on the observation that any two quorums will have an intersection that includes at least one server that has not been rolled back. We must address the fact that in the presence of rollbacks, Lemma 3 in Ongaro [65] does not hold. This poses a significant challenge, and forces us to introduce a new concept of *live committed* entries that is subtly different from the prior notion of committed [65]. With our definition, future leaders may not have a live committed entry in their log, but if they do not then they will be unable to commit new entries, so we retain safety at the expense of liveness. The major point where the argument from Ongaro [65] breaks down in our setting is in points 7.c.ii.B and 7.c.iii.B in the proof of their Lemma 8. Our argument uses the hash chain and promise index to show that there is a voter in the intersection of two quorums that has not been rolled back and will not replace the log entry. The complete proof of safety is in §D of the full version [17].

5.2.5 Liveness

We do not provide liveness for a trust domain under the setting of an attacker mounting physical rollback attacks, as the attacker could trivially deny client requests by taking the entire enclave cluster offline. When assuming no attacks within a trust domain, Raft$^{\circlearrowleft}$ requires $f_c \leq \lfloor (m-s)/2 \rfloor$ *crash* failures to be live under normal connectivity conditions, where m denotes the number of replicas in a trust domain (enclave cluster) and s denotes the supermajority parameter described in §5.2.3. This is due to the quorum size being $\lfloor (m+s)/2 \rfloor + 1$ enclaves. It remains an open problem to prove liveness of Raft in this setting (e.g., by formal verification [34]). Nevertheless, as discussed in §3.3, SVR3 still provides availability to clients when at least $t+1$ trust domains are operating correctly.

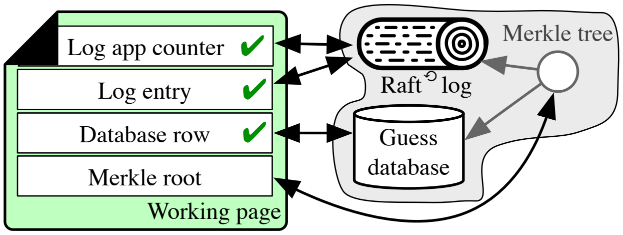

Figure 3: Integrity across database. In order to achieve global integrity, updates are only applied when all state on the working page validates under the same Merkle tree root.

5.2.6 Self-healing for simple maintenance

We implement the process for replica group membership changes described in the Raft paper [65] and add a layer of automation. In Raft$^{\circlearrowleft}$, a replica group has a configured target number of voting members. For a healthy configuration, a replica group in our system will have this number of voting members as well as several non-voting members that stay up to date and service client requests. If some voting member is not seen by the leader after a configurable timeout, the leader will initiate a membership change that demotes the missing replica to non-voting status. After an additional timeout, it will remove the replica from the group entirely.

Furthermore, whenever the number of voting members is below the configured target, the leader will check to see if a non-voting member is present and initiate a membership change promoting a non-voting member to voting status.

With these mechanisms in place, administrators simply need to launch new instances and direct them to the discovery service with group information. The new server will then request to join the group, be brought up to date by a peer, and become a non-voting member. As needed, the voting members may then promote this new replica to voting status.

5.3 Integrity across the database

Raft$^{\circlearrowleft}$ provides protection against rollback attacks on the contents of the log. However, our threat model (§3) assumes *page-level* rollback granularity on memory inside the enclave, which means that the attacker can replace pages of data in the enclave's memory with older pages from the same physical location and can mix and match old and new pages, thus violating *global* memory integrity.

In order to protect against rollback attacks on the backing in-memory database, SVR3 keeps a Merkle tree across the Raft$^{\circlearrowleft}$ log, database, and log application counter.

5.3.1 Merkle tree

The log application counter keeps track of the latest log entry that has been applied to the database. The Merkle tree contains every database row, the hashchain of the most recently committed log entry, and the log application counter. The hashchain of the last committed log entry, as described in §5.2.3, can be used to verify this entry and earlier entries in the log. As shown in Figure 3, the Merkle leaves for database rows and log application counter are updated each time the underlying object changes, and the update only succeeds if the current state of the Merkle tree is consistent with the previous value of that data.

5.3.2 Applying committed log entries

We describe how we process committed log entries in Algorithm 1. The executing thread holds a lock on the database, log, and log application counter throughout execution, so no honest process will have a thread outside this process change the Merkle tree during that execution. When applying a commited log to the local database, a replica will begin by reading the log application counter lac, the log entry at that index entry, and the database row row referenced by that log entry onto a single memory page, which we will call the *working page*. When reading each of these items, it will verify its Merkle proof ($\Pi_{\text{lac}}, \Pi_{\text{entry}}, \Pi_{\text{row}}$) and also copy the root of the Merkle tree for each read onto the working page. After copying this data, we verify that the Merkle roots associated with each read are equal, determine whether the number of uses of this row has surpassed the configured maximum, and update the row by incrementing the usage count and deleting the OPRF secret if the maximum usage count has been exceeded. We then update the row in the database and increment the log application counter, updating the Merkle tree entries for both, then proceed with evaluating the OPRF, if the key is present, and finally respond to the client.

If the attacker rolls back the database row to the contents of a previous timestep, it first has to roll back every entry from the row to the Merkle tree root. However, the root also covers the log entries and log application counter, which are modified when a database row is modified (how SVR3 achieves atomicity of this operation is described above). Thus, the attacker will have to roll back the log as well; rolling back the log is exactly what Raft$^{\circlearrowleft}$ protects against.

Atomic regions. Because all of our working memory fits on a single page, operations are atomic with respect to the attacker's ability to rollback memory at the page granularity. In order to support more modern enclaves that only have cache line granularity (e.g., 16B), we need to implement atomic regions that are guaranteed to run without interruption by an attacker. We describe in detail how to implement atomic regions on SGX and SEV-SNP in §C of the full version [17] by utilizing the interrupt handler in AEX-Notify [18]. AEX-Notify mitigates SGX-Step, an attack framework that makes it possible to single-step enclave programs [92]. It does so by introducing an instruction set architecture extension to support a custom handler on interrupt. The SGX-Step mitigation leverages this handler to speed up the next instruction so that the attacker is statistically unlikely to 'hit' the next instruction's execution with an APIC timer. This mechanism also allows us to implement atomic regions, in a similar fashion to restartable sequences [8]. At a high level, we set a flag in a fixed register when an interrupt occurs, and we check this flag at the end of the atomic region to determine whether to restart the atomic region. If the flag is set, we restart and retry until it runs without any interrupt. We leave optimizing this approach in a secure manner to future work.

Algorithm 1 Applying a committed log entry. We describe in text how we process committed log entries in §5.3.2.

```
$\text{workspace}_R \leftarrow (\text{lac}, \Pi_{\text{lac}}, \text{entry}, \Pi_{\text{entry}}, \text{row}, \Pi_{\text{row}})$
Atomic region.
                                  ▷ Abort on any Verify failure.
    $\text{failure} \leftarrow 0$
    $\text{Verify}(\Pi_{\text{lac}}.\text{root} \overset{?}{=} \Pi_{\text{entry}}.\text{root} \overset{?}{=} \Pi_{\text{row}}.\text{root})$
    $\text{Verify}(\text{entry.clientid} \overset{?}{=} \text{row.clientid})$
    $\text{Verify}(\text{lac}, \Pi_{\text{lac}}); \text{Verify}(\text{entry}, \Pi_{\text{entry}});$
    $\text{Verify}(\text{row}, \Pi_{\text{row}})$
    if $\text{row.guess\_cnt} < \text{max\_guesses}$ then
        $\text{evaluated} \leftarrow \text{OPRFEval}(\text{row.sk}, \text{blinded})$
        $\text{row.guess\_cnt} \leftarrow \text{row.guess\_cnt} + 1$
    else
        $\text{failure} \leftarrow 1$
        $\text{row.sk} \leftarrow 0, \text{row.guess\_cnt} \leftarrow \text{UINT\_MAX}$
    end if
    $\text{workspace}_W \leftarrow (\text{row}, \text{UpdatePrf}(\text{row}, \Pi_{\text{row}}))$
$\Pi'_{\text{row}} \leftarrow \text{UpdatePrf}(\text{row}); \Pi'_{\text{lac}} \leftarrow \text{UpdatePrf}(\text{lac})$
Check that leaves on path in $\Pi'_{\text{row}}, \Pi'_{\text{lac}}$ match $\Pi_{\text{row}}, \Pi_{\text{lac}}$.
if failure then return MISSING
else return (OK, evaluated)
end if
```

6 Operations

Production systems need upgrades. This is a challenge for us because we want to defend against malicious administrators: a secure system can become completely insecure if a malicious administrator can push arbitrary code to the system. At a high level, we defend against malicious code updates by ensuring that users can audit the code that is running; the code is open source, and enclaves attest to the security-relevant server code and configurations running.

Adding new servers. When a new server is launched in a trust domain, it connects to a discovery service and registers a new group if no replica group is registered. If there is an existing replica group, the new server will select a peer in that group, validate that its enclave measurements match, and create an attested connection with that peer. By checking that enclave measurements match, SVR3 ensures that an administrator cannot add a server running different code. The new server then requests to join the group, and the existing server transfers all log entries and database rows to the new server. This is done over a Noise protocol [71] channel with key resetting and hybrid post-quantum forward secrecy [70] to provide robust forward secrecy. Once the transfer is complete, the replica group goes through the membership change process to add the new server (which requires a quorum).

Sometimes security-required microcode updates need to be applied to all servers. Since all data is kept in volatile enclave memory, there is no way to reboot the machine without losing all replica data. In this situation, *all members of the cluster must be replaced.* This can be done by sequentially adding new servers on patched hardware, then terminating old servers.

Clients. Android, iOS, and desktop clients are deployed through app stores with auditable, open-source code. Each client contains hard-coded information about which enclave measurements (for remote attestation), platform versions, and cluster configurations to accept. If a client attempts to connect to a SVR3 cluster and finds unexpected measurements or configuration, it will abort the connection.

Service upgrades and data migration. Since server enclaves can only communicate with peers that share the same enclave measurements, there is no mechanism to migrate data directly from an old version of an enclave-backed service to a new one. Instead, data migration flows through the client. To accomplish this, when a new version of a client is released that contains measurements for the new enclave, this client will recover its secret from the old servers (if it is not cached in local storage), and then it will back up its secret to the next version of the service. It takes approximately 90 days for a new client software release to fully reach the user base, so the new enclave-backed service must run alongside the older version during this 90-day window.

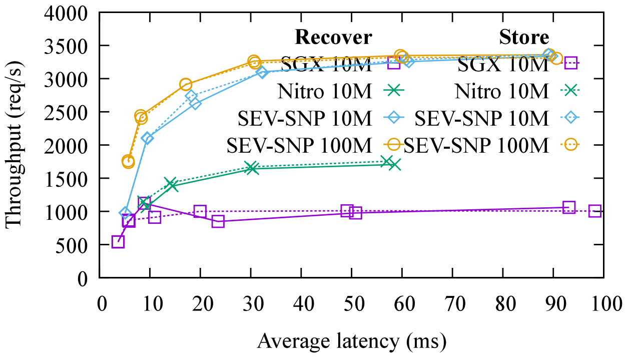

Figure 4: Average latency vs. throughput.

7 Implementation

We implemented SVR3 in ~8,800 lines of C++ for the enclave and ~5,300 lines of Go for the untrusted host. For the SGX deployment we use the OpenEnclave framework v0.19 [67] and Intel SGX v2.22. For the Nitro deployment we use the Nitro Security Module library v0.4 [63]. We use a Noise protocol [71] channel on top of TCP for communication between replicas and websockets for communication with clients. We use protobuf [73] to define formats for all wire messages. In addition to handling client and peer requests, the host offers a control interface for administration as well as sophisticated metrics collection that is integrated with our internal monitoring and reporting systems. Our implementation assumes enclave page-level integrity, and we estimate overheads for supporting 16B-level rollback granularity in §8.1. The implementation is open source and the consensus system is already in production use. The full system is being deployed to production at the time of publication. Production deployments use 7 geographically distributed servers and a supermajority parameter of 2. Further details about the production deployment are in §B of the full version [17].

8 Evaluation

We investigate the overheads of running SVR3 (§8.1) and the performance perceived by the end user (§8.2).

Evaluation setup. For the purposes of this paper, we evaluate end-to-end performance on our organization's staging system, configured to handle 10 million users. This limit is due to available enclave memory, not compute. Staging clusters are configured with a supermajority parameter of 1 and consist of 3 environments (trust domains), each with 5 replicas deployed in the same region:

- AWS Nitro: `m5.xlarge` instances with 2 cores and 10 GB RAM per enclave ($142/month/server).
- Intel SGX at Azure: `DC2s_v3` instances with 2 cores and 8 GB EPC RAM per enclave ($140/month/server).

Figure 9: SVR3 performance without network latency from Raft$^{\circlearrowleft}$.

Enclave	**Network (B/user)**			
	StoreSecret		RecoverSecret	
	C ↔ S	S ↔ S	C ↔ S	S ↔ S
SGX	20,717	288–1,276	20,717	224–1,212
SEV-SNP	4,406	288–1,276	4,406	224–1,212
Nitro	4,593	288–1,276	4,593	224–1,212

Table 10: Network usage for a single client request to a 3-replica cluster. S=server, C=client. C ↔ S for SEV-SNP is an estimate.

- AMD SEV-SNP at GCP: 2 `n2d-standard-2` instances per enclave (one "confidential" and one for the untrusted host) with 2 cores and 8 GB RAM ($2 \cdot (\$70) =$ \$140/month/server).

In total, the staging cluster costs \$2,110/month to run (\$0.0025/user/year). For microbenchmarking, we evaluate on a testing cluster with the same machine types as our staging cluster but with 3 replicas per trust domain instead of 5 and a supermajority parameter of 0 instead of 1.

Our production infrastructure has more replicas (with more cores and RAM per replica) and is set up to handle over 500 million users (more details in §B of the full version [17]). We provision for 1 req/s/1M users and ~256B of RAM/user. Our experience operating this system gives us confidence that evaluating on the staging infrastructure is meaningful and that SVR3 scales gracefully. To validate this claim, we also evaluate on an AMD SEV-SNP cluster with 100 million users using `n2d-standard-4` instances (4 cores and 16 GB RAM).

8.1 Microbenchmarks

Throughput. We plot an average latency vs. throughput curve for write and recovery requests in Figure 4. We generate each point by varying the number of client threads and measuring the average latency and throughput of requests. Requests are spread out across all 3 servers. For the 10M-user deployments, the throughput of recovery requests levels off around 1,700 req/s for Nitro, 1,000 req/s for SGX, and 3,300 req/s for SEV-SNP (for both 10M-user and 100M-user deployments).

Latency. We plot CDFs of the latency of write and recovery requests in Figure 5, Figure 6, and Figure 7 for Nitro, SGX, and SEV-SNP, respectively. Within each figure, we plot the latency when requests are sent only to the leader, when requests are sent only to followers, and when requests are sent to all 3 servers. Requests sent to followers are forwarded to the leader, so the average latency of requests at followers is higher than at the leader. The latency distribution of requests when sending requests to all 3 servers improves compared to sending requests to only followers. The latency distribution is better than sending requests to only the leader for Nitro and SGX, and the tail latency is worse than sending requests to only the leader for SEV-SNP. At 100 client threads, the average latency for requests sent to all servers for key recovery is 56.9ms for Nitro, 98.3ms for SGX, and 32.3ms for SEV-SNP. We also plot the CDFs of recovery request latency for the 100M-user SEV-SNP deployment in Figure 8. The latency distribution of the 100M-user deployment is very similar to the 10M-user deployment and the average latency of the requests sent to all 3 servers for key recovery is 30.9ms.

We note that a majority of the latency is due to network latency when appending to the Raft$^{\circlearrowleft}$ log, which we validate in Figure 9. We run the same experiment as above, but with 1 client thread and 1 SGX node (effectively disabling the network requests of Raft$^{\circlearrowleft}$). We plot the CDF of request latencies under this regime in Figure 9a, and the average latency of these requests is 1.47ms. We also profile the server and plot the percentage of CPU ticks in Figure 9b. On average, the Noise handshake is about 35%, applying the log entry is about 21%, and 13% is encrypting peer messages for Raft$^{\circlearrowleft}$. The yellow spikes are due to periodic updating of environment statistics, which also contributes to the long tail request latencies in SGX (Figure 6).

Impact of supporting 16B-granularity. Informed by latency measurements, we can upper-bound the impact of latency from achieving page-level integrity from 16B-granularity using atomic regions (§5.3.2). Applying the log entry (which we will conservatively make an entire atomic region) takes $1.47 \cdot 0.21 = 0.3$ms. We could be interrupted by the APIC timer, the end of a thread scheduling quantum, or by a page fault from a memory access, of which there are $5 \cdot \log_2(100,000,000) = 120$ (from the Merkle tree accesses in Algorithm 1). In the worst case, we would repeat execution of the atomic region 122 times, resulting in a worst-case additional latency of 36.6ms. Note that this is a (very) loose upper bound and is still below user perceptibility.

Network usage. We measure the network usage of SVR3 running on each enclave type for a 3-replica cluster in Table 10. There is a range of network usage for Server ↔ Server because it depends on how many requests have been batched into a single Raft$^{\circlearrowleft}$ append request. The network usage between servers also depends on the number of servers in the cluster, growing proportionally to $m-1$ for m servers. From a deployment perspective, we are more concerned with the Client ↔ Server bandwidth, which is under 20KB for all enclave types. This is because exchanging more data between the client and the server can become a usability issue for users with limited data plans.

Memory usage. We measured the memory usage of SVR3 on SGX, varying the number of users in the system. Note that we expect the memory usage to be similar for all enclave types, since they are storing the same amount of data for each user. We find that memory usage grows by $\sim$450B/user until we start truncating the log at 100MB and then settles into a steady 170B/user added. At 100 million users, SVR3 uses 18.5GB of memory on each server, which is 185B/user/server.

8.2 End-to-end performance

We measure the end-to-end performance of SVR3 by running a client that stores its secret key by sending a (sequential) request to a server in each enclave cluster. For a more representative deployment, we geographically distribute the SGX cluster (`centralus`, `eastus`, `eastus2`, `southcentralus`, `westus`), the SEV-SNP cluster (`us-central1`, `europe-west3`, `asia-southeast1`, `europe-west4`, `europe-west3`), and the Nitro cluster (`us-east-1`, `us-east-2`, `us-west-1`, `us-west-2`, `eu-north-1`). The performance for recovering a key is almost identical to the performance for storing a key, so we only report the performance for storing a key. We plot the CDF of the latency of these requests in Figure 11a. The average end-to-end latency is 365ms, which is reasonable for a user to wait for a key recovery or key backup request. We plot the breakdown of the latency in Figure 11b. The majority of the latency is from waiting for servers to respond (69.3%), followed by remote attestation with the servers (29.9%).

9 Related work

Secret recovery systems. A number of companies have deployed secret recovery systems using secure hardware: Apple protects user iCloud data using hardware security modules (HSMs) [4, 43], Google protects Android backups using secure microcontrollers [96], and WhatsApp protects message histories using HSMs [98]. WhatsApp runs vanilla Raft [65] on a geographically distributed cluster of HSMs and uses OPAQUE [39] for key recovery. WhatsApp's consensus only requires one round trip between the leader and the replicas while SVR3 requires an extra round of communication (to guarantee safety in the face of rollbacks). Davies et al. analyzed the security of the WhatsApp encrypted backup protocol [24].

Like SVR3, all of these systems use secure hardware to allow a user to recover a cryptographic secret using a low-entropy secret (e.g., a 4-digit PIN). Unlike SVR3, they rely on a single type of secure hardware: the compromise of one secure hardware device can compromise many users' secrets.

Juicebox [88] is a key recovery protocol that distributes trust across one type of secure hardware and multiple trust domains in the traditional manner (across organizations). SVR3 has a simpler protocol that is not a multi-round PAKE as our servers never learn whether the PIN is guessed correctly or not (keys are deleted unconditionally when guesses run out). Secret shares are also stored directly on the servers in Juicebox. Thus, to prevent an attacker who compromises a threshold number of trust domains from reconstructing all the secrets without needing to mount a dictionary attack, they must mix the reconstructed secret with the PIN to create an encryption key that is then used to encrypt the target secret.

SafetyPin [20] is a PIN-based end-to-end encrypted backup system that defends against an attacker that can adaptively compromise some percent of HSMs. While SafetyPin protects against a more powerful attacker model, it requires a comparatively large number of HSMs.

Tutamen [78], Acsesor [11], and CanDID [52] split trust across multiple entities to allow users to recover their secrets (among other operations). Chen et al. [13] use cloud storage for secret recovery. These systems do not use secure hardware; the use of enclaves in SVR3 provides additional security and requires us to design for their limitations (e.g., rollback attacks). CALYPSO [42] also shards user secrets across different entities but, unlike SVR3, uses a blockchain. PreVeil [72] shards secret keys across other peers in a social or work graph, but requires manual setup from the user.

Another line of work has taken a more theoretical approach to the problem of secret key backups. Benhamouda et al. [7] use a proof-of-stake blockchain to allow users to store secrets while protecting against an attacker that can adaptively compromise a percent of the stake. Subsequent work improves efficiency in this model via batching [30].

Orisini et al. [68] also describe a scheme for end-to-end encrypted backups, but in their scheme, the user does not need to remember a PIN or something similar. Instead, users continuously monitor for illegitimate recovery attempts, allowing an honest user to thwart malicious recovery attempts but later recover their backup. While this approach is appealing in that it eliminates the PIN, it does not work for our setting where clients may go offline for extended periods of time.

Multi-party computation and secure hardware. Cryptocurrency wallets protect user secrets by distributing them across hardware enclaves or HSMs [27, 29, 41, 77, 81]. Cryptocurrency wallets are designed to avoid materializing the key in a single location rather than to enable users to recover secrets. Myst provides security by splitting trust across many hardware devices and operations like signing and decryption [54]. More broadly, prior work has examined composing multi-party computation and secure hardware for efficiency [6, 25, 44, 64]. Our use of secure hardware with multi-party computation is tailored to encrypted backups and, while this line of work uses secure hardware to reduce the costs of multi-party computation, we use it to augment the security of the system. In prior work [21], we observed that heterogeneous secure hardware hosted by different clouds can be useful for deploying systems that split user secrets, including encrypted backups, but we had not yet worked through and built out such a deployment.

Rollback prevention in enclaves. There has been a rich line of work on preventing rollback attacks in enclaves. Memoir [69] and Ariadne [86] store a small amount of state inside non-volatile memory (NVRAM) and use that to reconstruct application state during recovery. Both approaches are scoped to single machines, and do not provide availability in the event of a machine permanently failing. ROTE [53] uses a broadcast algorithm across enclaves to maintain a distributed counter, but requires NVRAM to update group membership, whereas we use our Raft$^{\circlearrowleft}$ log to update membership. Additionally, the abstraction that ROTE offers is one of a counter instead of generic log entries. Engraft [97] examines the safety issues of running off-the-shelf consensus inside enclaves. They use an underlying broadcast protocol similar to ROTE to maintain a distributed counter and introduce additional mechanisms to support node recoverability. However, in our setting, we can simply start a new node in the event of a node failure, so we do not need to support node recoverability.

Nimble [3] is a lightweight replication protocol that provides a freshness-guaranteed ledger. The ledger can be used to keep track of the state of untrusted storage, enabling applications that run on enclaves to persist their state to external (untrusted) storage and detect potential rollbacks on that storage. Note that our system is already protected against the class of rollback attacks on external storage described in §1 of [3] because *all data is stored and maintained in memory*. Nimble's threat model does not include physical rollback attacks on the enclave (both endorser and application). However, minimizing SVR3's trusted computing base (TCB) is an interesting and important future direction, and we discuss potential design decisions and open challenges in §10.

TrInc [49] shows that a secure log can be implemented with a secure counter. However, realizing a secure counter on enclaves is difficult. We cannot write PCRs to the TPM from inside an SGX enclave, and additionally, TPMs can limit the speed of counter updates (§6.1.1, [86]). CPU registers are written to the SSA, which can be rolled back. On SGX there is no CPU register where only an enclave can write to it. We are unaware of an (efficient) secure counter primitive on newer enclaves after consulting with Intel.

Consensus protocols. As Dinis et al. [26] point out, rollback behavior can be considered a subset of Byzantine behavior, so the Byzantine fault tolerant (BFT) model is stronger than necessary for our setting. Consequently, Raft$^{\circlearrowleft}$ is lighter weight than BFT flavors of Raft protocols like Tangoroa [19] which requires $O(m^2)$ communication scaling in the number of replicas. The supermajority parameter in Raft$^{\circlearrowleft}$, which increases the quorum size, is comparable to PBFT's [10] Byzantine nodes value. Engraft [97] and RR (TEEMS) [26] address data-sealing (software) rollback attacks. SVR3 not only defends against these data-sealing rollback attacks, but also defends against physical rollback attacks.

10 Discussion

Consensus in the enclave. Nimble [3] is able to maintain a secure log while removing the consensus mechanism from the TCB, and an important future direction for SVR3 would be to similarly minimize its TCB. However, it is not entirely straightforward, and there are interesting design and engineering challenges to address. First, Nimble will need to be hardened against physical rollback attacks, which seems straightforward to do. More significant is that since this log—which contains OPRF secrets—will be held in untrusted storage, it must be encrypted. This has important consequences for our system as we describe below, and addressing them may result in significant additional complexity (and thus increase the TCB).

First, we note that we will need enclaves similar to the ones we have today to handle client requests. These enclaves will now need to share a common encryption key to encrypt and decrypt these log messages. This shared key becomes a new single point of failure for the system. To maintain the forward secrecy we have today due to our use of Noise protocol [71] channels with rekeying between enclaves, it seems the enclaves will need to participate in some sort of continuous group key agreement (CGKA) [2] to rotate the key periodically and on membership changes.

Second, if this new system aims to keep the TCB small by maintaining the database state outside of the enclave, as with Juicebox [88] or WhatsApp [98], then the encryption key for the database becomes another single point of failure, but in this case it is not clear how we can achieve forward secrecy without periodically re-encrypting the entire database. If, on the other hand, we maintain the database in enclave memory, as we do now, then the use of CGKA to protect the encrypted log means that new members of a replica group will not be able to read old log messages to construct the database state. While we have a state transfer mechanism in our current system to handle truncated logs, we will need to refine it to ensure that new members are correctly initialized.

Taken together, we see removal of the consensus mechanism from the TCB as a project that requires careful design and analysis and significant engineering work that adds its own complexity. We note that the consensus protocol is a relatively small (1,541 LOC in C++) and well-understood part of our current codebase, so we need—and hope to find—clear rationale for its removal.

In-memory vs. disk-based storage. While disk-based storage solutions are cheaper than keeping the entire database of key recovery shares in memory, they are more susceptible to rollback attacks because the secrets are taken out of the enclave, and even enable rollback attacks that are software-based and can be performed without physical access.

Data privacy compliance. In general, a multi-cloud deployment may complicate compliance with data privacy laws. The design of SVR3, however, keeps compliance simple since by preventing any user data from being processed by our servers and blocking our administrators from accessing sensitive keys.

Malicious clients. SVR3 provides security guarantees for users using our clients, which we assume are well-behaved. Our client code is open source [55–57], and scrutinized by the community. If the user's client is compromised and malicious (e.g., the user has malware), it can affect the security of that user, but not the security or experience of other users with uncompromised clients.

Honest cloud providers? If we could assume that most cloud operators are honest, then that could change the parameterization of SVR3 (e.g., setting the number of trust domains that can be compromised t to 1), though this would also require assuming that the enclaves were not susceptible to any future vulnerabilities that could be exploited remotely. We would still use enclaves to prevent malicious system administrators from running arbitrary server code.

11 Conclusion

SVR3 demonstrates the potential of systems that provide security through a combination of cryptography and a diverse set of hardware enclaves, without putting trust in any single hardware component. Using different types of enclaves leads to an array of deployment challenges stemming from heterogeneous and shifting attacker models. SVR3 is a powerful defense against the evolving landscape of enclave security: by distributing trust across enclaves, even if a new threat arises in one type of enclave, user secrets are still secure. SVR3 costs \$0.0025/user/year and takes 365ms for a user to recover their key, which is a rare operation.

Acknowledgments. We are very grateful to our shepherd, Jay Lorch, for his detailed feedback, as well as to the collective OSDI reviewers for their suggestions, which greatly improved the presentation of this paper. We thank Trevor Perrin for the pointer to the PPSS construction [37]. Mark Johnson helped develop the early stages of this project. Ravi Khadiwala contributed significantly to SVR3's implementation. We thank Natacha Crooks, Christopher Fletcher, Jack Humphries, and Sky security students for their helpful feedback. The UC Berkeley authors are supported by NSF Graduate Research Fellowships, a Microsoft Ada Lovelace Fellowship, and gifts from Accenture, AMD, Anyscale, Google, IBM, Intel, Microsoft, MBZUAI, Samsung SDS, SAP, Uber, and VMware.

Flock: A Framework for *Deploying* On-Demand Distributed Trust

Darya Kaviani[1]* Sijun Tan[1]* Pravein Govindan Kannan[2] Raluca Ada Popa[1]

[1] *UC Berkeley* [2] *IBM Research*

Abstract

Recent years have exhibited an increase in applications that *distribute trust* across n servers to protect user data from a central point of attack. However, these deployments remain limited due to a core obstacle: establishing n distinct trust domains. An application provider, a *single* trust domain, cannot directly deploy *multiple* trust domains. As a result, application providers forge business relationships to enlist third-parties as trust domains, which is a manual, lengthy, and expensive process, inaccessible to many application developers.

We introduce the *on-demand distributed-trust architecture* that enables an application provider to deploy distributed trust automatically and immediately without controlling the other trust domains. The insight lies in *reversing* the deployment method such that each user's client drives deployment instead of the application provider. While at a first glance, this approach appears infeasible due to cost, performance, and resource abuse concerns, our system Flock resolves these challenges. We implement and evaluate Flock on 3 major cloud providers and 8 distributed-trust applications. On average, Flock achieves 1.05x the latency and 0.68-2.27x the cloud cost of a traditional distributed-trust deployment, without reliance on third-party relationships.

1 Introduction

Existing systems typically suffer from a central point of attack: an application provider holding many users' private data becomes the target of data breaches [117]. As a result, an increasing number of applications are using *distributed trust* [35, 38, 46, 47, 66, 67, 72, 77, 108, 161, 177–179, 195, 198]. This powerful paradigm avoids a central point of attack by distributing the users' sensitive data among n parties to protect its confidentiality or integrity. A typical requirement is that these n parties are in different *trust domains*, each of which corresponds to a distinct organization to ensure that they are controlled by different entities. Fig. 1 illustrates the stakeholders of this setting: the application provider, its users, and $n-1$ other trust domains. Even if $n-1$ out of n parties are compromised, the sensitive data remains secure: an attacker would have to breach all n parties to compromise the sensitive data. Various cryptographic tools rely on distributed trust, such as secure multi-party computation (MPC) [112, 128, 147, 163, 164, 202, 213, 219] and two-party private information retrieval (PIR) [105, 116, 124, 146].

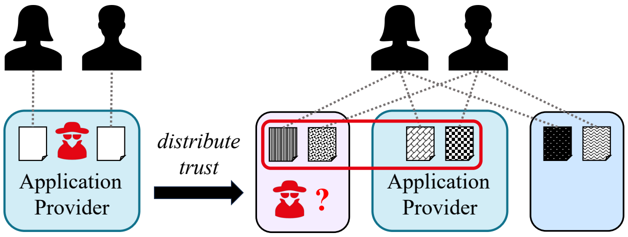

Figure 1: Secret-sharing data over 3 trust domains: breaching 2 trust domains reveals nothing.

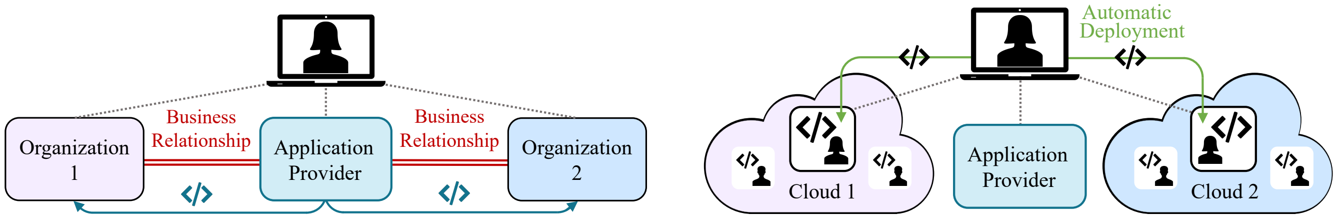
Recent years have exhibited an increased adoption of distributed trust by application providers who aim to *protect their users' data* [161] (§6), including Signal [178, 179], Coinbase [35, 177], Fireblocks [46], Google [108], Apple [108], Meta [198], and J.P. Morgan [195]. For example, Signal's secure value recovery project aims to enable users to securely back up their private keys through distributed trust [178, 179]. Likewise, MPC wallets [35, 38, 42, 46, 47, 66, 72, 77, 97, 134, 177], including Coinbase [35, 177] and Fireblocks [46], secure billions of dollars by distributing their users' private keys and using MPC for signing [196].

The deployment challenge. Despite this interest, the adoption of distributed-trust applications remains limited. Recent works [130, 178, 198] discuss a core challenge: the *difficulty of deploying n distinct trust domains*. Indeed, the application provider must find $n-1$ organizations in different trust domains, who are willing to run the provider's workload while restricting access to anyone, including the provider itself. These organizations must offer sufficient availability, security, fault tolerance, logging, swift recovery, and must have a credible reputation in the user community—criteria that have empirically been challenging to satisfy [178]. Moreover, such business relationships are costly and require both time and manual effort to set up. While large corporations were able to forge such partnerships [108, 198], this is a barrier to entry for application developers [178] who lack the same resources.

For clarity, consider the **running example** of digital asset

*Equal contribution



(a) *Traditional Distributed Trust*: The application provider forms manual, costly relationships with third-parties, who deploy code.

(b) *On-Demand Distributed Trust*: The user's client automatically deploys code to $n-1$ clouds, which also have other user deployments.

Figure 2: Deployment workflow in traditional vs. on-demand distributed trust.

custody (although our work applies to a wide range of applications, as discussed in §4). Cryptocurrency [119, 189] users exchange digital assets by signing transactions with their private keys. A compromised private key can be used to steal any assets in the user's wallet [101, 118, 142, 184, 203]. This is why wallets like Coinbase [35, 177] and Fireblocks [46] secret-share the private key among n different parties. When Alice initiates a transaction, the n parties engage in MPC, inside which they reconstruct her key and sign the transaction. Although their desired design is to secret-share among multiple entities, many wallets only secret-share between the application provider and the client due to the difficulty of setting up other trust domains [178].

More generally, many academic papers on distributed trust simply assume the presence of n servers in different trust domains [126, 127, 131, 132, 138, 149, 165, 211], but do not offer guidance on how to establish such deployments in practice. In this paper, we address the following systems challenge with deploying distributed trust:

> How can an application provider, which is inherently a *single* trust domain, deploy a *multi-trust-domain* system?

To address this challenge, we propose the **on-demand distributed-trust** architecture, which enables an application provider to offer distributed-trust services to its users *automatically*, *immediately*, and *without* requiring third-parties. This is the first architecture that removes the burden of setting up cumbersome, manual business relationships with $n-1$ parties. We provide an intuition and overview in §1.1. Our second contribution is the design and implementation of *Flock*,[1] a system that realizes our on-demand distributed-trust architecture across major cloud providers. Flock enables an application provider to setup $n-1$ trust domains on $n-1$ cloud providers without the application provider being able to control the deployment. A straightforward instantiation of the on-demand architecture suffers from significant scalability and security issues. Flock overcomes these challenges with two additional technical contributions that are reusable beyond Flock: the *Flock Relay* and a *three-tier authentication protocol*, both overviewed in §1.2.

1.1 On-Demand Distributed Trust

To understand our approach and its challenges, first consider a natural strawman of using n reputable cloud providers as trust domains. Recent years have exhibited a spike in multi-cloud services [4, 11, 63, 94] and multi-cloud applications [12, 135, 153, 156, 193, 204, 218]. While *accounts* within a *single* cloud can be accessed by the cloud's administrators, *distinct* cloud providers have their own data centers, storage, compute resources, networking solutions, and, crucially, administrators. While the clouds are indeed distinct trust domains, this approach suffers from a central point of attack: the application provider that deploys VMs to each cloud controls them all, reducing the system to a single trust domain. As we discuss in §6, some proposals attempt to approximate trust domains with hardware enclaves [130, 179], but enclaves are vulnerable to side-channel attacks [115, 175, 188, 209] that allow the application provider to once again fully control the deployment. Hence, we seek an approach to deploying $n-1$ trust domains that the application provider cannot control, without depending on trusted hardware.

The primary insight of on-demand distributed trust is a paradigm shift in the deployment approach: Instead of the application provider deploying the n parties to distinct clouds, *each user* drives the deployment for *their own data*. At a first glance, this approach appears infeasible with respect to ease-of-use and cost because every user has a *separate* deployment. From a security standpoint, though, it is fitting: a user Alice is the trusted owner of her *own* sensitive data. Hence, she can deploy VMs across $n-1$ major clouds, with the application provider as the n-th party. Alice can secret-share her sensitive data—for example, her private key for digital asset custody—across these n VMs because no other party can control all of them, not even the application provider. Fig. 2 compares the deployment workflow of traditional and on-demand distributed trust.

The on-demand architecture enables a wide range of distributed-trust applications, but not all of them:

> Flock can support all applications where every distributed-trust computation takes as input only data that is owned by *exactly one user* or is public.

[1] Multi-species bird flocks may not always trust each other, but flock together among the clouds to increase the likelihood of detecting predators [62].

We show that Flock can support 8 types of distributed-trust applications, including secret key recovery for end-to-end encrypted systems (as in Signal [179]), password managers, digital asset custody (as in Coinbase [35], Fireblocks [46] and other MPC wallets [38, 42, 47, 66, 72, 77, 97, 134, 177]), certificate authority signing, code signing, two-server private information retrieval, and data rollback protection. These applications demonstrate different aspects of Flock's expressivity: they enable 5 major cryptographic modules, which showcase protection for data confidentiality, data integrity, data-sharing, or query privacy on a public database. An example of an application that Flock does not support is privately training a machine learning model over *all* users' private data because the input to the training process is the combined data of all users that no *individual* user owns and is not public.

1.2 Summary of Techniques

We now summarize Flock's techniques. A careful reader may be concerned about the cost of the on-demand approach. Continuously running one VM *per* user *per* cloud would be prohibitively expensive and shutting them off intermittently would introduce significant startup time.

We identify *serverless computing* [18, 24, 52, 102] as the most fitting paradigm (§3.1) for Flock. Their "pay-as-you-go" model means that we can invoke a serverless instance exclusively when the user runs an operation, and incur no cost when the user is idle. For example, in the digital asset custody application, Alice's serverless instances only run when Alice wants to perform a transaction. Further, executing a serverless instance on-demand is fast, unlike typical VM boot times. Thus, Flock offers a **cross-cloud serverless system for secure computation (§3.1)**, which runs sophisticated cryptographic libraries in serverless across clouds. A challenge is that serverless offerings cannot innately form peer-to-peer connections [150, 214] because they are publicly inaccessible and ephemeral. To enable end-to-end secure cross-cloud serverless networking, we design a relay that leverages the application provider to connect the serverless instances without trusting the provider with the contents of the communication. To achieve this, we introduce a two-phase TLS establishment protocol that only requires a *single* TCP connection per serverless instance, which is used for both authentication and end-to-end TLS. By reducing secure message-forwarding to copying bytes across sockets, the relay achieves 27x higher throughput (Table 4) than the current best potential approach. We expect the relay to have independent utility in any application that requires end-to-end secure cross-domain (e.g. cross-cloud, cross-region) serverless communication.

Flock's **automatic deployment mechanism (§3.4)** empowers *regular* users to *automatically* setup cross-cloud accounts and serverless deployments without being exposed to underlying cloud-level intricacies. First, each user's Flock client automates multi-cloud account creation by filling in the corresponding forms for the user through the webpage automation framework Playwright [65]. Second, the Flock client conducts programmatic deployment through cloud-provided APIs. The user experience of a Flock application is comparable to that of a regular application. Users will not have to conduct manual cloud registration or serverless deployment per cloud, and the only difference is that users may need to complete $n-1$ authentication steps for cloud registration (e.g. SMS, email).

To secure this deployment, Flock contributes a **three-tier authentication protocol (§3.2)**, which safeguards against the impersonation of a user Alice, her deployments, or the application provider. Our new setting of user-driven distributed-trust deployment introduced new attack vectors, requiring a novel design for authentication: *How can an application provider secure a deployment they do not control?* We first identified the required security "checkpoints" across three tiers—cloud, network, and application—leading us to design a unified protocol spanning these layers. At the cloud level, fine-grained access keys prevent unauthorized users from invoking Alice's serverless instances. At the network level, a secure deployment protocol guards the communication amongst Alice and her "flock." At the application level, Alice's "flock" must authenticate her before conducting operations on her sensitive data. However, it is onerous for each user to authenticate n times, once *per* party. To avoid this, we identify MPCAuth [206] as particularly well-suited in this scenario. MPCAuth enables a user to perform the usual work of authenticating to a *single* "logical" server—which is an MPC of the n servers—with the same security as authenticating to n servers independently.

User-centered deployment introduces a new axis of challenges: Flock should allow the provider to manage **billing without controlling users' cloud instances (§3.3)** or exposing the provider to resource abuse. We use cloud billing infrastructure to prevent malicious users from draining application provider funds and cloud access keys to prevent an attacker from wasting serverless compute resources before they are detected by application-level authentication.

1.3 Evaluation Summary

We implement and evaluate Flock (§5) across three major cloud providers: Amazon Web Services, Azure, and Google Cloud Platform. We have also successfully deployed Flock to IBM Code Engine. When compared to the traditional distributed-trust setup (Fig. 2a), Flock has 1.05x latency and 0.68-2.27x the cloud cost, averaged over all 5 modules. This value does not account for the traditional method's additional cost of business relationships with the $n-1$ third-party organizations (e.g. employee salaries, operational costs)—expenses that do not exist in Flock. Moreover, Flock achieves this without the manual and time-consuming process of identifying and setting up other organizations as trust domains. By removing this deployment barrier, we believe that Flock can foster a new wave of adoption for distributed trust.

2 Threat Model & Security Guarantees

System model. An application provider seeking to offer distributed-trust security to its users invokes the Flock API in its client and server code. Users install an *application client* on their device. The application provider runs the *application server*, which we consider to be a logical server (even if it comprises of multiple physical servers). We refer to the n distinct trust domains that execute the distributed-trust modules as *parties*. The application provider constitutes one party, and the $n-1$ clouds constitute the other $n-1$ parties.

Security guarantees. Flock is not a specific cryptographic scheme or application, but a *system for deploying* distributed trust across the clouds for a variety of applications with different threat models. The guarantee of the on-demand distributed-trust architecture is that each of the n parties are deployed independently of each other, without any one party being able to control the others. Hence, none of these parties are a central point of attack, and crucially, the application provider cannot control the deployments in the $n-1$ clouds. To provide this guarantee, Flock relies on the security mechanisms of each cloud in a black-box manner. As long as cloud i upholds its guarantees, party i stands as an uncompromised trust domain in the Flock deployment.

When running a distributed-trust application App using Flock, the resulting security guarantees are a *combination* of the guarantees of App and Flock, and often, the weaker of the two. The Flock system and modules provide the strong guarantee of malicious security against $n-1$ out of n compromised parties. In particular, an attacker cannot see any secret data distributed across the parties or tamper with the integrity of sensitive operations. Hence, if App *also* provides malicious security, so does the overall App-Flock deployment. If, on the other hand, App provides the weaker semi-honest security, so does the overall App-Flock deployment.[2]

Availability. While the application provider is not trusted with confidentiality and integrity, it is trusted for availability because it is the entity that wishes to provide this service. We also assume that the clouds are available given their service-level agreements [20,51,78]. In each cloud, Flock uses cloud services that are fault-tolerant. If, despite this, the provider or a cloud are not available, Flock does not offer availability.

Application code. Like prominent end-to-end encrypted applications [69,79,86,95,98] and blockchains [111,119,189], Flock assumes that the application client code is not compromised and that it is open source and community-scrutinized. Likewise, Flock is open source (§5.1). Flock's focus is to protect against attacks to the application servers. Application servers are a prolific target of attack because they aggregate data across all users. They can also read user data and alter server execution unchecked, which is more difficult to perform with openly scrutinized client code.

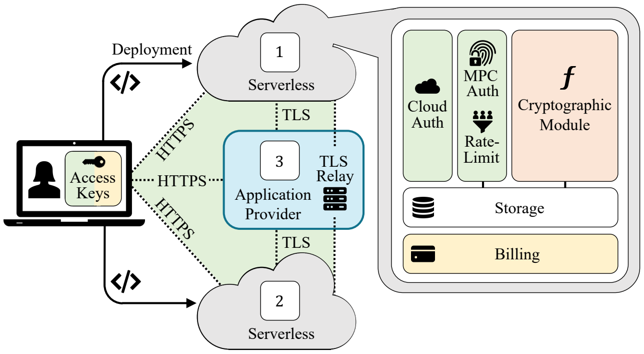


Figure 3: The Flock system architecture. *Client:* Programmatic deployment. *Authentication (green):* Cloud-level via access keys, network-level via TLS, and application-level via MPCAuth. *Resource Protection (yellow):* Unauthorized client abuse is prevented by access keys, while user abuse is prevented through billing. *Cryptographic modules (orange).*

Compromised client devices of a user do not affect the security of *another* user in Flock. For the same user, If Alice's device is compromised *during an active Flock session*, Flock does not provide security guarantees for Alice. This is not specific to Flock, and is the case for many distributed-trust applications. For example, Signal's SVR [79,179] saves Alice's private keys on her device and distributes them among parties for the purpose of backup. However, if Alice is logged out (and thus not in an active session) during the compromise of her device, Flock's security guarantees remain. Many apps, like password managers and digital wallets, log users out after sessions to bolster security upon a device compromise. Flock implements sessions and removes each user's sensitive key material from the client when the user is logged out.

Authentication (§3.2). Users in Flock authenticate through multiple factors, e.g. with email and SMS on cloud accounts, or PIN and U2F for MPCAuth. Naturally, Flock only protects the data of users with uncompromised authentication factors.

Resource protection (§3.3) in Flock prevents malicious users from draining compute resources and cloud funds from the application provider or denying its service.

3 Flock's System Design

Architecting an on-demand distributed-trust system poses several challenges along the dimensions of cost-efficiency, networking, authentication, resource protection, deployment, and registration. In this section, we describe how we address each challenge in building Flock. Fig. 4 illustrates the Flock system architecture.

[2] The on-demand distributed-trust architecture also supports applications with t out of n security for a threshold $t < n$, but our current implementation only supports $t = n$.

3.1 Serverless Architecture

As discussed in §1.1, the straightforward method of implementing on-demand distributed trust is having *each user* deploy one always-on VM on each of $n-1$ clouds. Despite the infrequency of operations like secret recovery due to device loss, the clouds will charge constantly for each VM. A natural strawman is to have the user turn off each VM upon operation completion and reactivate them as needed. Unfortunately, the user would incur *minutes* of additional latency for VMs to boot *per* operation. This delay is prohibitive for applications like password managers, where users frequently invoke Flock.

We observe that the *serverless* computing paradigm [102, 176, 180] alleviates this problem by charging only for active use with a "pay-as-you-go" model [176]. Developers upload code that exclusively consumes resources at execution [102, 180]. Serverless instances are *event-driven*, so they can be triggered with minimal start-up time through a programmable HTTPS interface [176]. The most common serverless compute offerings are serverless functions [18, 24, 50], where a client triggers an API query, it is validated by the cloud provider, and a previously deployed function is invoked in an isolated environment [73–75, 176, 182]. However, basic serverless functions [24, 50] do not naturally support multi-language codebases or runtimes for programming languages that are commonly used to implement cryptographic tools, such as C++. This makes them inconvenient for porting existing cryptographic frameworks and codebases in Flock. Instead, we turn to serverless *containers*, which are light-weight, standalone executable software packages that include the code, runtime, and system libraries. Containers can support multi-language codebases and any runtime, and are offered by AWS Lambda [18] and Google Cloud Run [52].

MPC requires high interactivity, often with one party awaiting another's response. Unfortunately, serverless instances commonly communicate via services like cloud storage, which is prohibitively slower and pricier than direct networking [107, 150]. The challenge is that serverless instances possess private IPs under unique network address translations (NATs), so they cannot accept incoming network connections. Serverless offerings that expose public IP addresses [16, 22] are intended for long-running workloads, and therefore suffer significant coldstart delays [3], and even charge for a minute-long minimum runtime for AWS Fargate [16].

Several works employ NAT traversal and hole-punching to facilitate serverless communication [137, 139, 186, 214], but this method is not robust since it relies on a cloud provider's NAT configurations, which are prone to change. Both Lambda and Google Cloud Run only support cross-cloud hole-punching through NAT gateways and virtual private clouds [29] with impractical per-user cost. Instead, prior systems have facilitated serverless communication through a central relay [140, 141, 210], but do not consider security. A secure relay-based approach for connecting publicly inaccessible endpoints is Wireguard [96] over Tailscale DERP relay servers [37]. As we show in §5.4, this setup incurs significant overhead since Wireguard conducts per-packet encryption and must redundantly layer TLS over Wireguard to supplement it with mutual authentication. Also, Wireguard does not use a federally approved encryption protocol [5], unlike TLS.

3.1.1 Secure Cross-Cloud Serverless Networking

To resolve this challenge, we architect a NAT-independent Flock Relay protocol for secure serverless networking at the transport layer (L4). To deploy the relay, we employ the help of the application provider for availability without trusting it otherwise. The application provider runs a multi-user relay that connects serverless instances by accepting their *incoming* connections, then securely routes messages between them with authentication and end-to-end encryption. The relay observes only message lengths, which do not reveal the private user inputs because of the oblivious nature of MPC. Hence, the provider, though capable of barring the *availability* of the relay, cannot compromise data confidentiality or integrity.

To facilitate secure serverless-to-serverless communication, the Flock Relay must authenticate each serverless instance to ensure that the correct endpoints connect to one another, and facilitate their communication without serving as a central point of attack. While standard TLS connections are established between two endpoints directly, the Flock Relay needs to facilitate end-to-end TLS establishment between two authenticated endpoints.

An insecure strawman for establishing serverless-to-serverless TLS is the following: (1) After a serverless instance initiates a serverless-to-relay connection, the relay verifies the serverless instance and provides it with an authentication token. In future connections, the token will inform the relay that it has previously authorized the serverless endpoint. (2) The serverless instance sends the token to the relay to authorize the end-to-end serverless establishment. Crucially, however, the second step would require the token to be sent in *plaintext*. A passive network eavesdropper could use the token to impersonate valid connections in the future.

Two-phase connection establishment. To ameliorate this issue, we architect our relay to connect serverless instances with the *same* sockets that were already authorized. The Flock Relay executes two phases of TLS establishment to form a *single* end-to-end TLS session, as we show in Fig. 4.

(1) *Serverless-to-relay* (S2R): Every pair of serverless instances s_1 and s_2 each initiate an independent TLS connection with the relay. The relay needs to maintain access control to ensure that only the instances within a single user's "flock" can connect to one other. Thus, the TLS handshake in this phase authenticates the serverless instances. Over the S2R TLS session, each instance notifies the relay of the ID of the serverless instances it wishes to connect to, which hides these IDs from the public Internet. Next, the relay downgrades its

TLS connection with s_1 and s_2 to TCP, and begins forwarding messages between the two TCP sockets.
(2) *Serverless-to-serverless* (S2S): Every pair of serverless instances in a user's "flock" performs a TLS handshake over the TCP connection obtained after the S2R phase, setting up the S2S TLS session between them. To send a message to s_2, s_1 sends the relay a TLS-protected message under the S2S session, which the relay forwards to s_2.

For both S2R and S2S, we use mTLS (Mutual TLS), which enables *mutual* authentication. We also use the relay to connect serverless instances to the application provider (as if it were another serverless instance), for ease of implementation. We assume the user's application client obtains the relay's destination from the application provider.

3.1.2 Flock Relay Certificate Issuance

We now discuss how Flock sets up TLS certificates to ensure all communication occurs with intended parties. The client maintains hardcoded public keys for the application server and relay. For the serverless instances to verify each other in S2S sessions, an observation is that a user Alice is trusted within *her* "flock" and can therefore serve as its certificate authority. Alice's client creates a public-private keypair for each party in her deployment (serverless instances and application provider) and signs a certificate for each of their public keys. Each party stores its certificate and Alice's public key, allowing parties to mutually verify one another.

S2R sessions enlist the application provider as a certificate authority. Indeed, this phase of TLS only exchanges information about message recipients, which must be hidden from the public Internet, but visible to the relay. Overall, the Flock Relay is responsible for managing a public-private keypair for signing, engaging in a setup protocol for certificate issuance for each user, verifying these certificates per-invocation, and facilitating message-forwarding between serverless instances.

For client-to-serverless connections, upon invocation, Alice's client contacts each Flock instance and the application provider via HTTPS. Alice provides parameters including the IP address and port of the relay, as well as query-specific input, so the provider can redeploy or load-balance the relay without requiring Alice to redeploy her instances. Google Cloud Run [52] and AWS Lambda [18] URLs offer HTTPS with trusted CAs, so Alice knows that she is contacting the intended instances.

Reissuance. To prevent an attacker that steals Alice's device from issuing certificates, Alice deletes her certificate issuance secret key post-deployment. Because reissuance is uncommon, she can reauthenticate to each cloud, regenerate keypairs (including her own), and reissue. If the relay updates its public-private keypair, it must reissue a certificate for each user. The application client will be updated with this new relay public key and certificate.

The convenient aspect is that Alice can update her parties' certificates and public keys (both her own and the relay's) without redeploying the entire codebase because they are stored in cloud-provided secret managers [34, 91]. This process is more lightweight than a full-fledged application software update, which necessitates serverless redeployment. For a consistent certificate keypair, one can use Flock's secret recovery (§4.1) or signing (§4.2) to store Alice's secret key.

3.1.3 Flock Relay Protocol

We now detail the Flock Relay protocol, shown in Fig. 4. For simplicity, we only list parameters in certificates or message tuples that are specific to our protocol, but a deployment must contain all the other standard parameters and defenses.

Per-Relay Setup:

1: The application provider generates a keypair $(\mathsf{PK}_r, \mathsf{SK}_r)$, which is used to self-sign a certificate for the relay $\mathrm{RelayCert}_r = \mathrm{GenerateCert}(\mathsf{SK}_r; r, \mathsf{PK}_r)$.
2: The application provider deploys the relay with $(\mathsf{PK}_r, \mathsf{SK}_r, \mathrm{RelayCert}_r)$.
3: Relay listens for new users at RelayUserTarget and for serverless connections at RelayTarget.

Per-User Setup:

1: Alice generates $(\mathsf{PK}_u, \mathsf{SK}_u)$.
2: For each party $i \in \{1, \ldots, n\}$, Alice generates $(\mathsf{PK}_i, \mathsf{SK}_i)$ and certificate $\mathrm{E2ECert}_i = \mathrm{GenerateCert}(\mathsf{SK}_u; i, \mathsf{PK}_i)$.
3: Alice locally deletes SK_u.
4: Alice sends each PK_i to the relay at RelayUserTarget.
5: Relay generates the relay-specific user certificate $\mathrm{RelayCert}_i = \mathrm{GenerateCert}(\mathsf{SK}_r; \text{"Alice"}.i, \mathsf{PK}_i)$.
6: Relay sends $(\mathsf{PK}_r, \mathrm{RelayCert}_i)$ to Alice for each party i.
7: In each serverless deployment for party i, Alice embeds: $(\mathsf{PK}_u, \mathsf{PK}_r, \mathrm{E2ECert}_i, \mathrm{RelayCert}_i, \mathsf{PK}_i, \mathsf{SK}_i, i)$.

Per-Invocation Protocol (Fig. 4)**:**

1: Alice invokes each s_i using HTTPS, with the parameters $\{\mathrm{PartyID} : i, \mathrm{RelayTarget} : (\mathrm{IP}, \mathrm{Port})\}$.
2: Each s_i loads $(\mathsf{PK}_i, \mathsf{SK}_i, \mathsf{PK}_r, \mathrm{RelayCert}_i, \mathsf{PK}_u, \mathrm{E2ECert}_i)$.
3: To establish an S2R session, each s_i performs an mTLS handshake with the relay, in which PK_r is used to verify $\mathrm{RelayCert}_r$ is from the intended relay and $\mathrm{RelayCert}_i$ is from Alice's i-th party.
4: Over S2R, s_1 sends the relay "2" as its intended destination and s_2 sends the relay "1".
5: Over S2R, the relay arbitrarily assigns s_1 as "TLS Server" and s_2 as "TLS Client," declaring the assignment to both.
6: Over S2R, the relay sends s_1 (TLS Server) an SSL_shutdown OpenSSL message to close the SSL connection. s_1 confirms completion and starts listening on the same socket for a future TLS connection request.

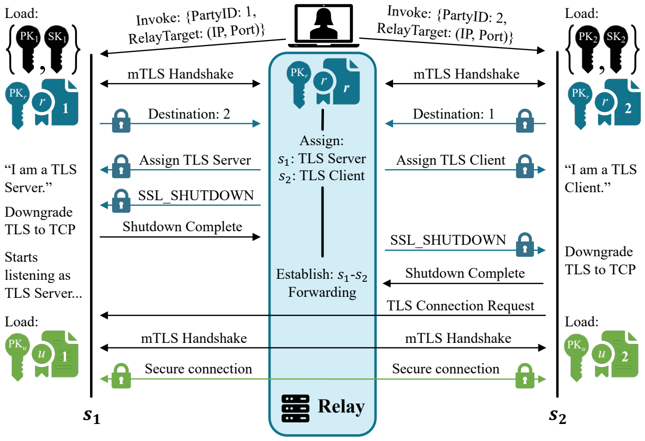

Figure 4: Flock Relay Per-Invocation Protocol. Certificates denote the signing entity in the circle. Teal denotes serverless-to-relay (S2R); green denotes serverless-to-serverless (S2S).

7: Over S2R, the relay sends s_2 (TLS Client) an SSL_shutdown message. When s_2 confirms, the relay establishes s_1-s_2 forwarding over the pair of sockets.

8: To establish S2S, s_2 sends s_1 a TLS connection request through the relay. s_1 and s_2 engage in an mTLS handshake, in which they verify the other's E2ECert$_i$ with PK_u. s_1 and s_2 now share an end-to-end TLS connection.

Hence, the Flock Relay only requires a *single* TCP connection per serverless instance, which is used for *both* authentication (S2R) and end-to-end TLS (S2S). By reducing secure message-forwarding to merely copying bytes across sockets, the relay achieves high throughput, as we show in §5.

3.2 Three-Tier Authentication

Authentication in Flock differs from a traditional system because of the three-layered nature of Flock's design: Alice must authenticate to her cloud deployments, their network sessions, and their running application to be able to execute sensitive operations. We have already described Flock's network-level authentication via certificates in §3.1.2. We now present the application-level and cloud-level authentication in Flock.

3.2.1 MPCAuth for Application-level Authentication

To perform a sensitive operation, Alice needs to authenticate to her serverless instances and the application provider. The natural approach is for her to run multi-factor authentication with each one of these parties. In an application with m authentication factors, Alice must authenticate m times for each party, which is burdensome. For example, Alice must input her password $n = 3$ times, perform 3 U2F authentications or lookup 3 emails with security codes, amounting to $n \times m$ total authentications. For applications like cryptocurrency transaction signing (§4.2) or password retrieval during web browsing (§4.1), such repetitive tasks are on the critical path.

Instead, we employ a recent cryptographic protocol, MPCAuth [206], as a black box. MPCAuth enables users to authenticate once, achieving the security of n distinct authentications. At a high level, MPCAuth performs an MPC computation between the n parties to simulate a "trusted server inside MPC" to which the user authenticates. This imaginary server, an amalgamation of the n parties, ensures that as long as one server remains honest, authentication proceeds correctly. A user seeking to trigger an operation will authenticate to the n serverless containers using their m pre-configured authentication factors. If the user successfully authenticates, the sensitive task is executed. The user's experience is unchanged: Alice authenticates to one logical server, when in fact, she is authenticating to all n servers via MPCAuth.

Any factors supported by MPCAuth can be integrated into Flock, including PIN, passcode, U2F, email, SMS, server-side biometrics, and security questions. Distributed-trust applications like Signal's SVR employ PIN because it does not rely on an outside provider like email or SMS. U2F keys are also a common choice because the authentication secret resides on separate hardware. Flock currently integrates U2F, PIN, and passcode. MPCAuth does *not* require cloud support because it is embedded directly in the Flock deployment.

Supplementing MPCAuth. We remark that using MPCAuth alone is insufficient: it does not offer protections for the cloud tier or our more complex network tier because in MPCAuth, the n servers are fixed and known. Supporting n ephemeral, cross-cloud, user-owned instances introduces attack vectors at the cloud and network layers. To secure these layers, Flock ensures serverless instances are invoked by authorized users (§3.2.2) and have authorized network connections (§3.1.2) per invocation.

Rate-limiting is essential for thwarting brute force attacks in distributed-trust applications, particularly those using low-entropy PINs. Flock supplements MPCAuth with a rate-limiting protocol that tracks two parameters at each party: a counter for remaining attempts and a timestamp for the last failed attempt. Upon a failed authentication, the counter decreases. If it hits zero and the time since the last attempt is less than a set lockout period, further attempts are halted. Successful authentication resets this counter. Even if $n - 1$ instances are malicious, a single honest instance preserves the rate-limit's integrity by locking out malicious users eventually. While this framework provides a solid rate-limiting foundation, it is also flexible, allowing integration of sophisticated mechanisms tailored to application needs, including serverless product offerings [17, 70, 71].

3.2.2 Access Keys for Cloud-level Authentication.

An attacker might continually invoke other users' serverless instances, depleting application provider funds. Upon invocation, the serverless instances run MPCAuth, preventing the attacker from authenticating and executing a sensitive operation. However, executing MPCAuth incurred a charge. Further, if rate-limiting is in place, the attacker can even lock the legitimate user out of their account.

To address this, Flock ensures that only pre-approved users can activate their serverless containers. In each cloud, we leverage specialized cloud access keys for local device storage, configured with fine-grained IAM permissions [9, 25, 32]. Without these, an attacker cannot invoke a user's instances. The owner and authorized users of the instances (see data-sharing applications in §4) store access keys locally. Even if an attacker compromises a user's device, the keys do not grant access to the user's secrets, but only to the invocation of the serverless instances. In the unlikely scenario that a user loses their device with the serverless URLs and cloud access keys, the user can manually authenticate with the cloud providers to retrieve them for a new client installation.

3.3 Resource Protection & Billing

Billing is challenging because the provider must pay for user storage and compute *without* being able to access them. At the same time, even though the provider relinquishes its deployment control to the users, malicious users should not be able to deplete the provider's funds. As we outline in §3.2.2, *invocation access keys* prevent an attacker from invoking other users' parties and draining the provider's funds. Now, we must ensure that a user cannot abuse provider resources through its own deployment, especially since attackers can also create user accounts. Hence, in Flock, application providers set a maximum spending limit per user.

To enforce this spending limit, we first discuss what cloud providers offer in this direction, and then describe a solution based on virtual cards. Prominent cloud tools like AWS Organizations [19, 215] and GCP Projects [53] allow a billing account to pay for other accounts' resources without having access to them. AWS Budgets [14] and GCP Budgets & Alerts [48] grant providers policies which trigger alerts and halt spending [30, 45] if a user's spending surpasses a limit. While these services provide what we need, they are not foolproof because cloud providers have not previously operated in the model of strictly preventing a billing account from accessing the accounts it funds. Hence, it is likely that the billing account can gain access in a case-by-case basis to the paid-for account, e.g. by calling a cloud admin for support. However, the fact that these mechanisms already exist suggest that it would be a small change for these clouds to turn this into a strict enforcement, which we advocate for.

Meanwhile, Flock can use virtual cards, which render Flock fully functional today with existing tools. *Virtual card services* such as Karta offer credit cards with set monthly limits for Azure, AWS, and GCP [159], and AWS also accepts pre-paid cards [93]. These providers can issue capped digital cards to users, replenishing funds as needed. Payment platforms like Stripe offer APIs to issue standard cards with spending limits [84], which only incur a few cents per user.

`create_acc(user_info, module, auth_policy)`
`(cloud_auth)`
Create user account: programmatic registration & deployment.

`deploy(user_info, module, auth_policy)` Called in `create_acc` & for application & Flock updates.
`setup_module(module, auth_policy, new_state)` Authenticates the client & sets sensitive data for the parties.
`execute(module_inputs, auth_inputs)` Authenticates the client & executes a sensitive module.

Table 1: Flock API

3.4 Programmatic Registration & Deployment

Table 1 presents the Flock API used by application developers. A key feature of Flock is that we automate the user experience for clients, so that it is similar to a regular application. The main difference from the standard experience is that the user's application client may surface $n-1$ interactive authentication steps, one for each cloud. However, the Flock API ensures that the user does not bear the burden of manually registering for $n-1$ cloud accounts or interfacing directly with the clouds to deploy the serverless instances.

3.4.1 Registration

When registering for an application, the user's client needs to create $n-1$ cloud accounts. To ensure that the *user* does not manually perform this work, Flock utilizes Playwright [65], a webpage automation framework [65, 76]. Users input their details (name, password, email) in the UI of the application only once at account setup, as they typically do. Flock then automatically populates these details across the $n-1$ cloud registration forms, deriving unique passcodes from the user's provided passcode. Flock inputs application-provided data without user intervention.

Cloud registration requires multi-step user interactions like SMS, email, or CAPTCHAs. To handle these, the `create_acc` function (Table 1) takes the initial `user_info` input that can be automatically populated. Next, the function returns the interactive `cloud_auth` object, which surfaces the steps that necessitate user intervention during registration. For example, AWS registration [109] (1) sends an email with a code to input, (2) asks for contact information, (3) requests billing data, and (4) sends an SMS with a code to input. Thus, Flock anticipates `user_info` to initially collect an email, contact information, billing data, and phone number. This data is held in-memory and fed programmatically into each cloud form as registration proceeds, while `cloud_auth` surfaces mid-registration interactive user input requests (e.g.

SMS codes or CAPTCHAs) to the application UI, transferring the resulting input to the cloud frontends.

3.4.2 Deployment

Once all cloud accounts are instantiated, `create_acc` calls `deploy` (Table 1), which deploys the serverless containers corresponding to the `module`. This deletes any previous deployments, and performs the setup for the cryptographic module and `auth_policy` authentication factors by calling `setup_module` (Table 2). Upon deployment, the client device locally stores cloud access keys (§3.2.2).

4 Applications & Cryptographic Modules

Flock enables a diversity of applications where every distributed-trust computation only takes input data from a single owner or from public sources. Some applications naturally meet this criteria because sensitive data often equates to user-owned secret values. Other applications might initially appear as if they do not fit the on-demand distributed-trust model (e.g. data-sharing, private information retrieval). By *reframing* these applications to the Flock setting, we demonstrate how they, too, can benefit from on-demand deployment. We show how Flock can enable 8 types of distributed-trust applications, based on 5 fundamental cryptographic modules. Across these applications, Flock enables data confidentiality and integrity, private queries on public data, and data-sharing. Table 2 summarizes how each module is encapsulated by the Flock API functions `setup_module` and `execute`.

4.1 Secret Recovery

Secret recovery applications allows a user to back up her secret key k in the form of n secret-shares $\{k_1,\dots,k_n\}$ [202], each one stored at each party. Even if an attacker compromises $n-1$ parties, it cannot reconstruct the key k without the n-th share. The user retrieves all shares to reconstruct k. For integrity, the client initially stores a salted hash of k at each party and confirms the hash of the reconstructed key matches.

Secure key recovery for end-to-end encryption (E2EE) applications [56, 69, 79, 86, 95, 98] has been a long-standing issue. If a user loses their private key k (e.g. by losing their device), they lose access to their data. However, backing up the key on the application server breaks the guarantees of E2EE by introducing a central point of attack. To avoid this, application providers like Signal secret-share user keys [179]. The user can authenticate to the n servers using a PIN [200] to retrieve the shares of k. One honest party prevents brute force attacks through PIN rate-limiting and allows the client to detect if the recovered key is incorrect.

Password managers [6, 7, 26, 59, 60, 83, 205] store encrypted or hashed versions of user passwords in the cloud. When a single cloud or cloud account is compromised as in the recent high-profile LastPass hack [133], an attacker can brute-force passwords [190]. Flock secret-shares passwords across n parties, and allows the user to reconstruct the passwords locally upon use. If up to $n-1$ parties are compromised, the attacker cannot brute-force the passwords.

4.2 Signing

Signing applications secret-share a signing key k among n parties. Later, the client authenticates to the parties, who run MPC to sign the client's message m with the secret key k. The secret key is never materialized, and the MPC produces the signature. Flock uses a maliciously-secure multi-party signature generation protocol [143].[3]

Digital asset custody is offered by MPC wallets [35, 38, 42, 46, 47, 66, 72, 77, 97, 134, 177], who secure billions [101, 196]. While these wallets typically secret-share between the the client and the application server, Flock enables them to achieve their roadmapped objective of increasing the number of trust domains to $n > 2$ [178]. To send assets to Bob, Alice's client formulates a message tx and invokes the parties, who reconstruct her key within MPC to sign tx.

Certificate authorities [39, 43, 49, 61] routinely sign certificates that bind digital identities to cryptographic keys. Breached signing keys have led to fraudulent certificates that green-light malware and impersonate trusted websites [216]. Flock enables certificate issuance without ever materializing the signing key on one server, providing a more cost-effective alternative to hardware security modules [15, 23].

Code signing services [2, 33, 39, 49, 57, 68, 87, 92] allow organizations who provide critical software to sign code updates. With Flock, the attacker cannot endorse malicious software unless all n parties are breached.

4.3 Decryption

Using Flock, Alice can secret-share an encryption key k_{Alice} among her n parties. An authorized user, say Bob, can provide a ciphertext c to the parties, who will reconstruct k_{Alice} within MPC and decrypt c for Bob. Unlike secret recovery, Bob cannot obtain k_{Alice}, but can use it to perform decryptions that satisfy a certain access policy, as exemplified below. Flock uses a maliciously-secure AES-in-MPC protocol [41, 129], guaranteeing the decryption's integrity.

4.4 Data-sharing in Hierarchical File Systems

End-to-end encryption systems [21, 28, 36, 56, 67, 81, 85, 88] typically operate hierarchically: a user or group key encrypts a directory key, which then encrypts a group of file keys, each of which encrypts a file. If Alice, for instance, is unavailable, and Bob urgently needs a file F encrypted with k_F under

[3] While an attack for the GG18 [143] and GG20 [144] protocols was recently discovered [181], the patch was integrated into the library we use [89].

	`setup_module`	`execute`
Secret Recovery	Shard k as $k_1 \dots k_n$, $\texttt{cloud}_i$ stores k_i.	$\texttt{cloud}_i$ sends k_i to client, who reconstructs k from $k_1 \dots k_n$.
Signing	Clouds gen. $k_1 \dots k_n$ in MPC, each store k_i.	Client sends m. Clouds retrieve k_i, sign m in MPC.
Decryption	Shard AES key as $k_1 \dots k_n$, $\texttt{cloud}_i$ stores k_i.	Clouds retrieve k_i, AES decrypt ciphertext in MPC.
PIR	No client setup.	Send clouds DPF requests, reconstruct $d[i]$ via responses.
Freshness	Store file k in $\texttt{cloud}_1$, $h = H(k)$ in $\texttt{cloud}_2$.	Client retrieves k and h, and checks $h = H(k)$.

Table 2: Setup & execution specification for Flock modules.

Alice's key k_{Alice}, he should be able to access the file based on an access policy (e.g. a period of inactivity, signatures from users with authority), but without learning the key k_{Alice}, which would grant him excessive access. During setup, Alice shares her invocation access keys with Bob and configures her parties with the access policy and the authentication factors to verify from Bob (e.g. Bob's U2F) (§3.2.2). Bob can then authenticate, supply the encrypted k_F to Alice's n parties, which, after policy verification, allow Bob to decrypt k_F.

4.5 Private Information Retrieval

Private information retrieval (PIR) [113, 116, 124, 125, 146, 152, 169] enables users to query a public database at index i, without the servers learning i, and has many use cases [27, 105, 106, 110, 148, 149, 157, 158, 166, 174, 191, 197, 201, 211, 212].

The integration of two-party PIR in Flock showcases a different type of sensitive data access compared to aforementioned modules. Instead of storing a user-specific secret at the parties, we have a public dataset accessed by all the users and the sensitive data of each user is their *query*. In a traditional deployment, each PIR server stores the database. In Flock, we observe that the user's parties can serve as PIR parties since the data is public. However, the cost of storing the entire database in *each* user's cloud would compound. Instead, the database owner can place a public database copy in each of the n cloud providers, accessible by any Flock user deployment. For instance, if Alice queries index i from her Flock deployment in AWS, she would only need to access the AWS database copy, eliminating cross-cloud latency and egress. We port an existing PIR implementation [10] to Flock.

To introduce malicious security, a trusted database owner can store each entry with a signature of the entry, which the client can verify upon reconstruction. If one party tampers with the signature and the other is honest, all queries will fail. In contrast, adding malicious security to single-server PIR exhibits significant costs [125]. Public databases are community-scrutinized to prevent the database owner from tampering with the database. However, a known approach of encoding MAC key into DPF keys can remove this trust assumption from the database owner [125, 132].

4.6 Data Freshness

Data freshness applications often power rollback protection and file integrity, which are long-standing obstacles in systems where the application provider has control over stored user data [104, 155, 160, 167, 183]. Flock utilizes a hash-based freshness module based on Verena [160]. This application demonstrates that Flock's sensitive data does not need to be *secret* data; rather, the sensitive data is the *integrity* of the file system. In Flock, the application provider acts as the file storage server, while a hash server is deployed by the user via Flock. Users safeguard against tampered or outdated file versions by storing a hash of their latest file in the hash server, allowing users to guarantee *their own* file integrity. When a file is stored, its latest hash is saved and signed by the hash server for client verification. During retrieval, the hash server sends the client a signed hash, confirming the file's latest version. Flock's freshness module also incorporates access control. The deploying user retains ownership, granting `read` and `write` permissions so other users can view or update the latest file hash. Signatures from the hash server guarantee the integrity of the file.

5 Evaluation

In this section, we answer: *How do the performance and cost of Flock compare to traditional distributed trust?*

5.1 Implementation

We implemented Flock using ∼2,000 lines of Go (signature protocol, relay), ∼2,000 lines of Python (freshness protocol, client, deployment, storage, server-side "frontend"), and ∼2,000 lines of C++ (passcode, decryption, PIR, relay client). We used cloud SDKs and black-boxed foundational cryptographic libraries: `tss-lib` [89] for the Multi-Party Threshold Signature Scheme [143], `emp-agmpc` [41] for Global-Scale Secure Multi-Party Computation [213], and Google's implementation [10] of incremental distributed point functions [113]. For the relay, we used OpenSSL [64] and its Go bindings[4] for the SSL_shutdown [82] procedure (§3.1).

[4] We fork and adapt github.com/spacemonkeygo/openssl.

Module	System	Breakdown (ms)		End-to-End (ms)	
		Client	*Server*	Mean (μ)	SD (σ)
Secret Recovery:	*Baseline*	80.50	252.74	356.05	20.03

Table 3: Latency of modules & authentication factors. We fix 2^{10} as the input size for brevity.

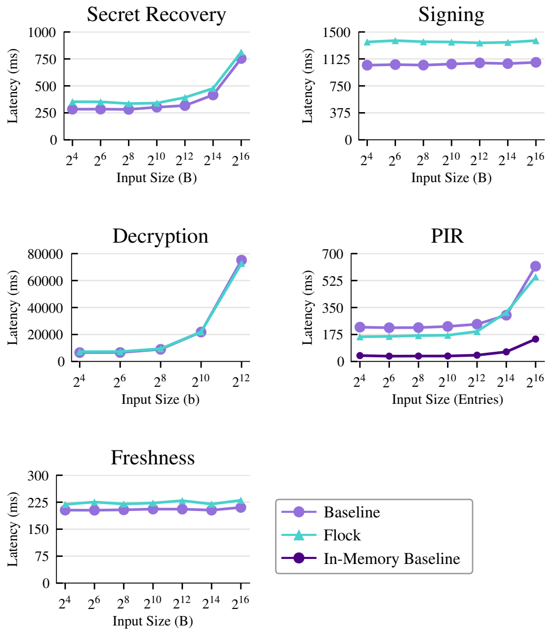

Figure 5: End-to-end latency of cryptographic modules across varying input sizes: number of database entries (Entries) for PIR, bits (b) for decryption, bytes (B) for all other modules.

Our implementation is open-sourced at github.com/flock-org/flock.

5.2 Experiment Setup

The **baseline** is a traditional distributed-trust setup consisting of three VMs in the three major clouds. We use 2 vCPU, 8 GB memory servers in California for AWS (m5.large, \$80.64/month), Azure (Standard_D2as_v4, \$80.64/month), and GCP (n2-standard-2, \$85.16/month). Selecting servers in close proximity minimizes network delays, in-line with typical MPC deployments. The client is an AWS m5.large. This setup is comparable to that of traditional distributed-trust systems in prior literature (§6).

In **Flock**, application providers typically run one party and users deploy $n-1$ parties (§1.1). It is more cost-efficient for an application provider to run their party on a single VM because they can amortize costs among many users without halting the instance [154]. The application server is in Azure and has the same configuration as the baseline's application server in Azure. The client and the regions for the parties are also like in the baseline. We use an Azure Standard_B2s VM (2 vCPU, 4 GB, \$36/month) for the Flock Relay. For the serverless containers of signing, decryption, and PIR, we used 2 vCPU AWS Lambda [18] (3,538 MB memory, \$0.0000575/s) and Google Cloud Run [52] (512 MB, \$0.00006895/s) instances. For secret recovery and freshness which primarily conduct cloud storage operations rather than server-side compute, we use smaller serverless instances: 0.5 vCPU AWS Lambda (895 MB memory, \$0.0000144/s) and 0.75 vCPU Google Cloud Run (512 MB, \$0.00002695/s). We selected the smallest available memory size for serverless instances.

5.3 Latency

We evaluate the latency of the baseline and Flock for each cryptographic module (described in §4), scaling with their respective input sizes: the secret size for secret recovery, message size for signing, plaintext size for decryption, number of database entries for PIR, and file size for freshness checks. We chose sizes reflective of typical workloads (e.g. size of a cryptocurrency transaction, certificate, or encryption key). For PIR, input size is the number of *database entries* of size 128 B. For decryption, input size is the number of *bits* since our suggested application only requires efficient file key encryption. For all others, input size is the *byte count*. Latency benchmarks were averaged over 10 runs. For the two-party modules (PIR and freshness), we use the application provider server and the Lambda.

Fig. 5 depicts the latency-input size relationship for both baseline and Flock. Table 3 breaks down latency results for an input size of 2^{10} into client, server, and end-to-end times, with the latter also accounting for client-server network time. We also break down the latency of MPCAuth authentication factors PIN (standard 4-digit format) and U2F. The PIN implementation also supports long passcodes. The function-independent phase in the decryption and PIN circuits can be executed offline to further reduce latency. Utilizing Flock for PIR necessitates streaming and deserializing the database from cloud storage for each request; in a traditional two-server PIR, databases can be held in-memory so we also evaluate a version of our baseline with an in-memory database.

As evidenced in Table 3 and Fig. 5, Flock does not significantly impact the latency of the 5 major cryptographic modules and their MPCAuth factors. More modules exhibit slightly higher standard deviation in Flock, which is expected due to the burstiness of serverless computing. The relay is used in decryption, signing, and PIN: While decryption is 1.01x the latency of the baseline since it is more compute-heavy, signing is 1.28x since it is communication-heavy and the relay slightly impacts performance, as we will concretize in §5.4. As anticipated, Flock exhibits considerably higher latency that the PIR in-memory baseline variant. In exchange, Flock PIR deployments reap the benefits of automatic trust domains and practical malicious security (§4.5). For consistency between Flock and the baseline, as well as between the modules, we use the S3 storage PIR baseline for the remainder of experiments and calculations. Flock-enabled PIR can be enhanced by employing latency-optimized cloud storage services at an extra cost [8] or by parallelizing computation while streaming the remainder of the database.

Averaged over all modules, Flock has a 1.05x latency overhead compared to the S3 baselines. As expected, most cryptographic modules exhibit higher latency with greater input size. Signing remains constant since the protocol [143] signs a *hash* of the message. Freshness is also constant since it is bottlenecked by reads and writes to cloud storage, which are fast at this file size.

Serverless coldstart & deployment latency are factors in Flock, unlike traditional distributed trust. We opted for serverless containers with low coldstart [18, 52, 58] over those with high coldstart [3, 16, 22] and designed lean Docker containers (634 MB pre-compression, 225 MB post-compression). Containers are stored in the application provider's Elastic Container Registry on each cloud, so that users need not build containers. Deployment latency averaged 16.13s for AWS Lambda and 15.88s for Google Cloud Run across 10 tests. For coldstart measurements, we used AWS CloudWatch's X-Ray and invoked Google Cloud Run after idle periods, resulting in 1.02s (AWS Lambda) and 2.10s (Google Cloud Run), averaged over 10 runs. Providers can minimize (or eliminate) coldstart times by keeping containers warm through periodic polling [1]. Applications can also deploy smaller containers with only necessary module dependencies, not all 5.

	Per-Conn.	Setup Latency (ms)		Concurrent Users	
	Gb/s	*S2R*	*Total*	*Sign*	*Decrypt*
Baseline	1.94	–	24.48	–	–
Flock	1.72	20.66	49.72	11,700	1,900
Wireguard	0.063	25.5	78.43	–	–

Table 4: Single connection throughput & establishment latency, and number of concurrent users supported by the relay. S2R includes steps 1-7 of the per-invocation protocol (§3.1.3).

5.4 Relay Evaluation

Per-connection latency & throughput. Table 4 compares the setup latency of the Per-Invocation protocol (§3.1.3) and the throughput[5] of a Flock Relay TLS connection to the baseline's direct TLS connection. We use our Azure and GCP VMs as endpoints, with the relay hosted in the AWS VM. Averaged over 50 runs, a Flock connection's throughput is 0.89x that of a direct TLS connection since all traffic is forwarded through the relay. The setup latency is 2x that of a direct connection due to the additional S2R handshake.

We also benchmark the method used by Tailscale DERP [37], which connects Wireguard [96] endpoints with a relay that re-encrypts Wireguard packets into TLS messages. The Wireguard setup is significantly less performant than the Flock Relay at 0.03x the per-connection throughput of the baseline. As we explain in §3.1, the Wireguard setup incurs significant overhead from encrypting packets at the more granular IP layer, decrypting and re-encrypting all traffic using TLS at the relay, and redundantly TLS-encrypting the Wireguard packets at the endpoints. Setting up Wireguard interfaces and iptable routes introduces 3.2x the setup latency of the baseline. Therefore, Flock Relay connections outperform prior work and nearly match the efficiency of direct TLS.

Cross-user throughput. To evaluate the maximum capacity of the relay, we measure its concurrent user throughput, independent of external factors like application server performance and the compute of cryptographic modules. By emulating traffic patterns for the signing and decryption modules from multiple threads, we saturated the CPU utilization of the relay VM. Results in Table 4 show it can handle 11,700 concurrent signing or 1,900 decryption requests, using 1.9 GB memory. The application provider can further scale the relay deployment based on user demand. We remark that these values represent a worst-case scenario where *all* users invoke Flock, generating traffic patterns in a burst without compute-induced delay. Typically, the Flock Relay can support additional users when they spend intermittent time on compute tasks.

[5] We use github.com/udhos/goben/ for throughput measurements.

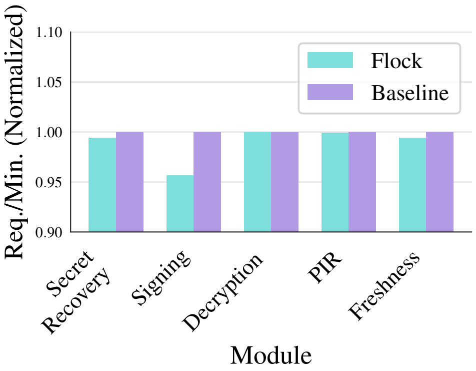

Figure 6: Maximum requests/min. of Flock (F), normalized over the baseline (B). (Secret Recovery: F-1376, B-1384; Signing: F-66, B-69; Decryption: F-5, B-5; PIR: F-1195, B-1196; Freshness: F-1162, B-1169)

5.5 Throughput & Cost

System throughput. Flock achieves throughput comparable to the baseline, as illustrated in Fig. 6. We demonstrate this by fixing an input size of 2^{10} and invoking as many Flock requests as possible.We verify that the CPU utilization of the VM(s) in both Flock and the baseline is 100% at the maximum load, which is the threshold at which additional threads cannot further increase the number of successfully completed requests per minute.

Cost. We use this experiment to calculate the cloud cost estimates for the baseline and Flock in the worst case (Table 5) and across varying server utilization rates (Fig. 7). For each module, we use the baseline's request-per-minute from Fig. 6 to calculate the cost-per-request by dividing the monthly server cost by the number of monthly requests. We then measure Flock's cost-per-request using the per-second vCPU and memory costs, and the same method as the baseline to calculate the application provider's server cost. Finally, we aggregate all cloud expenses to get the total computational cost per operation. We measure the bytes of network traffic transferred by each protocol. AWS, GCP, and Azure charge a network egress fee of \$0.09/GB, \$0.085/GB, and \$0.087/GB, respectively, which we use to calculate the cross-cloud and cloud-to-client data transfer fees. Each module also includes a persistently stored state. For one month, AWS, GCP, and Azure charge \$0.026/GB, \$0.023/GB, and \$0.021/GB, respectively. We include the resulting bandwidth, storage, network, and compute cost per invocation in Table 5.

Averaging across modules, Flock is 2.27x the worst-case cost of the baseline. Table 5 assumes server load is saturated, yielding the lowest possible cost-per-user. However, application providers rarely operate at full server capacity and often provision excessive resources to handle spikes in usage. Fig. 7 shows Flock and the baseline's module average of the per-invocation cost, varying the server utilization from 5-100% of the maximum requests-per-minute. For operating at 50% utilization, the cost of Flock is only 23% more. Flock is actually less expensive on average than the baseline when the monthly requests completed are up to 20% of the baseline's maximum capacity, because of the serverless compute model.

Finally, we emphasize that the baseline has *additional costs* beyond the cloud cost, which do not exist in Flock (§1.1). First, the application provider must compensate its business partners (who have employees or seek profit). Second, the hidden price of the traditional setup is the manual, time-consuming, and difficult challenges of finding suitable business relationships to setup distributed trust.

6 Related Work

Traditional distributed-trust deployments have exhibited a host of obstacles [178] for industry-leading teams, including Signal [79], ISRG [54], and Coinbase [177]. Prio has been employed for private analytics in COVID-19 exposure notifications and Firefox telemetry [100, 108, 126, 136], but ISRG encountered difficulties with cross-organizational inconsistencies in testing and debugging [99, 145, 178]. Signal struggled to deploy traditional distributed trust for its secret recovery application [179], citing reliance on third-parties for security, constant up-time, and user trust [79, 178]. Meta's Private Lift leverages MPC for private advertising, yet advertiser onboarding is time-consuming [187, 198]. Astran [12] has attempted secret-sharing user data across clouds, but their servers see the plaintext data and are therefore a central point of attack [13]. Thus, while the cryptographic guarantees of distributed trust have been instrumental in securing several impactful applications, *deployment* has been a central challenge.

MPC [112, 128, 147, 162–164, 213, 219] **and PIR** [40, 105, 113, 116, 125, 146, 152, 169] **applications** are growing in relevance. MPC applications include private analytics [114, 126] and MPC wallets [35,38,42,46,47,66,72,77,97,101,134,177]. PIR applications include private contact discovery [158], credential reporting [174, 191, 207, 212], blocklist lookups [166], and media delivery [149]. Both primitives have been used for private search [131, 132, 151, 194, 197, 211], private advertising [110, 148, 157, 187, 201], and anonymous messaging [105, 106, 123, 127, 138, 170, 171, 217]. **Data freshness** is important for preventing rollback attacks, e.g. in trusted execution environments [104, 167, 183]. Prior work introduces hash servers for file integrity [155, 160]. Flock's contribution is orthogonal and focuses on *deploying* such systems. Many of the systems that Flock supports can be mapped to our baseline setup in §5, and use an underlying cryptographic module that we benchmark. Another line of work [172] aids in the deployment of non-cryptographic distributed trust by offering different privileges to each trust domain; our work instead focuses on offering a deployment mechanism for distributed trust based on strong *cryptographic* guarantees.

Module	*Bandwidth (KB)*	*Storage*	*Network*	*Compute*	***Total***	*Compute*	***Total***
Secret Recovery	25.83	0.0000	0.0002	0.0004	0.0006	0.0016	0.0018
Signing	67.38	0.0000	0.0006	0.0083	0.0089	0.0213	0.0219
Decryption	59,763	0.0000	0.5219	0.1141	0.6360	0.3340	0.8559
PIR	1.38	0.0009	0.0000	0.0005	0.0014	0.0024	0.0033
Freshness	2.89	0.0000	0.0000	0.0005	0.0005	0.0011	0.0011

Table 5: Worst-case cost per one user invocation (USD *cents*). We show the maximum number of requests per minute that the baseline can handle, bandwidth (KB), storage cost, networking cost, and the compute cost for each a single invocation in the baseline and Flock.

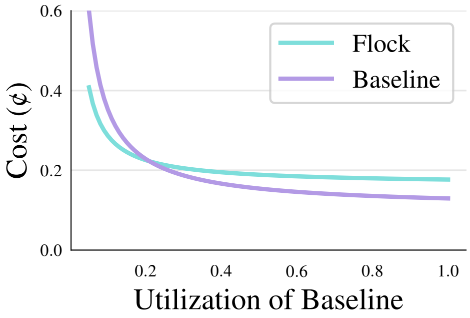

Figure 7: Average per-invocation cost (¢) across all modules for Flock and the baseline, between 5-100% utilization of the maximum baseline capacity.

Serverless networking is a longstanding limitation [107, 150] of serverless computing. While service meshes [31, 55] and proxies [44] can connect services by abstracting network connections, they do not handle *private* endpoints. As we discuss in §3.1, a line of work employs NAT traversal and hole-punching for serverless communication [137, 139, 186, 214], but requires costly per-user services like private clouds or NAT gateways. Recent systems use a relay to enable serverless networking [140, 141, 210], but do not consider security. Some works conduct TLS over multi-step network connections [80, 208], but cannot handle publicly inaccessible endpoints. Wireguard [96] and Tailscale DERP relays [37] securely connect private endpoints, but are unsuitable for serverless as we explained in §3.1. We build upon the the relay-based technique in the literature to architect the first *end-to-end encrypted* relay which has negligible detriment to performance.

Hardware enclaves have been proposed [130, 179] as a replacement to deploying $n-1$ trust domains to safeguard secrets and execution from the application provider. However, enclaves are vulnerable to side-channel attacks that compromise remote attestation, including leaks through SGAxe [209], Plundervolt [188], AEPic Leak [115], and CIPHERLEAKS [175]. With root access to deployment servers, application providers can exploit such side-channels to access secrets. Hence, while enclaves are often utilized as a *supplementary* defense alongside cryptography, applications often opt for cryptography as the primary security measure [178]. In contrast, Flock sets up distributed trust on n major clouds without relying on trusted hardware.

User-centric deployment has been validated in traditional systems work [90, 103, 120–122, 168, 173, 185, 192, 199] in which users deploy components of the applications to retain privacy from a provider. Users sandbox and isolate components of their application to enforce user control. Unlike Flock, these methods do not utilize distributed trust, and thus position a cloud, device, or server as a central point of attack. Flock draws from the underlying principles of user-centric deployment by applying this framework to distributed trust.

7 Conclusion

This work introduces the on-demand distributed-trust architecture, which enables application providers to automatically deploy distributed-trust applications, thus surpassing the cumbersome, manual, and time-consuming process of setting up business relationships. To reverse the deployment from provider to users, our platform Flock consists of a cost-effective cross-cloud serverless framework supporting a variety of distributed-trust applications. We hope that Flock catalyzes an increase in the deployment of distributed trust.

FairyWREN: A Sustainable Cache for Emerging Write-Read-Erase Flash Interfaces

Abstract

Datacenters need to reduce embodied carbon emissions, particularly for flash, which accounts for 40% of embodied carbon in servers. However, decreasing flash's embodied emissions is challenging due to flash's limited write endurance, which more than halves with each generation of denser flash. Reducing embodied emissions requires extending flash lifetime, stressing its limited write endurance even further. The legacy Logical Block-Addressable Device (LBAD) interface exacerbates the problem by forcing devices to perform garbage collection, leading to even more writes.

Flash-based caches in particular write frequently, limiting the lifetimes and densities of the devices they use. These flash caches illustrate the need to break away from LBAD and switch to the new Write-Read-Erase iNterfaces (WREN) now coming to market. WREN affords applications control over data placement and garbage collection. We present FairyWREN[1], a flash cache designed for WREN. FairyWREN reduces writes by co-designing caching policies and flash garbage collection. FairyWREN provides a 12.5× write reduction over state-of-the-art LBAD caches. This decrease in writes allows flash devices to last longer, decreasing flash cost by 35% and flash carbon emissions by 33%.

1 Introduction

DATACENTER CARBON EMISSIONS are a topic of growing concern. At current emission rates, datacenters' share of global emissions are projected to rise to 20% by 2038 [48] and 33% by 2050 [53]. In the next few decades, many companies — including Amazon [1], Google [2], Meta [11], Microsoft [71] — are looking to achieve Net Zero, i.e., greenhouse gas emissions close to zero. To achieve this goal, many datacenters are adopting renewable energy sources such as solar and wind [11, 39, 64, 71]. Google, AWS, and Microsoft are expected to complete their transition to renewable energy by 2030 [30, 49, 59]. However, this switch in energy source does not reduce datacenters' *embodied emissions*, the emissions produced by the manufacture, transport, and disposal of datacenter components. Embodied emissions will account for more than 80% of datacenter emissions once datacenters move to renewable energy [39].

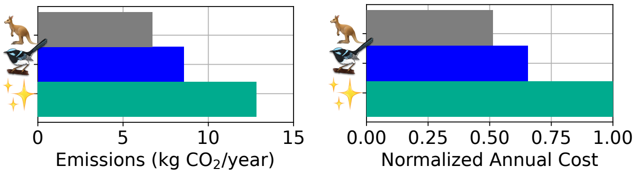

Fig. 1: Carbon emissions and cost for flash in Kangaroo (🦘), FairyWREN (🐦), and "minimum writes" (✨)—an idealized cache with no extra writes—over a 6-year lifetime for a production Twitter trace and a target 30% miss ratio. Compared to Kangaroo, FairyWREN reduces carbon emissions by 33% and cost by 35%.

Embodied emissions are produced by one-time lifecycle events. Datacenters can reduce these emissions by: *(i)* replacing hardware with less carbon-intensive alternatives, and *(ii)* extending the lifetime of components to amortize embodied emissions over a longer period. Recent work has studied embodied emissions in processor design [24, 38, 39, 85], but considerably less attention has been paid to memory and storage, even though they constitute 46% and 40% of server emissions, respectively [64]. It is therefore crucial to both move from carbon-intensive technologies like DRAM to flash, which has 12× less embodied carbon per bit [38], *and* to extend flash lifetimes to amortize flash's embodied carbon.

However, flash introduces a new challenge: *limited write endurance*. A flash device can only be written a limited number of times before it wears out. Each new generation of flash has lower write endurance as a result of manufacturers packing more bits into each cell. This packing, however, does improve sustainability by storing more capacity in the same silicon (i.e., less carbon per bit). To realize the benefits of denser flash, applications must write to flash much less frequently. The write-rate budgets that applications must operate under to achieve longer lifetimes are tiny: to achieve a six-year lifetime on a 2 TB QLC drive, the application can write only 14 MB/s,

[1] Fairywrens (🐦) are vibrant birds native to Australia. Common varieties include Superb Fairywrens, Splendid Fairywrens, and Lovely Fairywrens.

or 0.09% of available write bandwidth (Sec. 2).

Reducing carbon from caching. Hence, write-intensive flash applications present a major challenge in reducing overall datacenter emissions. This paper focuses on reducing carbon from flash caching, an increasingly popular use of flash in the datacenter [3,16,21,22,35,36,83]. We aim to demonstrate, through caching, how to *leverage emerging flash interfaces* to reduce writes, in particular by *re-purposing garbage collection to do useful work.*

Caching is fundamentally write-intensive, as new objects must be frequently admitted to maintain hit rates [15,18]. Datacenter caches also store many small objects [16,67], which is particularly problematic because flash can only be written at a coarse granularity. Because of this mismatch, admitting small objects to the cache can lead to significant *write amplification*: i.e., more bytes are written to the underlying flash device than requested by the application.

Most current flash devices are *Logical Block-Addressable Devices (LBAD)* that present the same block device abstraction used by hard disks. This abstraction hides significant details about how SSDs work. In particular, while the interface allows reading and writing 4KB blocks, the underlying flash device can only erase large (MB to GB) regions. To implement the LBAD interface, the flash firmware performs garbage collection, copying blocks of valid data and erasing entire regions to make room for new writes. Current flash caches have a limited ability to optimize these internal writes, which can amplify the total bytes written by 2× to 10× [67].

Opportunity: WREN. New flash SSD interfaces, such as ZNS [19] and FDP [66], allow closer integration of host-level software and flash management. The key difference between these interfaces and LBAD is that these interfaces include `Erase` as a first-order operation, allowing the cache to control garbage collection. We use the name *Write-Read-Erase iNterfaces (WREN)* to collectively refer to such interfaces, and we describe the necessary and sufficient operations for flash caches to minimize write rate. However, we also show that merely porting existing flash caches to WREN does not reduce flash writes. *Flash caches must be re-designed to leverage the additional control provided by WREN.*

Our solution: FairyWren. We design and implement FairyWren, a flash cache that harnesses WREN to reduce writes. The main insight in FairyWren is that every flash write, whether from the application *or from garbage collection*, is an opportunity to admit objects to the cache. When flash is written during garbage collection, FairyWren can admit objects "for free". This idea cannot be realized on LBAD, since these devices offer no control over garbage collection. FairyWren uses the features of WREN to perform a "nest packing" algorithm on *every* write, *unifying cache admission and garbage collection in a single algorithm.* FairyWren also leverages WREN to enable large-small object separation and hot-cold set-partitioning, further reducing writes.

Summary of results. We find that, without major changes to flash interfaces and cache designs, deploying denser flash will not reduce the carbon emissions of flash caches. *For current caching systems, the reduced write endurance of denser flash outweighs the gains in density.* Only by changing the flash interface and optimizing the cache to this new interface can we realize the significant emissions savings of denser flash.

To illustrate this point, we implement FairyWren as a flash cache module within CacheLib [16]. We evaluate FairyWren on production traces from Meta and Twitter using both simulation and a real ZNS SSD. *FairyWren reduces flash writes by 12.5×* vs. the research state-of-the-art. By enabling caching on denser flash, *FairyWren reduces flash's carbon emissions by 33%* vs. the research state-of-the-art (Fig. 1). FairyWren performs close to an idealized, minimum-write cache on both carbon emissions and cost.

Contributions. This paper contributes the following:

- *Flash trends (Sec. 2):* By studying flash trends, we identify opportunities for more sustainable flash caching as well as challenges that prevent current flash caches from realizing these benefits (Sec. 3).
- *Critical elements of flash interfaces (Sec. 4):* We identify the `Erase` operation and control over garbage collection as the essential features of emerging flash interfaces. We describe tradeoffs and fundamental constraints of flash interfaces, showing that some features are, contrary to prior work, unhelpful for caching.
- *FairyWren (Sec. 5):* FairyWren's key insight is to leverage emerging flash interfaces to unify garbage collection and cache admission as one operation, greatly reducing overall flash writes. FairyWren further reduces writes by partitioning objects by size and popularity (hot vs. cold).
- *Analysis of flash emissions (Sec. 6):* We develop a model to analyze carbon emissions from flash. We show that FairyWren's write reduction allows flash caches to improve sustainability using denser flash for longer lifetimes.

2 Opportunities in flash caching

Flash is an increasingly attractive option for caching [16, 21,22,35,57,67,68,83]. In this section, we discuss how trends in the design of flash devices present growing opportunities to reduce the cost and carbon emissions of caching.

Opportunity 1: *Flash is less carbon-intensive than DRAM, so caches are more sustainable with less DRAM.*

DRAM often makes up 40% to 50% of server cost [58, 79,82] and is no longer scaling (Fig. 2). DRAM also has a large embodied carbon footprint and has large operational emissions due to requiring up to half of system power [38].

Flash is cheaper per-bit, embodies 12× less carbon, and requires less power per-bit than DRAM [38]. Thus, datacenters should use flash over DRAM whenever possible [37], even for traditionally DRAM workloads, such as caching [16,35, 67,68] or machine learning [95].

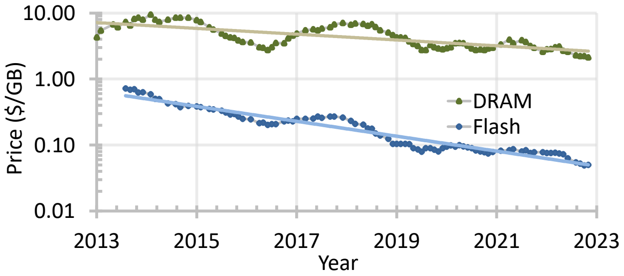

Fig. 2: Cost for flash and DRAM over the last 10 years [4, 6]. Flash prices have decreased over 14×, while DRAM prices have only decreased by ≈2×.

Opportunity 2: *Flash caches should use denser flash where possible to reduce emissions.*

Flash is becoming denser, moving from *single-level cells (SLC)*, which store 1 bit/cell, to *tri-level cells (TLC)*, which store 3 bits/cell. Flash SSDs will soon use *quad-level cells (QLC)* and *penta-level cells (PLC)* [73]. Denser flash is cheaper; e.g., PLC is forecast to be 40% cheaper per-bit than TLC [9]. Denser flash also reduces carbon emissions, since more bits are packed onto roughly the same silicon.

Opportunity 3: *Lengthening device lifetime is an effective way to improve datacenter sustainability.*

Traditionally, datacenter hardware replacement cycles have been around three years [64] due to the rate of improvement in hardware performance and energy efficiency. Today, datacenters deploy devices for longer. Longer replacement cycles have become common due to their cost advantages and the slowing of Moore's Law. For example, Microsoft Azure increased the depreciable lifetime of servers from four to six years [42, 65], and Meta recently started planning for servers to last 5.5 years [12]. Additionally, hyperscalers are finding that servers do not fail quickly: failure rates at Azure have little evidence of increasing before eight years [17, 64].

Moving to longer lifetimes amortizes both cost and embodied carbon. As datacenters shift to renewable energy, they are rapidly reducing operational carbon. As a result, embodied carbon now dominates datacenter carbon emissions [12, 38, 39, 84]. The major challenge, though, is how to extend *flash* lifetime, given its limited write endurance.

3 Challenges in flash caching

Flash SSDs have limited write endurance and are warrantied only for a stated write budget [10]. Exceeding this write budget can cause the device to fail. Hence, while flash caching presents carbon-saving opportunities (Sec. 2), caches must severely limit the amount they write. Here, we discuss the challenges of flash caching in detail and describe how current systems fail to address these challenges.

3.1 Wherefore device write amplification?

Flash devices cannot write new values without first erasing a large region of the device. To support random writes, devices must read all live data in a region, erase the region, and then write the live data back to the drive along with any new data. As a result, flash SSDs perform more writes than requested by the application. The *device-level write amplification* (DLWA) [23, 35, 41, 54, 57, 62, 83] captures this relative increase in bytes actually written to flash vs. bytes written by an application. (If an SSD writes 3GB to serve 1GB of application writes, then DLWA is 3×.) DLWA can be large: a factor of 2× to 10× is common [67]. DLWA causes write-intensive applications to quickly wear out flash devices, increasing their replacement frequency and embodied emissions over time.

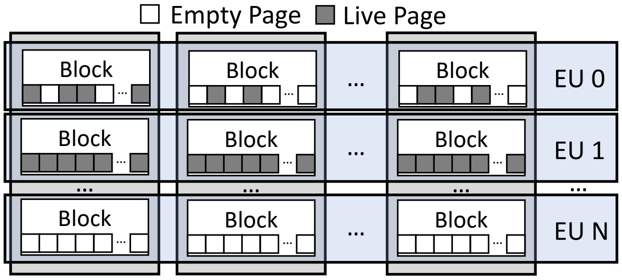

Fig. 3: The internal arrangement of flash devices into planes, blocks, pages, and EUs. Each EU has blocks in multiple pages. EU 0 is a partially full, EU 1 is entirely full, and EU N has just been erased.

DLWA is primarily caused by the physical limitations of flash storage. Flash devices are organized in a physical hierarchy (Fig. 3). The smallest unit is the *page*, usually 4 KB. Flash can be written at page granularity, but a page must be erased before it can be rewritten. To avoid electrical interference during erasure, pages are grouped into *flash blocks* [13, 19, 20, 41, 63]. A flash block is the minimum erase size. In practice, however, flash drives stripe writes across blocks to improve bandwidth and error correction. Striping increases the effective *erase unit (EU)* size to gigabytes [19].

The mismatch between the granularity of writes and erases is the root cause of DLWA. To maintain the 4 KB read/write block interface, flash devices garbage collect (GC), moving live pages from partially empty EUs (such as EU 0 in Fig. 3) to a writable EU (such as EU N) before erasing the EU and freeing dead pages. The less the available capacity on the device, the more frequently it has to GC, introducing a tradeoff between flash utilization and flash writes.

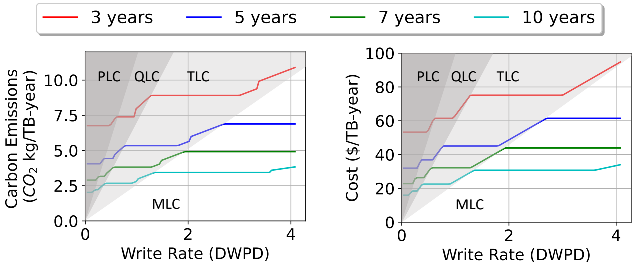
One might hope that technological advances would decrease EU sizes, closing the gap between write and erase granularities. However, *flash EU sizes have gotten larger as flash has gotten denser*. Effective block sizes on an SLC flash device were 128 KB [86], MLC and TLC flash devices are around 20 MB [81], and QLC devices will be 48 MB [80]. Striping these blocks with hundreds of 3D-stacked layers [80] results EUs in the gigabyte range [19, 69].

Lesson for flash caches: Write amplification is caused by the size mismatch between writes and erases in flash. This mismatch will keep increasing.

3.2 Denser flash has lower write endurance

As flash becomes denser, its write endurance drops significantly. For example, while PLC flash is up to 40% denser than TLC, PLC is forecast to have only *16%* of TLC's writes [9]. Additionally, because denser flash has to differentiate between more voltage levels, even small voltage changes can make data unreadable. TLC uses two-phase writes and more frequent refresh to prevent data loss [70]. Two-phase writes require the device to have enough RAM and capacitance to remember all in-flight writes, limiting the number of EUs that can be "active" (i.e., writable) at any point in time, often to less than ten. Writing to more EUs than this requires closing an active EU, incurring more internal device writes.

Fig. 4 models how write rate affects both emissions and cost when varying lifetimes and flash density. Each line shows a device of a different lifetime, and shaded regions show which flash density is best for a given write rate. The model calculates how much capacity must be provisioned for each technology to achieve the desired lifetime at a given write rate. For example, a device lasting 7 years (green) has lower annualized carbon emissions than one lasting 3 or 5 years, and it should use dense flash (e.g., TLC) only at write rates below two device-writes-per-day.



(a) Carbon emissions.

(b) Cost.

Fig. 4: The annual carbon emissions and cost of flash depending on the required average write rate and desired lifetime.

Lesson for flash caches: Device lifetime is the most important factor in reducing carbon emissions. Moreover, denser flash can improve sustainability, but only if flash write rate is very small — much less than one device-write per day.

3.3 Shortcomings of existing solutions

To limit embodied emissions, sustainable flash caches must minimize *(i)* idle flash space — which incurs emissions for no benefit; *(ii)* DRAM usage for object metadata — which can add up to tens of GBs [35, 67]; and *(iii)* flash write rates — which wear out the device, reducing lifetime. No prior flash-cache design meets these criteria (Table 1). In particular, although caches must admit new objects to maintain hit rates, flash caches must be designed to minimize application- and device-level write amplification to extend device lifetime.

Flash caches ≠ DRAM caches. Both flash caches and DRAM caches try to reduce misses, but flash caches must also contend with flash's limited write endurance, leading to much different designs. Flash caches are designed to achieve low end-to-end write amplification, i.e., the product of *application-level write amplification* (ALWA) (e.g., from having to write 4KB to flash to admit a 100B object) and DLWA.

	Flash caches should minimize ...			
	Unused flash	**DRAM**	**ALWA**	**DLWA**
Key-value stores	✗	✓	✓	✓
Log-structured caches	✓	✗	✓	✓
Set-associative caches	✗	✓	✗	✗
Kangaroo [67]	✓	✓	✓	✗
FairyWren	✓	✓	✓	✓

Table 1: Comparison of FairyWren vs. prior cache designs. FairyWren is the only design to minimize all important overheads.

Flash caches ≠ key-value stores. KV stores [5, 7, 33, 55, 60, 75, 90] support a similar read-write interface as caches and likewise minimize flash writes and DRAM overhead. However, flash caches have significantly different design goals.

The main difference is that `delete` operations are uncommon in KV stores, but very frequent in caches. Caches frequently evict objects and must reclaim space immediately to admit new objects [67]. Most KV stores do not support deleting objects quickly enough to implement cache eviction policies. Specifically, standard KV store data structures like LSM trees [5, 7, 31, 32, 60, 75, 90] will not work well for caching unless the KV store is massively overprovisioned, often by more than 2× the cache capacity [21, 22, 83].

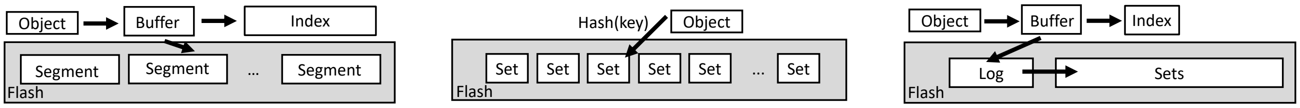
Moreover, KV stores do not exploit a cache's biggest advantage: caches are free to evict objects whenever it is convenient. Evicting objects opportunistically can greatly reduce writes and maximize space utilization, but KV stores are not built to exploit this cache-specific optimization.

Existing flash caches do not address DLWA. Because of the unique challenges of flash caching, there is a growing body of work devoted to improving flash cache designs. Prior flash caches generally fall under three categories (Fig. 5): log-structured, set-associative, and hierarchical.

Log-structured caches. To minimize writes, many flash caches are log-structured [16, 27, 35, 83]. These caches append objects to an on-flash log (Fig. 5a), locating objects through a DRAM index and evicting objects in large groups. The log allows large sequential writes to flash and thus achieves nearly ideal write amplification.

While log-structured caches work well for larger objects, the DRAM index becomes prohibitively large for small objects, even if it is highly optimized [67], significantly increasing overall emissions and cost (see Fig. 11). Flash caches are thus often partitioned, using a log-structured cache for large objects and a different design for small objects [16].

Set-associative caches. Set-associative caches, such as the Small Object Cache in Meta's CacheLib [16], replace the DRAM index with a hash function that maps each object to a unique set (usually a 4 KB page) on flash (Fig. 5b).



(a) Log-structured *(b) Set-associative* *(c) Kangaroo*

Fig. 5: Designs of prior flash caches: (a) Log-structured caches write objects segments to flash sequentially, (b) Set-associative cache write objects to a set based on the key's hash, and (c) Kangaroo is a hierarchical design that combines a log-structured and a set-associative cache.

The downside of these caches is that they cause significantly more writes. When a set-associative cache admits a small object (say, 100 B), it must write at least one flash page (4 KB), resulting in large ALWA (40×). Even worse, these caches perform random writes, leading to DLWA of 2× to 10× [67]. Since write amplification (WA) is the product of ALWA and DLWA, *a set-associative cache's WA easily exceeds 100×*. To mitigate this, Meta's flash caches use only 50% of the drive [16], increasing miss ratio and carbon emissions.

Hierarchical. FairyWREN builds on Kangaroo [67, 68], a hierarchical flash cache for small objects that combines a small log-structured cache (KLog) and a large set-associative cache (KSet) (Fig. 5c). Kangaroo uses KLog to reduce ALWA and KSet to reduce DRAM. Objects are first buffered in KLog and then admitted in batches to KSet, amortizing its ALWA across several admitted objects. KSet comprises more than 90% of the cache capacity, limiting the DRAM needed to index KLog. Kangaroo also includes a selective admission policy to reduce flash writes and a partitioned index data structure to reduce DRAM. Due to its low DRAM overhead, Kangaroo achieves large emission reductions over a memory-optimized log-structured cache, Flashield [35], for workloads with many small objects (Fig. 11 in Sec. 6.2).

While Kangaroo optimizes both DRAM and ALWA, it still has too many writes because *Kangaroo does not address device-level write amplification.* KSet performs random 4 KB writes, the worst case for DLWA. As a result, Kangaroo's emissions do not reduce with denser flash. Fig. 4 shows that, for a 10-year lifetime, QLC requires fewer than 0.37 device-writes per day (DWPD) and PLC requires fewer than 0.16 DWPD, whereas Kangaroo performs 1.46 DWPD in our evaluation.

4 Write-Read-Erase iNterfaces (WREN)

Prior flash caches incur excessive DLWA (Sec. 3). The root causes are the mismatch between write and erase granularities and a legacy LBAD interface that hides this mismatch from software. This section discusses recent *Write-Read-Erase iNterfaces (WREN)*, such as ZNS [19] and FDP [66], that include `Erase` as a first-order operation. We show that WREN is necessary but insufficient: a new flash interface does not reduce writes by itself, changes to the cache design are required.

4.1 Today's interface is LBAD

Most flash SSDs today are *logical block addressable devices (LBAD)*, sharing the same interface as disks. LBAD presents the flash device as a linear address space of fixed-size blocks[2] that can be independently read or written.

LBAD eased the transition from HDDs to SSDs, but does not expose the erase granularity of flash (Sec. 3). As a result, the LBAD device firmware must perform garbage collection (GC) that can cause high DLWA and tail latency. Although there has been work to decrease DLWA [40, 41, 44, 56, 89, 91], LBAD devices still hide erase units and GC from applications, preventing co-optimization to minimize overall flash writes.

4.2 Challenges of new interface design

While a variety of flash interfaces have been proposed [20, 44, 51, 52, 72, 78, 88, 96], none have gained widespread adoption. Two proposals, Multi-streamed SSDs and Open-Channel SSDs, illustrate the pitfalls of designing a new flash interface.

Multi-streamed SSDs [51, 52] allow users to direct writes to different *streams*. Streams provide isolation between workloads: different streams write to different EUs. When objects with similar lifetimes are grouped into the same stream, GC is more efficient. However, because the application does not control GC directly, DLWA remains a significant issue.

Open-Channel SSDs [20] remove all flash-device logic and force applications to handle *all* of flash's complexities, even beyond those described in Sec. 3. While the hope was to develop layers of abstraction in software to hide some of this complexity, this software was never widely deployed.

Lesson for flash caches: An ideal flash interface for caching would allow the cache to control *all* writes, including GC, but still present a simple abstraction to application developers.

4.3 What makes an interface WREN?

We call interfaces that delegate `Erase` commands and garbage collection to the host *Write-Read-Erase iNterfaces (WREN)*. WREN is defined by three main features:

1) WREN operations. WREN devices must let applications control which EU their data is placed in and when that EU is erased. Specifically, WREN devices must, at least, have `Write`, `Read`, and `Erase` operations.

These operations can be implemented differently. For example, *Zoned Namespaces* (ZNS) [19] and *Flexible Data Placement* (FDP) [66] are both WREN. Both interfaces are NVMe standards with strong support from industry and provide an abstraction for writing to an EU[3]. However, they have different philosophies, which can be seen, for instance, in their `Write` operations. ZNS provides either sequential writes to an EU or nameless writes through Zone Append [96]. FDP

[2] These fixed-size blocks correspond to pages, not flash blocks (Sec. 3)

[3] This abstraction is called a *zone* in ZNS and a *reclaim unit* in FDP.

provides random writes within an EU as long as the application tracks that the number of pages written is less than the EU size. Despite these differences, both provide the control over data placement into EUs required by WREN.

Moreover, the aforementioned Open-Channel interface is also WREN. But Open-Channel SSDs expose the full complexity of the device to the host, which is additional complexity *not* required to reduce a cache's DLWA.

2) The `Erase` requirement. Unlike LBAD, WREN devices do not move live data from an EU before erasing it. Applications are responsible for implementing GC to track and move live data before calling `Erase`. `Erase` is different from a traditional `trim` because `Erase` targets an entire EU rather than individual pages. Failure to perform correct and timely GC is subject to implementation-specific error handling by the device. A major difference between FDP and ZNS is how they treat violations of `Erase` semantics, but this error behavior is inessential to reducing DLWA and thus beyond WREN.

3) Multiple, but limited, active EUs. An *active EU* is one that can be written to without being erased. WREN devices support a few active EUs at one time. Since an active EU typically requires a device buffer for the EU's data, the maximum number of active EUs is implementation-specific. FairyWREN requires four simultaneously active EUs, which we expect will be supported in the vast majority of WREN devices.

4.4 WREN alone is not a cure for WA

WREN devices make it easy to perform large, sequential writes with no WA. When writing sequentially, the user can maintain a single active EU and fill the EU completely before activating the next EU. Furthermore, if all writes are large and sequential, it is generally easy to find an EU consisting of invalid data when GC is required, resulting in low WA.

Set-associative flash caches also want low WA for small, random writes, which incur high DLWA on LBAD devices. One might hope that WREN devices can achieve lower WA. A reasonable first attempt at implementing a set-associative cache on WREN is to treat each set as an object in a log-structured store, allowing the cache to write updates sequentially to a single active EU. We find that this naive approach does not reduce WA because it just moves the GC from the device to the cache.

The impact of smaller EUs. One idea for mitigating WA under small, random writes is to reduce the EU size, e.g., from a GB to tens of MB, by removing error correction between flash blocks, which caches can tolerate. Prior systems literature uses smaller EUs to minimize GC [14, 69] because, intuitively, lowering the number of sets per EU creates more EUs that are either mostly invalid (good candidates for GC) or mostly valid (bad candidates for GC that are skipped). However, other prior work that analyzes the WA of FIFO GC policies [34, 46] has largely ignored the effect of EU size. In fact, this modeling work assumes that changing the EU size will not change the WA from GC. To remedy this discrepancy in prior work, we model the WA of a FIFO GC policy for a set-associative cache, capturing the effect of EU size.

Following the approach of [46], we approximate the distribution of the number of live pages in the EU at the tail of a log-structured store (see Appendix A for details). Our approximation shows that when EU sizes are small, FIFO is more likely to find EUs that are mostly invalid or completely valid. To quantify this effect, we approximate the long-run average WA under FIFO. Our approximation (Fig. 6) matches simulation results, with a R^2 value of 0.9996.

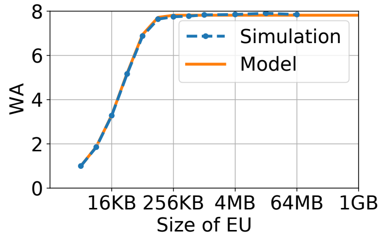


Fig. 6: The DLWA for a set-associative cache running on WREN with 7% overprovisioning. EUs have to be less than 128 KB to significantly reduce DLWA.

Lesson for flash caches: We find that *reducing EU size only improves WA for very small EU sizes*. To realize a significant reduction in WA, the EU size must be tens of KBs, but that is unachievable in current devices (Sec. 3). Hence, we conclude that WREN alone does not reduce WA for caches. To reduce WA, we must also re-design the cache.

5 FairyWREN Overview and Design

FairyWREN uses WREN to substantially reduce WA by unifying cache admission with garbage collection. The resulting reduction in overall writes lets FairyWREN use denser flash while extending device lifetime to improve sustainability.

5.1 Overview

How FairyWREN reduces writes. FairyWREN uses WREN's control over data placement and garbage collection to reduce writes in two main ways. First, FairyWREN introduces *nest packing* to combine garbage collection with cache admission and eviction. When live data is rewritten during GC, FairyWREN has an opportunity to evict unpopular objects and admit new objects in their place. In LBAD, by contrast, these objects would have to be rewritten separately for GC and admission/eviction.

Second, FairyWREN groups data with similar lifetimes into the same EU, separating data that in prior caching systems would have been in the same page. If all of the data in each EU has roughly the same lifetime, EUs will either consist mostly of live data or mostly of dead data. FairyWREN can then GC the mostly dead EUs with few additional writes. FairyWREN leverages two main techniques to enable this grouping: large-small object separation and hot-cold set partitioning.

Architecture of FairyWREN. FairyWREN partitions its capacity into a large-object cache (LOC) and a small-object cache (SOC), as seen in Fig. 7. Incoming requests first check the LOC and then check the SOC.

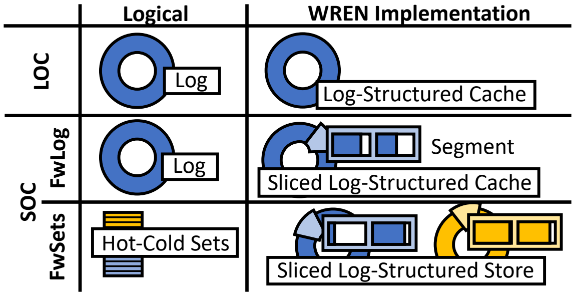

Fig. 7: The components of FairyWREN.

The *large-object cache* (Sec. 5.2) stores objects larger than 2 KB and uses a simple log-structured design, since it can tolerate higher per-object DRAM overhead.

The *small-object cache* (Sec. 5.3) uses a hierarchical design based on Kangaroo [67]. The SOC contains two levels: FwLog and FwSets. FwLog is a log-structured cache with a relatively high per-object DRAM overhead. The main function of FwLog is to buffer objects so they can be written efficiently to FwSets. Therefore, FwLog can have a fairly low capacity ($\approx 5\%$), keeping its DRAM overhead low. FwSets is a set-associative cache, but, since WREN does not support random writes, the sets are kept in a log-structured store. FwSets stores sets, not individual objects, in the log to minimize DRAM. When this log-structured store is garbage collected, objects are opportunistically moved from FwLog into FwSets. Finally, each set in FwSets is further partitioned into hot (frequently accessed, long-lived) objects and cold (recently admitted, short-lived) objects (Sec. 5.4).

5.2 The LOC

The LOC is a log-structured cache. Adapting log-structured caches to WREN is straightforward, since they only perform large, sequential writes. The LOC is broken into large segments, each the size of an EU. Segments can then be evicted in LRU or FIFO order with minimal WA. The LOC uses DRAM in two ways: *(i)* an in-memory, EU-sized buffer for log insertions, and *(ii)* an in-memory index tracking object locations on flash. Because the LOC stores large objects, it contains relatively few objects and needs little DRAM. Besides the segment buffer, all LOC objects are stored on flash.

Insertions. Objects are first inserted into an in-memory segment buffer and added to the in-memory log index. Once the segment buffer is full, it is written to an empty EU in the log.

Lookup. Reads look up the object's key in the log index. If found, the cache reads the object from the indicated EU.

Eviction. Eventually, the log will fill up and LOC will evict a log segment based on the eviction policy. Since log segments are aligned to EUs, eviction simply `Erase`s an EU, evicting those objects from the cache. This design does not rewrite any objects, incurring minimum WA of 1×.

5.3 The SOC

The focus of FairyWREN is the SOC. Log-structured caches are impractical for caching small objects because a large flash cache can fit billions of small objects, requiring a large DRAM index to track them all (Sec. 3.3). FairyWREN's SOC is based on Kangaroo [67], a recent flash cache designed for small objects with low DRAM overhead and low ALWA. The SOC is a hierarchy of two levels: FwLog, a small log-structured cache, and FwSets, a large set-associative cache. FwLog contains about 5% of the SOC's capacity, with the remaining 95% for FwSets. We describe FwLog and FwSets individually, and then how they work together.

FwLog design. FwLog's goal is to buffer new small objects for insertion into FwSets. Like the LOC, FwLog is a log-structured cache that uses an in-memory segment buffer and an in-memory index to track objects in the FwLog. All other objects in the FwLog are stored on flash.

FwSets design. FwSets is a set-associative cache that maps each object to a unique set by hashing its key. When admitting an object, FwSets evicts old objects from the object's set then overwrites it. However, overwriting is impossible in WREN, so FwSets stores *the sets themselves* as objects in a log-structured store. FwSets uses an in-memory index to track the location of each set on flash, but, unlike prior work [56,61,78], it does not track individual objects, since this would incur too much DRAM overhead. The index's DRAM overhead is low because a set is at least 4 KB, whereas objects can be just 10s of bytes. (Larger sets reduce the size of FwSets's DRAM index, but increase average read latency.)

When FwSets's log-structured store is close to full, it must garbage collect in order to admit new objects to the cache. The simplest scheme would be to erase the EU at the tail of the log, evicting all sets — and thus their objects — mapped to this segment[4]. However, since each set contains a mixture of popular and unpopular objects, throwing away entire sets would significantly increase miss ratio. Instead, FwSets rewrites live sets during GC before erasing the EU.

SOC operation. FwLog and FwSets operate as a hierarchy:

Lookup. Lookups first check FwLog for the object. If not found, FwSets hashes the object's id and looks up the *set's* location. The set is read and scanned for the object.

Insertion. FairyWREN first inserts objects into FwLog. When FwLog is full, objects are evicted from FwLog and inserted into FwSets, as described next. Similarly, inserting into FwSets can cause cascading eviction from FwSets.

Eviction (nest packing). If either FwLog or FwSets is running out of space, FairyWREN needs to perform *nest packing* (Fig. 8). FairyWREN's SOC chooses an EU for eviction from FwLog or FwSets, depending on which is full. If both logs are full, FwSets is chosen because FwSets must have space

[4] In this scenario, FwSets would be on a log-structured cache.

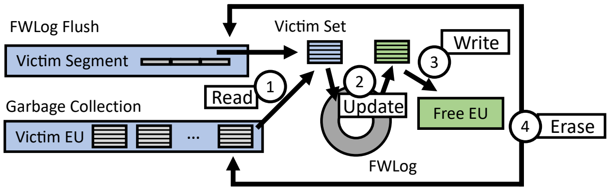

Fig. 8: Nest packing in FairyWREN's small-object cache.

to receive objects evicted from FwLog.

The victim EU is first read into memory. If evicting from FwLog, each object in the EU hashes to a *victim set*. Otherwise, when evicting from FwSets, each set in the EU *is* a victim set. Then, ① FairyWren rewrites each victim set by: ② finding all objects in FwLog that map to a given set, forming a new set containing these objects (evicting objects as necessary), and ③ rewriting the set by appending it to FwSets's log. Finally, ④ FairyWren erases the victim EU.

SOC design rationale. Prior flash caches relied on LBAD GC to reclaim flash space from evicted sets, causing DLWA. *The key difference of FairyWren from prior flash caches is its coordination of cache insertion and eviction with flash GC.*

FairyWren's nest packing algorithm combines previously distinct processes. LBAD caches pay for eviction as ALWA and for garbage collection as DLWA. In the worst case, a set is copied by garbage collection and then is immediately rewritten to admit objects from FwLog. It is impossible to merge these flash writes in LBAD. FairyWren leverages WREN to eliminate unnecessary writes by aligning the eviction and garbage collection cadences of FwLog and FwSets.

5.4 Optimizing the SOC

The SOC is the main source of DRAM overhead and WA in FairyWren. We employ a variety of optimizations to improve the memory and write efficiency of the SOC.

Reducing flash writes by separating hot and cold objects. Even after using nesting to decrease writes, FwSets is still the primary source of flash writes in FairyWren. FairyWren further reduces writes by separating objects by popularity, as determined by a modified RRIP algorithm [45, 67]. Instead of a set being *one unit* that is written every insertion, each set in FwSets is split in twain, into a subset for popular objects and a subset for unpopular objects, each backed by its own log-structured store. Each subset is at least a page. Paradoxically, since the unpopular objects are most likely to be evicted, the subsets with unpopular objects correspond to hot (i.e., frequently written) pages on flash. Hence, we refer to the subsets with unpopular objects as *hot subsets* and we refer to the subsets with popular objects as *cold subsets*.

With hot and cold subsets enabled, objects evicted from FwLog are inserted into the hot subset. The cold subset is not typically written during insertion. Every *n* nest packing operations on a subset, both the hot and cold subsets are read. In memory, these subsets are merged and redivided by object popularity, as seen in Fig. 9. Any popular objects found in the hot subset are moved into the cold subset, since these objects are likely to remain in the cache for longer and do not need to be rewritten as frequently. The least popular objects found in the cold subset are moved into the hot subset so that FwSets can evict them if they remain sufficiently unpopular.

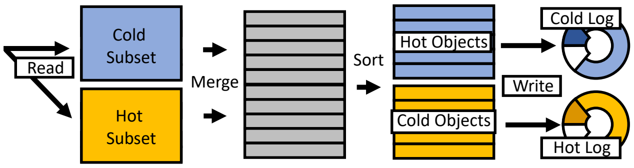

Fig. 9: FwSets is split in two: hot subsets with cold objects and cold subsets with hot objects. Most of the time objects are inserted into the hot subset. However, every n subset updates, both subsets are read, merged, split by object popularity, and then both rewritten.

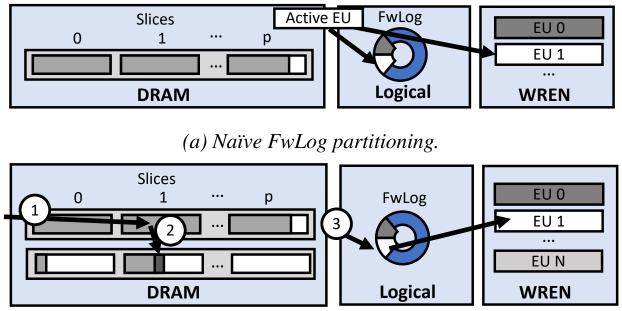
Hot-cold object separation can nearly halve FwSets's write amplification. If *n* is 5 and sets are 8 KB (two 4 KB subsets), FairyWren without hot-cold object separation would have to write all 8 KB on each insertion to a set. With hot-cold object separation, FairyWren writes 4 KB for the hot subset on every insertion, but only has to write 4 KB for cold subset on every fifth insertion. Thus, FwSets writes only 24 KB instead of 40 KB every five inserts to a set, a 40% reduction.

Theoretically, FairyWren could further reduce writes by further dividing sets. However, there are some practical limitations to this, namely that WREN devices only support a limited number of active EUs, often less than 10. FairyWren currently needs 4 active EUs: 1 for LOC, 1 for FwLog, and 2 for FwSets. Using only 4 active EUs allows FairyWren to run concurrently with other programs on the flash without interference and ensures compatibility with a wide range of WREN devices while still achieving low write rates.

Moreover, separating objects by popularity yields diminishing returns since it increases miss ratio, which will then require more cache capacity to reduce the miss ratio. Wrong object-popularity predictions, which are frequent since very few bits of metadata are used to track each object's popularity, can lead to increases in both writes and miss ratio. The miss ratio will increase if popular objects are placed in hot subsets and evicted prematurely. This type of error becomes more frequent as one tries to separate objects by popularity at finer ganularity. In fact, even our single layer of hot-cold separations causes a modest increase in miss ratio (Sec. 6.5).

Minimizing DRAM in FwLog by slicing. Like Kangaroo [67, 68], FwLog is implemented as 64 *slices*, i.e., 64 independent log-structured caches that operate in parallel over subsets of the keyspace. This is done to save $\log_2 64 = 6$ bits per flash pointer in the DRAM index.

A naïve implementation of slicing on WREN would require one active EU for each slice. Many WREN devices do not permit 64 simultaneously active EUs due to the prohibitively large DRAM overhead this would impose on the flash device. Instead, FwLog uses a single active EU and shares segments among all 64 slices, giving each slice an equal static share of



(a) Naïve FwLog partitioning.

(b) Inserting to FwLog with overflow memory buffering.

Fig. 10: FwLog *uses partitioning to minimize memory and overflow buffers to ensure the log segments are full.*

each segment (Fig. 10a). The downside of sharing FwLog segments is that one slice could fill up its share of the segment before the others. In the worst case, one slice fills before the others contain any objects, causing internal fragmentation in FwLog. This fragmentation reduces FwLog's ability to minimize WA in FwSets. Via simulation and stochastic models, we found that fragmentation could exceed 20%.

FwLog reduces fragmentation via double buffering (Fig. 10b). On insertion, FwLog ① attempts to insert an object into its slice in the "primary" segment buffer. If the primary is full, ② the object is inserted into its slice in the secondary, "overflow" segment buffer. ③ When any slice in the overflow buffer becomes more than half full, FwLog writes the primary buffer to flash. The overflow buffer then becomes the new primary buffer and vice versa. Double buffering increases the number of objects seen before a buffer is written, reducing the variance in the number of objects in each slice. Using balls-and-bins [74] to approximate the maximum objects in a slice, we find that this optimization limits the capacity loss from fragmentation to <1%, even for small (16 MB) buffers.

Minimizing DRAM in FwSets by slicing. Like FwLog, FwSets also slices the log-structured store to reduce DRAM overhead, sharing segments to minimize active EUs and segment buffers. However, since sets are much larger than individual objects, FwSets is more susceptible to internal fragmentation than FwLog. FwSets therefore uses only 8 slices.

Reducing DRAM in FwSets by using larger sets. Finally, FwSets further reduces DRAM by using sets larger than 4 KB, reducing the number of sets that need to be tracked proportionally. Naïvely, one might expect that increasing set size would increase flash writes. In a pure set-associative cache, this would be true. However, FwLog buffers objects, and the number of objects that hash to a set also increases proportionally with set size, so FwSets's writes are roughly independent of set size. We see only a 5% increase in WA when going from 8 KB to 16 KB sets with a 4 KB hot subset and a 12 KB cold subset.

DRAM overhead breakdown. Compared to a LBAD set-associative cache, FwSets requires additional DRAM to track sets. Hot-cold object separation compounds this effect, doubling the number of (sub)sets to track.

Component	Kangaroo	Naïve SOC	SOC
Log total	*48 bits/obj*	*48 bits/obj*	*48 bits/obj*
Set index	–	≈ ***3.1 b***	≈ ***1.4 b***
Sets (other)	4 b	4 b	4 b
Sets total	*4 bits/obj*	*7.1 bits/obj*	*5.4 bits/obj*
Log metadata	≈ 0.8 b	≈ 0.8 b	≈ 0.8 b
Log size	5% = 2.4 b	5% = 2.4 b	5% = 2.4 b
Set size	95% = 3.8 b	95% = 6.7 b	95% = 5.1 b
Total	**7.0 bits/obj**	**9.9 bits/obj**	**8.3 bits/obj**

Table 2: Kangaroo and FairyWren's SOC's DRAM overhead for a 2 TB small-object cache with a 5% log. Despite tracking sets, FairyWren's SOC still needs fewer than 10 bits per object.

Table 2 shows the per-object DRAM overhead for Kangaroo and FairyWren's SOC. Due to partitioning and double buffering, FairyWren achieves the same log overhead as Kangaroo. FairyWren's added overhead shows up in FwSets. Naïvely, when FairyWren has 4 KB subsets and 200 B objects, each set would need 8 bytes, for 3.1 bits/obj. However, since FairyWren uses 8 KB subsets and slices FwSets in eighths, FwSets needs just 1.4 bits/obj to track sets.

FairyWren uses 19% more DRAM than Kangaroo, a 1.5 GB DRAM overhead increase for a 2 TB cache. However, FairyWren's DRAM overhead is still much lower than a log-structured cache, and this modest DRAM increase allows FairyWren to greatly decrease flash writes (by 12.5×), netting large savings in carbon emissions and cost.

6 Evaluation

We compare FairyWren to prior flash caches and find that: (1) FairyWren reduces flash writes by 92% over the research state-of-the-art Kangaroo, leading to a 33% carbon reduction and a 35% cost reduction, (2) FairyWren is within 11% of the minimum write rate, and (3) FairyWren is the first cache design to actually benefit from QLC.

6.1 Experimental setup and model

Implementation. We implement FairyWren in C++ as a module in CacheLib [16]. All experiments were run on two 16-core Intel Xeon CPU E5-2698 servers running Ubuntu 18.04 with 64 GB of DRAM, using Linux kernel 5.15. For WREN experiments, we use a Western Digital Ultrastar DC ZNS540 1 TB ZNS SSD, using the LOC and ZNS library

Parameter	FairyWren	Kangaroo
Interface	WREN (ZNS)	LBAD
Flash capacity	400 GB	400 GB
Usable flash capacity	383 GB	376 GB
LOC size	10% of flash	10% of flash
SOC log size	5% of SOC	5% of SOC
SOC set size	4 KB hot, 4 KB cold	4 KB
Hot-set write frequency	every 5 cold set writes	
Set over-provisioning	5%	

Table 3: FairyWren and Kangaroo experiment parameters.

	SLC	MLC	TLC	QLC	PLC
Write endurance	4.4×	4×	1×	0.32×	0.16×
Capacity discount	3×	1.5×	1×	0.75×	0.6×

Table 4: Scaling factors for different flash densities. We optimistically assume that increasing the bits per cell does not affect emissions or cost.

written by Western Digital [50]. The ZNS SSD has a zone (EU) capacity of 1077 MiB. The devices support 3.5 device writes per day for an expected 5-year lifetime.

We compare to Kangaroo [67] over the first ≈2.5 days of a production trace from Meta. FairyWren uses a ZNS SSD and Kangaroo uses an equivalent LBAD SSD with similar parameters (Table 3). Both caches use 400 GB of flash capacity and achieve similar miss ratios as Kangaroo's production experiments [67]. We overprovision FwSets by 5% to ensure forward progress during nest packing, giving several free EUs to the FwSets log-structured store. Thus, FairyWren effectively uses 383 GB. This idle capacity should decrease in larger flash devices. Kangaroo only uses 376 GB of capacity due to device-level overprovisioning. We approximate Kangaroo's DLWA based on results in the Kangaroo paper [67].

Simulation. In addition to flash experiments, we implemented a simulator to compare a much wider range of possible configurations for FairyWren. The simulator replays a scaled-down trace to measure writes and misses from each level of the cache, including the LOC, FwLog, and FwSets.

We evaluate our cache in simulation on a 21-day trace from Meta [16] and a 7-day trace from Twitter [92]. The Meta trace accesses 6 TB of unique bytes with a 13.8% compulsory miss ratio and an average object size of 395 bytes. Small objects (<2 KB) are 95.2% of requests, and these requests account for 60.2% of bytes requested. The Twitter trace accesses 3.5 TB of unique bytes, has a 17.2% compulsory miss ratio, and an average object size of 265 bytes. Small objects are >99% of requests, and these requests account for >99% of bytes requested. Both of these traces are higher fidelity than the open-source traces [16, 92]. We present results for the last 2 days of the trace.

Carbon emissions and cost model. We evaluate carbon emissions and cost while varying cache configuration, flash density, and device lifetime. We assume that a flash device will have the same caching workload for its entire lifetime and that flash write endurance is the main lifetime constraint. We normalize all results based on device lifetime and we assume that all required flash is purchased at the beginning of deployment.

We estimate emissions and cost from the total flash needed to cover both the cache's capacity and its writes over the desired lifetime. For example, a 2 TB cache with a 6-year lifetime will require at least 2 TBs of flash, but it may require 2.5 TB of flash to accommodate the cache's write rate over 6 years. LBAD devices use 7% overprovisioning, the standard on datacenter drives [8].

We base our write endurance and cost projections on Micron 7300 NVMe U.2 TLC SSDs. For other densities, we multiply the TLC write endurance by the write-endurance factors in Table 4, based on [9]. For cost, we interpolate linearly between flash capacities and include power as the operational expense. Cost is normalized to Kangaroo with a 30% miss ratio for the Twitter trace and 20% for Meta. We optimistically assume that different flash densities will have the same cost and emissions per cell; e.g., 1 TB of PLC has the same emissions as 600 GB of TLC (5:3 ratio). Our model can incorporate more data on denser flash if it becomes available.

We use the ACT model [38] to estimate operational and embodied emissions from CPUs, DDR4 DRAM, and flash. We assume the grid is a 50/50 mix of wind and solar, a common renewable-energy mix [12].

6.2 Carbon emissions of flash caches

We first examine the carbon emissions of different flash caches for a 6-year deployment. Fig. 11 compares FairyWren to three systems: Minimum Writes, Kangaroo, and a Flashield-like log-structured cache [35]. Minimum Writes is an unachievable, idealized cache with WA of 1× and no DRAM overhead. Flashield also assumes a WA of 1×, but requires a DRAM:SSD capacity ratio of 1:10, as originally proposed. Since we cannot faithfully replicate Flashield's ML eviction policy (and no working implementation is available), we assume that Flashield achieves FairyWren's miss ratios.

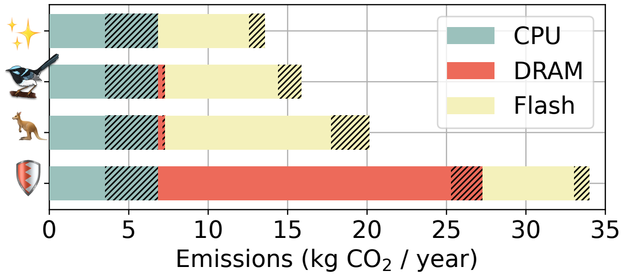


Fig. 11: Yearly carbon emissions for 4 caching systems: minimum writes (✨) with a write amplification of 1 with no additional DRAM, FairyWren (🐦), Kangaroo (🦘), and a Flashield-like log-structured cache (🛡). Our results include the embodied and operational (hatched) emissions from CPU, DRAM, and flash.

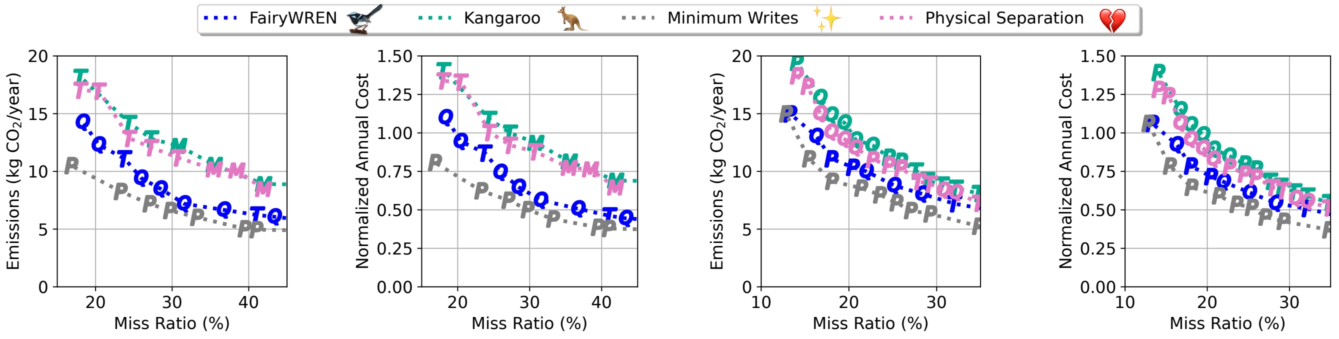
Takeaway 0: *Sustainable flash caches must use much less DRAM than log-structured cache designs.*

Although we optimistically assumed that Flashield incurs no write amplification, Flashield's overall carbon emissions are 1.7× higher than Kangaroo's. These emissions are due to its high DRAM overhead, despite several optimizations in Flashield designed to save DRAM. High DRAM overhead is unfortunately inherent in the design of a log-structured cache.

Kangaroo reduces DRAM overhead through its hierarchical design. Unfortunately, Kangaroo also incurs a far higher write rate than a log-structured cache. Kangaroo accounts for its



(a) Twitter Carbon Emissions *(b) Twitter Cost* *(c) Meta Carbon Emissions* *(d) Meta Cost*

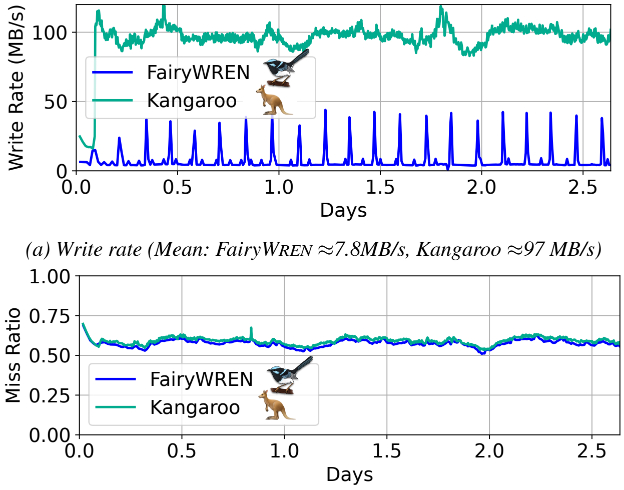
Fig. 13: The emissions and cost over six years for Kangaroo (🦘), FairyWREN (🐦), Min. Writes (✨), and Physical Sep. (💔).

increased writes by overprovisioning flash capacity, increasing embodied carbon emissions. While Kangaroo is far more sustainable than Flashield, it leaves room for improvement.

FairyWREN maintains Kangaroo's low memory overhead while greatly reducing the flash write rate. Consequently, FairyWREN reduces overall carbon emissions by 21.2% compared to Kangaroo. As this improvement comes from reducing flash emissions, we focus on flash emissions for the remainder of the evaluation.

6.3 On-flash experiments

To study how FairyWREN reduces flash writes, we evaluate FairyWREN on real flash drives using the setup in Sec. 6.1.



(a) Write rate (Mean: FairyWREN ≈7.8MB/s, Kangaroo ≈97 MB/s)

(b) Miss ratio (Mean: FairyWREN ≈ 0.575, Kangaroo ≈ 0.594)

Fig. 12: The miss ratio and write rate for Kangaroo and FairyWREN.

Takeaway 1: *FairyWREN greatly reduces flash writes while maintaining a slightly better miss ratio than Kangaroo.*

Fig. 12 plots the flash write rate and miss ratio over time for Kangaroo and FairyWREN. The figure shows small write rate spikes in FairyWREN. This is because FairyWREN performs nest packing at the granularity of an EU, ≈1 GB. Kangaroo's write rate appears smooth as it flushes more frequently, at 256 KB granularity.

The main goal of FairyWREN is to reduce writes, enabling the use of denser flash. In Fig. 12a, FairyWREN reduces writes by 12.5× over Kangaroo, from 97 MB/s to 7.8 MB/s. To achieve this, FairyWREN leverages WREN to combine cache logic and GC and to separate writes of different lifetimes.

However, reducing writes must not increase misses. Fig. 12b shows that, in fact, FairyWREN and Kangaroo have very similar miss ratios: on average, 0.575 for FairyWREN vs 0.594 for Kangaroo. FairyWREN's small advantage comes from reducing idle capacity due to overprovisioning.

We see very similar results for write amplification: a 12.2× reduction, from 23× in Kangaroo to 1.89× in FairyWREN. The slight difference between the write rate and WA comes from FairyWREN's slightly better miss ratio.

Takeaway 2: *FairyWREN outperforms Kangaroo for both throughput and read latency at peak load.*

While the primary performance metric for caches is miss ratio, FairyWREN must provide enough throughput that it does not require more servers — and thus more carbon emissions — to handle the same load. In our experiments, FairyWREN's throughput is 104 KOps/s whereas Kangaroo's is 40.5 KOps/s. FairyWREN's significant throughput increase is mostly due to lower write rate, but also due to better engineering that moved work off the critical path for lookups and inserts.

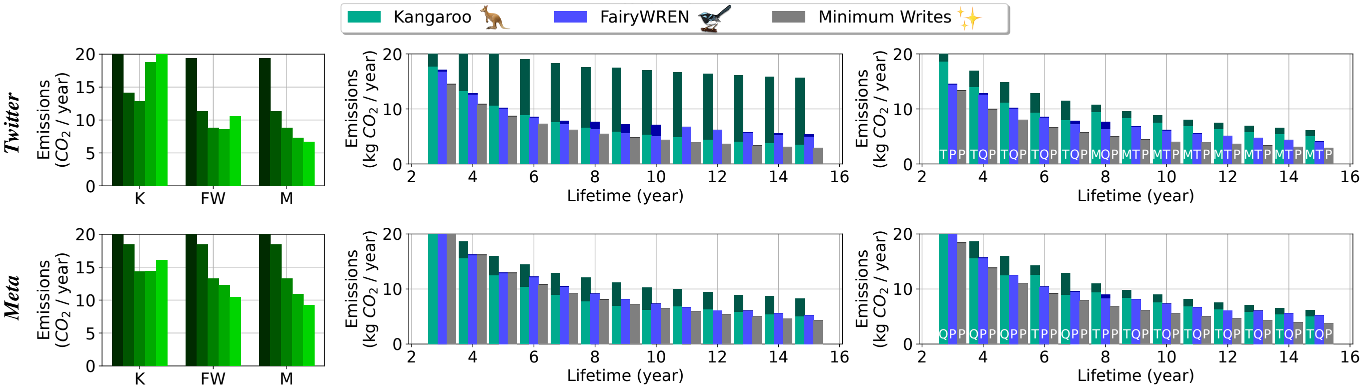
Similarly, we find that FairyWREN's and Kangaroo's 99th-percentile latencies are 170 µs and 1,370 µs, respectively. But note that, in practice, the overall tail latency is set by the backing store, not the flash cache.

6.4 FairyWREN reduces carbon emissions

We now evaluate carbon emissions and cost via simulation, comparing FairyWREN (🐦), Kangaroo (🦘), Minimum Writes (✨), and Physical Separation (💔). Physical Separation represents Kangaroo on WREN, where each cache component (e.g., LOC, KLog, KSet) is placed in its own EU to separate traffic and thereby allow LOC and KLog to have WA of 1×.

Takeaway 3: *FairyWREN's reduced writes translate into reduced carbon emissions and reduced cost across miss ratios.*

Fig. 13 plots emissions and cost for a 6-year lifetime vs. miss ratio over a wide range of cache configurations. Each point is labeled with the flash density used (e.g., TLC).



(a) Impact of density (6 years)

(b) Impact of lifetime (on QLC)

(c) Impact of lifetime (on best flash density)

Fig. 14: The carbon emissions to achieve a 30% miss ratio on Twitter trace or 20% miss ratio on Meta trace for (a) 6 years on SLC (darkest) to PLC (lightest), (b) different lifetimes with QLC flash, and (c) different lifetimes with any flash density. For (b) and (c), the darker part of each bar represents emissions due to overprovisioning.

For the Twitter traces (Fig. 13a, Fig. 13b), Kangaroo is limited to either MLC or TLC due to its high write rate, and likewise for Physical Separation because it does not reduce writes by much (Sec. 6.5). Meanwhile, FairyWREN leverages its low WA to use mostly QLC across miss ratios, giving it large carbon and cost reductions vs. Kangaroo. However, FairyWREN still has too many writes to use PLC. While the gap between Minimum Writes and FairyWREN grows at low miss ratios, there is only a 10.1% difference in their emissions at 20% miss ratio and a 7.7% difference in cost.

The Meta traces (Fig. 13c, Fig. 13d) are less write-intensive. However, even here we see that FairyWREN reduces cache emissions and cost compared to both Kangaroo and Physical Separation. In this case, FairyWREN is able to lower the write rate sufficiently to use QLC and PLC. As a result, FairyWREN performs close to Minimum Writes, even at low miss ratios.

Takeaway 4: *FairyWREN benefits from using denser flash when Kangaroo cannot.*

Flash devices are becoming denser over time (Sec. 2). Fig. 14a shows the carbon-optimal cache configurations over a 6-year lifetime at a target miss ratio of 30% for Twitter and 20% for Meta, varying flash density from SLC (left) to PLC (right). Kangaroo performs best when using TLC on the Twitter trace and QLC on the Meta trace. Using PLC increases Kangaroo's emissions due to the excessive overprovisioning needed to compensate for PLC's lower write endurance. FairyWREN's lower write rate enables it to use QLC for Twitter and PLC for Meta, reducing emissions and cost. Since Twitter's trace is more write-intensive, using PLC increases carbon emissions by 24% due to overprovisioning.

For Minimum Writes on Twitter, emissions decrease by 17% going from TLC to QLC and by 8% from QLC to PLC. On Meta, emissions reduce by 18% and 15%. While these numbers show that denser flash reduces emissions, they suggest diminishing returns even for an optimal cache.

Takeaway 5: *FairyWREN's low WA allows it to avoid massive overprovisioning on dense flash as lifetime is increased.*

To explore the trend of increasing device lifetime (Sec. 2), Fig. 14b considers the emissions for caches on QLC devices, showing emissions from overprovisioning in a darker shade.

For a 6-year lifetime, Kangaroo requires 2.2× the emissions of FairyWREN on Twitter and 1.17× on Meta. At 12 years, the gap increases to 2.6× and 1.54×. Due to the DLWA in LBAD devices, Kangaroo's emissions are lowest when it has some amount of overprovisioning. FairyWREN does not need this overprovisioning due to its lower WA.

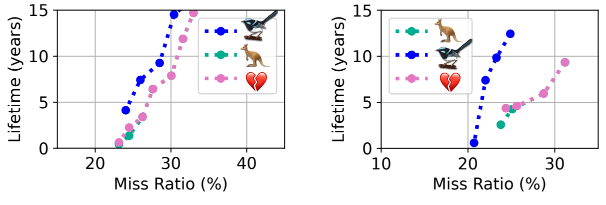
Takeaway 6: *Increasing flash density does not necessarily improve sustainability, as lifetime matters more than density.*

To minimize emissions, we need to optimize both lifetime and flash density. Fig. 14c shows each system's emissions for all lifetimes, with the best density displayed on each bar. Kangaroo usually prefers MLC and TLC because, to provide enough write endurance, QLC and PLC require too much overprovisioning. FairyWREN has fewer emissions than Kangaroo at all lifetimes and stays within 30% of Minimum Writes.

The best flash density decreases for longer lifetimes. FairyWREN prefers PLC on Twitter over 3 years, but TLC over 9 years. At these long lifetimes, the reduced write endurance of denser flash outweighs its sustainability benefits, and extending lifetime is more important than using denser flash.

Takeaway 7: *For a given flash device, FairyWREN extends lifetime by at least a couple of years.*

So far, we have evaluated emissions when deploying the optimal drive for a given lifetime and flash density. However, flash deployments are often constrained to specific devices with a pre-determined capacity and density. In these situations, emissions reductions come from extending lifetime. Fig. 15 evaluates device lifetime for a 3.6 TB drive at different miss ratios. Compared to Kangaroo, FairyWREN is able to extend the device's lifetime by at least 2 years and by over 5 years on the Meta trace. By contrast, Physical Separation barely improves lifetime vs. Kangaroo.



(a) Twitter *(b) Meta*

Fig. 15: The lifetimes for a 3.6 TB cache for Kangaroo (🦘), FairyWren (🐦), and Physical Separation (💔).

6.5 Where are benefits coming from?

We next explore how FairyWren's optimizations contribute to its write rate reduction. Fig. 16 shows the write rate on the Twitter trace starting with Kangaroo on LBAD (Log + Sets). We then add the optimizations of FairyWren incrementally. First, we port Kangaroo naively to WREN (+WREN), then we physically separate the large and small objects into different erase units (+Physical Sep.). Then we add nest packing (+Nest Packing), and, finally, hot-cold object separation (+Hot-Cold) to realize FairyWren. We first present the write rates for the different systems across different capacities and miss ratios, showing the emissions-optimal flash density for one capacity. We then show how the lifetimes of each design would vary if deployed on a QLC drive.

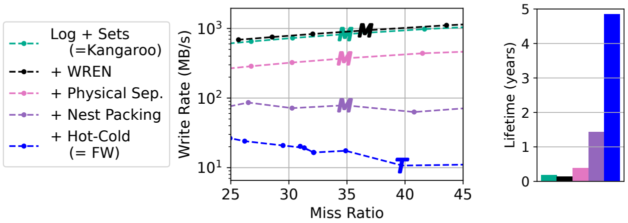


Fig. 16: Write rate (log-scale) and lifetime breakdown on the Twitter trace, incrementally adding optimizations to go from Kangaroo to FairyWren.

Takeaway 8: *Caches on optimal LBAD devices cannot achieve the same write rate as FairyWren.*

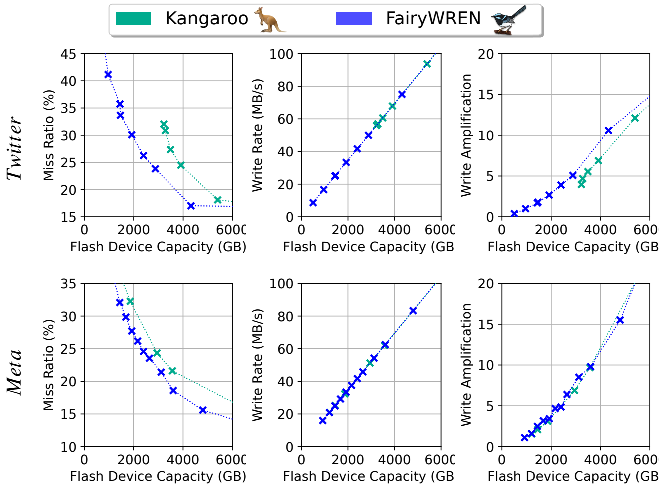
Three of the lines in Fig. 16 are achievable with LBAD devices: Log + Sets, +WREN, and +Physical Sep. Log + Sets represents the current Kangroo implementation on LBAD. +WREN is a naive port of Kangaroo to WREN devices that redirects all cache writes to a single log-structured store using FIFO garbage collection. This naïve port does not attempt any separation of objects by expected lifetime, and we assume it has the same WA as Kangaroo. However, current LBAD devices do try to separate objects belonging to different, concurrent streams, so one would expect an LBAD device to perform, in practice, somewhere between +WREN and +Physical Sep. But even in the best case, Physical Sep. still incurs far too many writes, limiting the lifetime of a QLC device to less than half a year.

Takeaway 9: *Both nest packing and hot-cold object separation are essential to FairyWren's write reduction.*

The other two systems we compare in this breakdown are +Nest packing and +Hot-Cold (i.e., FairyWren with all optimizations). Nest packing reduces writes by at least 3.7× and hot-cold object separation reduces writes by another 3.4×. We also observe that, while hot-cold separation can increase miss ratios, the reduction in write rate outweighs this increase, leading to a 33× increase in QLC lifetime over the Kangaroo baseline and a 13× increase over +Physical Sep.

6.6 Operating on a fixed flash device

We now compare Kangaroo and FairyWren with respect to miss ratio given a fixed flash capacity. We enforce the same constraints of a 6-year flash lifetime, TLC flash density, and 32 GB of DRAM for both systems. Unlike prior figures where we minimize emissions, FairyWren cannot not gain an advantage for using denser flash, and Kangaroo cannot increase write endurance by using less-dense flash. We show that FairyWren under the same capacity constraints, and thus write rate constraints, improves miss ratio over Kangaroo through its reduction in writes allowing it to more effectively use the capacity.



(a) Capacity *(b) Write Rate* *(c) WA*

Fig. 17: Pareto curve of cache miss ratio at different flash device sizes and the corresponding write rate and write amplification of these points. The DRAM capacity is limited to 32 GB, the desired lifetime is 6 years, and the caches use TLC flash.

Takeaway 10: *FairyWren achieves the same miss ratio at lower flash capacities than Kangaroo.*

Fig. 17 shows the effects of changing the flash capacity on miss ratio for both traces. For each flash capacity, we also plot the write rate and WA of both systems. We find that FairyWren needs less flash capacity than Kangaroo to achieve a given miss ratio. FairyWren also requires less overprovisioning due to its lower write rate. This trend is more prominent in the Twitter trace than the Meta trace, which is less write-intensive. For the Twitter trace, Kangaroo's use of TLC prevents it from achieving higher miss ratios. Kangaroo's higher write rate requires much more overprovisioning, increasing the overall flash capacity needed to survive 6 years above 3.6 TB.

We also see that flash capacity sets the write budget for the flash device, defining the write rate that the system can tolerate for a desired lifetime. One might expect a similar relationship for write amplification. However, the systems have different miss ratios, causing Kangaroo to need to have a lower WA through massive overprovisioning.

Takeaway 11: *FairyWREN maintains its advantage under a DRAM constraint.*

We investigated how DRAM restrictions affect Kangaroo and FairyWREN when both caches use 3.6 TB of TLC flash for a 6-year lifetime. FairyWREN maintains a constant miss ratio advantage over Kangaroo from 16 GB to 64 GB of DRAM for both traces. FairyWREN's miss ratio only begins to increase when DRAM falls to 8 GB on the Twitter trace. However, Kangaroo cannot handle the Twitter workload for 6 years with only 8 GB of DRAM. Hence, FairyWREN always outperforms Kangaroo in these experiments.

7 Related Work

This section discusses additional related work with similar techniques and goals to FairyWREN.

Hot-cold objects and deathtime. In caching, hot objects are the most popular objects. Caches use eviction policies to retain popular objects [15, 45, 47, 83]. FairyWREN adapts Kangaroo's RRIP-based eviction policy [45, 67].

Popularity is different than *deathtime*, the time when an object will be deleted [41]. To minimize GC, many storage systems will physically separate objects by their deathtime [26, 28, 41, 54, 76, 94]. Grouping objects with similar deathtimes reduces WA. Hence, accurately predicting deathtimes is vital for minimizing write amplification within LBAD. Recent work uses ML to make these predictions [26, 94]. Unfortunately, ML solutions require additional hardware that can increase emissions and cost.

Caches have more control over deathtimes than storage systems. Deathtimes are set by the eviction policy, and thus determining an object's deathtime is more straightforward. For instance, in caches that evict based on TTLs, the TTLs can be used to group objects [93]. FairyWREN leverages its eviction policy's popularity rankings and the WREN interface to physically group objects by deathtime.

Eviction and garbage collection. Prior flash caches have attempted to reduce in-device garbage collection. Many log-structured caches [27, 35, 56, 61] group objects into large segments and trim these segments during eviction to minimize garbage collection. These systems attempt to evict segments before device-level GC rewrites them. Unfortunately, this does not ensure GC is prevented on LBAD devices, so some work has proposed leveraging newer interfaces to guarantee alignment. DidaCache [78], for example, uses an Open-Channel SSD [20] to guarantee its segments will align with erase units. Other proposals to use more expressive interfaces re-implement LBAD-like GC on top of a ZNS SSD [29], prohibiting optimizations like FairyWREN's nest packing. All of these log-structured approaches suffer from high DRAM overheads and cannot evict individual objects without additional writes.

Grouping by object size. FairyWREN separates objects into two object size classes, large and small, similar to Kangaroo [68] and CacheLib [16]. This grouping is used to minimize memory overhead. Allocating memory using size-based slab classes is often used to reduce fragmentation [25, 43, 77, 78, 93]. Introducing additional object size classes in FairyWREN would result in additional flash accesses, since FairyWREN does not index the size classes to save memory. Instead, FairyWREN reduces fragmentation by grouping objects into either large segments in the LOC or sets in FwSets. These segments and sets are periodically rearranged to prevent fragmentation.

8 Conclusion

FairyWREN reduces flash's carbon emissions and cost by integrating flash management with cache policies. Doing so requires redesigning the cache to transition from old LBAD flash interfaces to a WREN interface. Experiments show that FairyWREN decreases flash writes by 12.5× vs. the state-of-the-art, allowing longer flash lifetimes that reduce carbon emissions by 33% and cost by 35%.

Appendix A Modeling of DLWA Under Random Writes

Our goal is to model the effect of EU size on DLWA. Specifically, we want to analyze the performance of the FIFO+ GC policy, which selects EUs for garbage collection in FIFO order and skips EUs which contain only valid data. Several prior papers [34,46,87] have noted that DLWA can be approximated using W Lambert functions, but this prior work tend to focus on the level of device overprovisioning rather than on the EU size. We use an approach similar to that of [46] to model the relationship between EU size and DLWA under FIFO+.

We define X to be the random variable representing the number of invalid pages an EU that is targeted for garbage collection. Because FIFO+ will erase an EU only if it contains invalid pages, our goal is to approximate $\mathbb{E}[X|X>0]$. This tells us the number of new pages that can be written every time GC is performed. Hence, if we let b be the number of pages in an EU, we can compute the DLWA as

$$\text{DLWA} = \frac{b}{\mathbb{E}[X|X>0]}. \tag{1}$$

Our approximation makes two simplifying assumptions.

First, we assume that each of the b pages in the target EU is invalid independently with probability p. This is reasonable when writes are random and the total number of pages in the device is large. This assumption implies that $X \sim \text{Binomial}(b,p)$. To approximate the expectation of X, we must approximate p.

Second, we assume that an EU is targeted for GC every k writes, where k is a constant. Specifically, we define t to be the total number of EUs in the device and assume $k = t\mathbb{E}[X]$. This is a reasonable approximation because k is the expected number of writes that occur between GC operations on a given EU and the total number of EUs, t is large. A particular page will be invalid if at least one of the k writes targets the page. Hence, the probability p that a page is invalid is

$$p = 1 - \left(1 - \frac{1}{ub}\right)^k$$

where u is the number of EUs available to store valid user data. Note that u is typically smaller than t, and $\frac{t}{u}$ represents the amount of overprovisioning in the device.

Combining these assumptions yields

$$\mathbb{E}[X] \approx b \cdot p \approx b\left(1 - \left(1 - \frac{1}{ub}\right)^k\right) \tag{2}$$

$$\approx b\left(1 - \left(1 - \frac{1}{ub}\right)^{t\mathbb{E}[X]}\right). \tag{3}$$

We can rewrite (3) using the W Lambert function to get the following approximation for $\mathbb{E}[X]$:

$$\mathbb{E}[X] = b - \frac{W\left(bt\left(1-\frac{1}{ub}\right)^{tb}\ln\left(1-\frac{1}{ub}\right)\right)}{t\ln\left(1-\frac{1}{ub}\right)}.$$

To compute $\mathbb{E}[X \mid X>0]$, we note that

$$\mathbb{E}[X \mid X>0] = \sum_{i=1}^{b} i \cdot \frac{P(X=i)}{P(X>0)} = \frac{1}{P(X>0)} \sum_{i=0}^{b} i \cdot P(X=i)$$

and thus

$$\mathbb{E}[X \mid X>0] = \frac{\mathbb{E}[X]}{P(X>0)} = \frac{\mathbb{E}[X]}{1-(1-p)^k}.$$

Hence, we now have an approximation that allows us to write DLWA as defined in (1) in terms of the device parameters t, u, and b. This approximation is validated against simulation in Figure 6.

Massively Parallel Multi-Versioned Transaction Processing

Shujian Qian
University of Toronto

Ashvin Goel
University of Toronto

Abstract

Multi-version concurrency control can avoid most read-write conflicts in OLTP workloads. However, multi-versioned systems often have higher complexity and overheads compared to single-versioned systems due to the need for allocating, searching and garbage collecting versions. Consequently, single-versioned systems can often dramatically outperform multi-versioned systems.

We introduce Epic, the first multi-versioned GPU-based deterministic OLTP database. Epic utilizes a batched execution scheme, performing concurrency control initialization for a batch of transactions before executing the transactions deterministically. By leveraging the predetermined ordering of transactions, Epic eliminates version search entirely and significantly reduces version allocation and garbage collection overheads. Our approach utilizes the computational power of the GPU architecture to accelerate Epic's concurrency control initialization and efficiently parallelize batched transaction execution, while ensuring low latency. Our evaluation demonstrates that Epic achieves comparable performance under low contention and consistently higher performance under medium to high contention versus state-of-the-art single and multi-versioned systems.

1 Introduction

There has been a growing need for high-throughput online transaction processing (OLTP) systems capable of executing tens of thousands of transactions per second. In-memory database systems, specifically designed for workloads with datasets that fit entirely in DRAM memory and provide durability and high availability via logging and replication, have been developed to address this demand. Although these systems offer considerable performance advantages over traditional disk-based systems, they suffer under contention, leading to low performance and limited scalability across cores.

Multi-versioning offers a promising solution for contended and read-heavy workloads. Multi-version systems maintain recent past versions of each record, enabling concurrent reads and writes to the same record; reads do not block writes because writes can safely create new versions while reads are accessing the old versions. Consequently, transactions can be serialized in ways unattainable in single-version designs, thereby enabling greater parallelism. Previous work has shown that multi-version systems can outperform single-version systems under high contention [17].

However, current multi-version designs have several drawbacks, including increased overheads during transaction processing, data storage, allocation and garbage collection. These designs store record versions in linked lists, introducing an additional layer of indirection and necessitating list traversal to locate the appropriate version. Accessing the versions results in a larger working set, leading to higher cache miss rates and performance degradation. Multiple versions also lead to higher memory requirements. To reduce the memory footprint, versions are frequently garbage collected, which incurs additional overheads. As a result, a previous study that compared carefully tuned, state-of-the-art multi-version and single-version systems demonstrated that under low contention, a multi-version system has roughly *half* the throughput of single-version systems [14].

Current multi-version designs allocate versions dynamically because transactions may write and thus create versions at any time. Thus, versions are stored in linked lists, reads require searching for versions, and garbage collecting versions has poor locality and requires expensive synchronization.

Our key insight is that deterministic databases employing transaction batching and known transaction read-write sets can avoid most of these multi-versioning costs, thus enabling good performance for all workloads. The transaction batching and known read-write sets requirements are commonly met by most deterministic databases [11, 12, 18, 19, 26, 28, 31, 35].

We introduce Epic, the first multi-versioned, GPU-based deterministic transaction-processing database. Epic batches transactions into epochs and establishes a serial ordering of transactions within a batch before transaction execution, similar to other deterministic databases.

Transaction batching enables splitting an epoch into an *initialization phase* during which concurrency control operations are initialized using the read-write sets, followed by an *execution phase* during which transactions are executed concurrently and synchronized to ensure the deterministic ordering. During the initialization phase, Epic allocates versions based on the write set. These allocation operations are performed efficiently because they do not interfere with transaction execution. In addition, Epic calculates the version location of each read/write operation based on the ordering of transactions and the known read-write sets. This approach enables transactions to access versions directly during the execution phase, without requiring any version search.

Epic's epoch-based design enables efficient garbage collection as well. Since transactions in the next epoch are serialized after all transactions in the current epoch, only the final write to a record is visible to the transactions in the next epoch. Thus all versions except the last one become obsolete when an epoch ends. Epic stores all intermediate record versions separately from the last version and reclaims them efficiently at the end of an epoch.

The challenge is that Epic's initialization phase is expensive, requiring both significant computation and memory bandwidth. Fortunately, Epic's initialization phase is highly parallelizable. With the rapid commoditization of general-purpose GPU computing, Epic harnesses the thread parallelism offered by modern GPU architectures to significantly accelerate the initialization phase.

Modern GPUs are well suited for Epic's execution phase as well because they offer high-bandwidth memory for memory-bound workloads. In addition, they perform zero-overhead context switching between thread contexts, which allows hiding memory access latency. These advantages help to counter the increased memory footprint and lower cache utilization commonly associated with multi-version systems. Consequently, Epic achieves high throughput and ensures low transaction latency even with its epoch-based execution scheme.

While GPU transaction execution performs well, it is limited by datasets that fit in GPU memory. Thus, Epic also supports larger datasets with a CPU execution model in which the initialization phase runs on the GPU while the execution phase runs on the CPU.

To demonstrate the effectiveness of Epic's design, we conduct extensive evaluation using the TPC-C and YCSB benchmarks and show that Epic significantly outperforms recent single- and multi-version systems on most workloads.

2 Background

This work builds on a rich body of research on multi-version concurrency control, deterministic databases, and GPU-accelerated computation, as discussed below.

2.1 Multi-versioned Concurrency Control

Multi-version concurrency control (MVCC) has a long history [29, 30], with early work evaluating its performance [8], ensuring snapshot isolation [5], providing serializable snapshot isolation [7], using dynamic timestamp assignment [20] and enabling efficient indexing [32], for disk-based databases.

With the advent of machines equipped with high core counts and terabytes of DRAM memory, much work has focused on in-memory database designs, and several MVCC schemes optimized for them have been proposed [15, 16, 22]. MVCC schemes are popular because they provide robust performance under a wide range of workloads. As a result, many commercial in-memory databases implement MVCC [10, 24, 25, 34].

Wu et al. conduct a detailed study of the costs associated with concurrency control, version storage, garbage collection, and index management in various in-memory MVCC schemes [37]. Cicada [17] outperforms previous MVCC schemes with several optimizations, including optimistic multi-versioning, contention regulation, version inlining, and rapid garbage collection. However, a study comparing state-of-the art multi-version and single-version systems showed that while MVCC outperforms OCC under high contention, its throughput is significantly lower under low contention [14]. Epic aims to minimize multi-versioning costs associated with version storage, lookup and garbage collection.

2.2 Deterministic Database Systems

Deterministic databases have gained increasing attention in recent years, driven by the need for efficient replication and improved scalability for distributed transactions [35]. These systems execute transactions deterministically by ensuring that the serial ordering of operations remains consistent across different runs. Determinism enables efficient replication [27, 31, 33] and live migration [18, 19] since all replicas execute transactions independently without coordination. Furthermore, deterministic systems reduce the need for two-phase commit, helping scale the performance of distributed transactions [35]. They can also effectively handle skewed and contended accesses, e.g., orders for popular items [28].

Deterministic systems typically batch transactions into epochs to perform deterministic concurrency control before execution [11, 12, 28, 35]. Thus these system require the read and write sets of transactions to be known before execution. When they are not fully known, they can be determined using reconnaissance queries [35]. Calvin [35] and PWV [12] are single versioned, while Bohm [11] and Caracal [28] utilize MVCC. Calvin uses a centralized lock manager, while PWV employs a more-scalable per-core dependency analysis for concurrency control. Bohm and Caracal allocate versions scalably during the concurrency control initialization phase, but Bohm performs partitioned initialization, while Caracal performs shared memory initialization. Bohm partitions the records in a table across cores. During the initialization phase, all partitions analyze each transaction's write set and insert placeholder versions in a linked list for the records they own. During execution, a read operation traverses the list to find the correct version based on its total order ID. Then, it synchronizes with a write operation that fills the corresponding placeholder version. Caracal uses shared-memory initialization, which enables better handling of skewed workloads. It scales version allocation for contended records by batching the allocations. It stores versions as sorted arrays and uses binary search to reduce version lookup costs during execution. Epic performs shared-memory initialization similar to Caracal. However, Epic avoids any version lookup costs and minimizes version storage and garbage collection overheads.

2.3 GPU Accelerated OLTP Databases

General-Purpose computing on Graphics Processing Units (GPGPU) has become popular with the rapid commoditization of GPUs, the advent of user-friendly programming models and frameworks like CUDA and OpenCL, and the growing demand for high-performance computing on large datasets. Modern GPUs contain an array of streaming multiprocessors (SMs), each of which contains many CUDA cores or stream processors, allowing execution of thousands of active threads concurrently. GPUs uses the Single Program, Multiple Data (SPMD) parallel programming model in which multiple threads execute the same program on different data elements.

GPU-based databases are an active area of research, but most work has focused on accelerating Online Analytical Processing (OLAP) workloads since typical OLAP operators, such as join and sort, are a good fit for parallelization using the GPU's SPMD execution model.

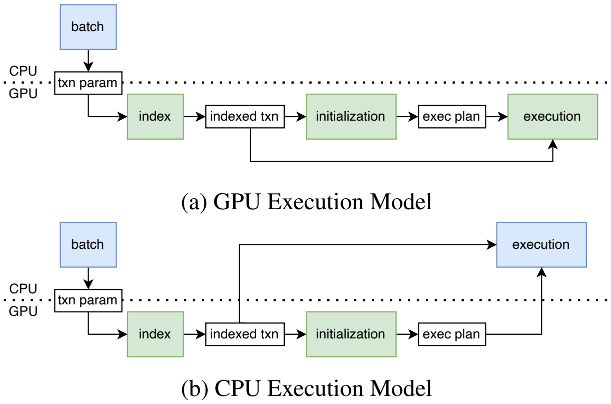
GPU-based transaction processing is relatively unexplored because transactional workloads comprise short-lived transactions with random accesses, and atomicity and isolation require significant synchronization. These requirements makes it hard to exploit the parallelism available in GPUs.

Previously, two GPU-based transaction processing systems, GPUTx [13] and GaccO [6], have been proposed. Similar to Epic, both batch transactions and use epoch-based concurrency control initialization and execution. GPUTx, an early attempt at executing OLTP workloads on GPUs, uses dependency tracking to group transactions into sets; transactions within each set are conflict-free and can execute without synchronization. However, we found that their efficient dependency tracking algorithm, K-Set, does not ensure that transactions in a set are conflict-free, thereby failing to guarantee correctness. GaccO is a deterministic database that uses single-version, deterministic locking, similar to Calvin. We describe Gacco in detail and compare it with Epic in Section 5.

3 Design

Epic is a GPU-accelerated, in-memory deterministic database that employs a novel multi-versioned concurrency control protocol. Epic assumes that transactions are one-shot and use stored procedures, similar to other high-performance in-memory databases [36].

Figure 1 shows the Epic architecture. Epic batches transactions into epochs and splits each epoch into indexing, initialization and execution phases. The transaction inputs, consisting of read-set and write-set keys and other transaction data, are batched on the CPU and then transferred to the GPU for indexing (shown as "txn param" in Figure 1). During indexing, the keys are used to retrieve and store the corresponding record IDs in a per-transaction data structure (shown as "indexed txn" in Figure 1). These record IDs are used during initialization and used as indices for accessing the record tables during transaction execution. The initialization phase performs multi-versioned concurrency control and generates a per-transaction execution plan, which consists of the locations of the record versions that a transaction then directly accesses during execution.



(a) GPU Execution Model

(b) CPU Execution Model

Figure 1: Epic Architecture

While indexing and initialization are always run on the GPU, Epic can execute transactions on the GPU (Figure 1a) or the CPU (Figure 1b). CPU execution is used to support databases larger than GPU memory. In this case, the GPU serves as an accelerator for indexing and initialization.

Sometimes a transaction's read and write sets are not fully known before the indexing phase. For example the TPC-C order-status transaction requires a secondary index to locate a customer's latest order. For these transactions, Epic runs an optional read-write set identification phase on the GPU before the indexing phase. The transaction inputs to the identification phase only contain the read-write keys that are known at transaction generation time. This phase runs reconnaissance queries [35] that use these partial transaction inputs to identify the remaining read-write keys.

The following sections describe Epic's storage scheme and then Epic's initialization and execution phases.

3.1 Epic storage scheme

Epic's storage scheme separates temporary versions created within an epoch from versions that exist across epochs. All writes to a record within an epoch, except the last one, are only read by other transactions within the epoch. This is because transactions from a later epoch are serialized after all transactions in the current epoch and thus can only read the last version of each record. We call the versions that are read by transactions within an epoch *temporary versions*. The final write to a record within an epoch may be read in later epochs and so this last version is saved across epochs.

Figure 2 shows an example of Epic's storage scheme with transactions T1 to T8 reading and writing Record 1 at Epoch 3. Epic places all temporary versions in a scratchpad area. During an epoch, the write transactions on a record, except

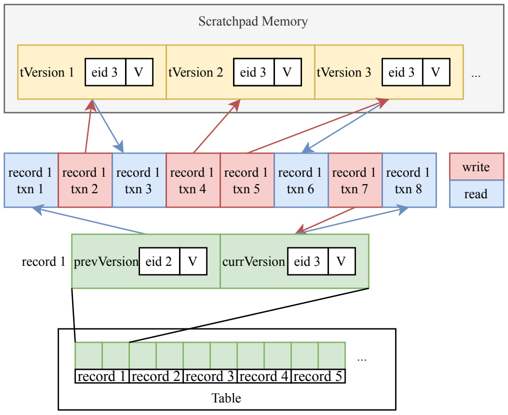


Figure 2: Epic Storage Scheme

the last one, fill these versions, and reads synchronize with the writes to ensure RAW dependencies are satisfied. At the end of an epoch, when all the reads for the temporary versions are done, the scratchpad is reclaimed and used in the next epoch, completely eliminating per-version garbage collection.

The final versions of each record are placed in a dense table area and do not require garbage collection. The last write in an epoch to each record updates the value in the table directly, leading to potential race conditions when transactions in the current epoch need to read data from the previous epoch. Epic addresses this problem by storing two versions for each record in the table: the previous version (*prevVer*) and the current version (*currVer*), as shown in Figure 2. In each epoch, *prevVer* holds the data from the previous epoch (original version). The last write (Txn 7) within an epoch updates *currVer* to avoid overwriting the original version. This write is performed directly on the table, so all temporary versions can be easily collected after an epoch. Reads after the last write to a record (Txn 8) read from *currVer*.

The locations of *prevVer* and *currVer* in each record depend on transaction history, as their positions only change when a record is written during an epoch. Therefore, Epic stores an epoch ID in each version, which helps distinguish the version from previous epochs (*prevVer*) from the version that should be updated in the current epoch (*currVer*). Algorithm 1 is used by transactions to distinguish between *prevVer* and *currVer*. In an epoch, before any write has happened to *currVer*, Epic ensures that the version with a larger epoch ID contains the more up-to-date value and should be used as *prevVer* (Lines 9–12). During the last write, the writer will update the epoch ID of *currVer* to the current epoch's ID (*current_eid*), after which *currVer* will have a larger epoch ID, but it is still distinguishable since its epoch ID matches the current epoch ID (Lines 4–7). The epoch ID is also used for synchronization between reads and writes, as discussed later in Section 3.3.

The record tables and the scratchpad memory are stored in GPU memory for the GPU execution model and in CPU memory for the CPU execution model.

Algorithm 1: Determining the *prevVer* and *currVer*

```
   // Takes the two table versions of a record
1  Function GetTableVersions ($V[2]$):
2      $eid0 \leftarrow atomicRead(V[0].eid)$
3      $eid1 \leftarrow atomicRead(V[1].eid)$
       // current_eid is the current epoch's ID
4      if $eid0 = current\_eid$ then
5          $prevVer \leftarrow V[1]$; $currVer \leftarrow V[0]$
6      else if $eid1 = current\_eid$ then
7          $prevVer \leftarrow V[0]$; $currVer \leftarrow V[1]$
8      else
9          if $eid0 > eid1$ then
10             $prevVer \leftarrow V[0]$; $currVer \leftarrow V[1]$
11         else
12             $prevVer \leftarrow V[1]$; $currVer \leftarrow V[0]$
13     return $\{prevVer, currVer\}$
```

3.2 Multi-Version Initialization

During the initialization phase, Epic uses the ordering of transactions and the knowledge of their read-write sets to allocate versions for all writes performed in the epoch. To avoid the expensive version search required in previous multi-versioned systems, Epic calculates the read-write version locations for each transaction in the epoch before any transactions execute. These operations are parallelizable because they are performed in a phase separate from transaction execution.

As shown in Algorithm 2, Epic employs a parallel GPU-based algorithm to perform concurrency control initialization efficiently. Figure 3 provides an example of this algorithm. The initialization phase starts by collecting all the read and write operations within the epoch (Step 1). Each entry in the *all_ops* operations array contains the *record_id* and the *txn_id* associated with the operation, the operation's index within the transaction (*op_id*), and the operation type (read/write). This operation is parallelizable because the order of operations does not matter for the next step, which sorts the operations array by *record_id* and *txn_id* (Step 2).

Then, Epic counts the number of write operations to each record that occur before and after each operation. Since the operations are already grouped by *record_id*, these operations use parallel prefix and postfix sum by key (Steps 3–4). Next, *GetOpType* in Algorithm 3 calculates the read-write location type for each operation (Step 5). A write operation writes to *currVer* for the last write to the record or else to *tempVer*. A read operation will read from the version written by the previous write as follows: *prevVer* if there is no preceding write preceding, *currVer* if there is no succeeding write, and *tempVer* otherwise.

The number of *tempVer* variables created in an epoch is equal to the number of *tempVer* writes. Thus, Epic places the *tempVer* variables in the scratchpad area in the same order as the *tempVer* write operations in the sorted operations array. To calculate the *tempVer* locations, Epic performs a parallel prefix sum over all operations, counting *tempVer* writes before each operation (Step 6). With this information,

Algorithm 2: Multi-Version Initialization Phase

```
Function Initialize (txns[NUM_TXN]):
    all_ops  // all read-write operations in the epoch,
    // contains tuples: {record_id, txn_id, op_id, read_write}
    // All local variables are arrays of size equal to all_ops size

    // Step 1: submit operations
    parallel foreach txn ∈ txns do
        op_id = 0
        foreach record_id ∈ txn.read_record_ids do
            op_id++
            all_ops.pushback({record_id, txn.id, op_id, Read})
        foreach record_id ∈ txn.write_record_ids do
            op_id++
            all_ops.pushback({record_id, txn.id, op_id, Write})
    // Step 2: sort first by record_id then by txn_id
    sorted_ops = Sort(all_ops, key = {record_id, txn_id})
    // Steps 3-4: count writes before/after each op on same record
    writes_before = PrefixSumByKey(sorted_ops,
                                   key = record_id,
                                   value = Write ? 1 : 0)
    writes_after = PostfixSumByKey(sorted_ops, key = record_id,
                                   value = Write ? 1 : 0)
    // Step 5: get operation type, can be:
    // prevVer read, currVer read/write, tempVer read/write
    op_types = GetOpType(sorted_ops, writes_before,
                         writes_after)
    // Step 6: count tempVer writes before each op in the epoch
    tw_before = PrefixSum(op_types, value=tempVerWrite ? 1 : 0)
    // Step 7: get read/write location for all ops
    rw_loc = GetRWLocation(op_types, tw_before)
    // Step 8: scatter rw_loc back to transactions
    parallel for i = 0 to sorted_ops.size do
        txn_id = sorted_ops[i].txn_id
        op_id = sorted_ops[i].op_id
        txns[txn_id].locations[op_id] = rw_loc[i]
```

GetRWLocation in Algorithm 4 calculates the read-write locations for all operations (Step 7). The ith *tempVer* write updates the ith *tempVer* in the scratchpad area. A read from *tempVer* reads the previous write in the sorted operations array. Finally, the read-write locations are scattered back to each transaction to be used in the execution phase (Step 8).

3.3 Transaction Execution

Epic's execution phase is considerably simpler than the initialization phase. A transaction accesses versions directly using the locations calculated during initialization, eliminating any version lookup during execution. Due to multi-versioning, write-after-read (WAR) and write-after-write (WAW) dependencies do not require explicit coordination. Epic uses the epoch ID associated with each version to synchronize read-after-write (RAW) dependencies between transactions.

Algorithm 5 shows Epic's transaction execution phase. The transactions in an epoch are scheduled in their predetermined serial order as thread resources become available, as explained further in Section 4.4. The *RunTxn* function shows an example of a transaction. The transaction accesses the versions directly using the location information calculated in the initialization phase (lines 11–25 for reads and lines 26–34 for writes). A transaction read waits for a version to be written by an earlier transaction by spinning on the epoch ID of the version until it matches the current epoch ID (lines 21–22). However, reads from *prevVer* do not need any synchronization since this version was updated in a previous epoch. A transaction writes to the data of the version before updating the version's epoch ID (lines 32–34). The GPU weak memory consistency model requires a memory fence between the data write and the epoch ID update to ensure that the data is visible to other threads before the updated version.

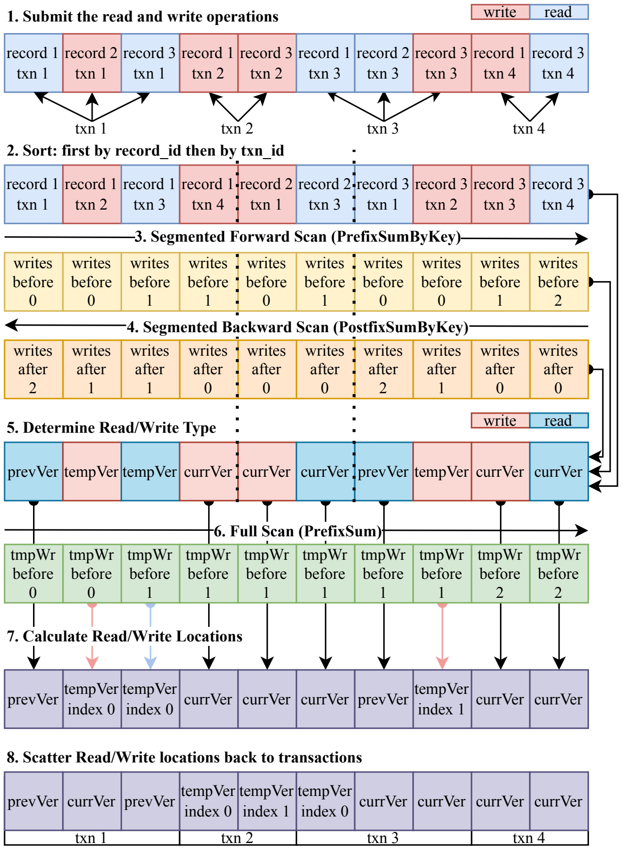

Figure 3: Example of Epic's Initialization Phase

CPU-side Execution Epic can also execute transactions on the CPU, which is particularly useful when the database size exceeds GPU memory capacity. In this case, Epic transfers the output of indexing (read and write record IDs) and the initialization phase (read-write locations) to the CPU, as shown in Figure 1. CPU-side execution utilizes the same synchronization mechanism as GPU execution.

Handling Inserts and Deletes Epic treats record insertions and deletions the same way as updates. Both insert and delete operations are considered write operations, so they create a new version of the record, similar to an update. For each version, Epic uses a valid flag to mark whether it contains

Algorithm 3: Calculate Read/Write Type

```
Function GetOpType (sorted_ops, writes_before, writes_after):
    op_types[sorted_ops.size]  // type of operations
    parallel for $i$ = 0 to sorted_ops.size do
        if sorted_ops[i].read_write == Write then
            if writes_after[i] == 0 then
                op_types[i] = currVerWrite
            else
                op_types[i] = tempVerWrite
        else // read operation
            if writes_before[i] == 0 then
                op_types[i] = prevVerRead
            else if writes_after[i] == 0 then
                op_types[i] = currVerRead
            else
                op_types[i] = tempVerRead
    return op_types
```

Algorithm 4: Calculate Read/Write Locations

```
Function GetRWLocation (op_types, tw_before):
    rw_loc[op_types.size]  // locations of read/write operations
    parallel for $i$ = 0 to sorted_ops.size do
        if op_types[i] $\in$ {currVerRead, currVerWrite} then
            rw_loc[i] = currVer
        else if op_types[i] == prevVerRead then
            rw_loc[i] = prevVer
        else // tempVer read/write, return tempVer index
            if op_types[i] == tempVerRead then
                // index is zero-based
                rw_loc[i] = {tempVer, index=tw_before[i]$-1$}
            else
                rw_loc[i] = {tempVer, index=tw_before[i]}
    return rw_loc
```

Algorithm 5: Transaction Execution Phase

```
1  Function Execute (txns[NUM_TXN]):
2      parallel for $i$ = 0 to txns.size do
3          RunTxn(txns[i])

4  Function RunTxn (txn):
5      value1 = ReadFromTable(txn.record_id1, txn.read_loc1)
6      value2 = ReadFromTable(txn.record_id2, txn.read_loc2)
       // perform transaction logic
7      if value1 is None or value2 is None then
8          abort()
9      result = SomeOperation(value1, value2)
       // no aborts can happen beyond this point
10     WriteToTable(txn.result_record_id, txn.write_loc, result)

11 Function ReadFromTable (rec_id, read_loc):
12     if rec_id = INVALID_RECORD then
13         return None
14     prevVer, currVer = GetTableVersions(table[rec_id])
15     if read_loc == prevVer then
16         read_ver = prevVer
17     else if read_loc == currVer then
18         read_ver = currVer
19     else // tempVer read
20         read_ver = tempVers[read_loc.index]
21     while read_loc $\neq$ prevVer and
           atomicRead(read_ver.eid) $\neq$ current_eid do
22         Spin()  // Wait until version is ready
23     if not read_ver.is_valid then
24         return None
25     return read_ver.data

26 Function writeToTable (rec_id, write_loc, data):
27     prevVer, currVer = GetTableVersions(table[rec_id])
28     if write_loc == currVer then
29         write_ver = currVer
30     else // tempVer write
31         write_ver = tempVers[write_loc.index]
32     PerformWrite(write_ver.data, data)
33     __threadfence()
34     atomicWrite(write_ver.eid, current_eid)
```

valid (V) data, as shown in Figure 2. An update or insert sets and a delete unsets the valid flag of the corresponding version. Read operations use the valid flag to determine if the record exists at the timestamp of the read, preventing transactions from reading invalid data (Algorithm 5, lines 23–24).

Deletion of records can happen at any point within an epoch, and a later write operation to a deleted record will re-insert it. Consequently, the record should be freed only when the last write operation to a record in an epoch is a delete. Epic tracks records that are deleted in an epoch by setting a per-record deleted flag when deletions occur to *currVer*. At the end of the epoch, these flags are scanned to generate a list of deleted records that are subsequently freed, as described later in Section 4.2. A full scan after each epoch is acceptable because the flag is one bit per record and parallel scans are efficient on GPUs.

Handling Aborts Epic eliminates concurrency-control related aborts because transactions are serialized in a predetermined order, similar to other deterministic databases. Epic allows application-level aborts (e.g., constraint violations) before any writes are performed to the database. Transactions are expected to perform their reads, buffer writes and issue aborts before any database writes. Since aborts do not occur after the first write, the writes of a transaction are made visible immediately [12].

In previous multi-versioned systems, a sentinel value is used to indicate an aborted version. Subsequent reads skip such versions and read the previous non-aborted version. This approach is not suitable for Epic since there is no version search. Instead, the aborted write operations must copy the previous version to the current version. Thus, for transactions that may abort, Epic also calculates the read location (i.e., of the previous version) for write operations during initialization.

3.4 Field Splitting

Database records often consist of multiple fields. Since Epic eliminates version search, each version of a record must contain a full copy of all of its fields. This approach adds copying overhead when a transaction updates only a few fields of a record since all of its fields must be copied from the previous version. In addition, it introduces unnecessary dependencies because every field update becomes a read-modify-write operation for the record.

Epic implements a field splitting optimization by storing different fields of a record separately. Each version now comprises only a single field. As a result, a write to a field does not require copying other fields and introduces no additional dependencies. However, the field splitting optimization adds overhead for full record operations, which need to be split into multiple per-field operations, leading to increased initialization and synchronization costs.

3.5 Recovery

Currently, Epic does not support recovery and replication. However, it can provide durability and high availability by using techniques similar to previous deterministic databases [35]. In each epoch, transaction inputs can be logged to storage on the CPU side concurrently with transaction execution. Once all inputs are logged, transaction results can be made externally visible to applications. Currently, Epic returns these results conservatively at the end of the epoch, which enables handling certain problematic transaction logic, such as infinite loops, by aborting the relevant transaction and its dependent transactions [12].

For recovery, the transaction inputs are used to replay all transactions deterministically until the last logged epoch. The replay uses the same mechanism as normal transaction processing. To reduce recovery time, Epic's two-version tables allow checkpoints to be created efficiently. The checkpointing process can run in parallel with an epoch and create a consistent database snapshot by copying the *prevVer* of each record to a different memory area (e.g., CPU memory). However, the next epoch must start after the checkpointing completes or else the resulting snapshot may be inconsistent. After creating a copy of the tables, they can be transferred to persistent storage in the background. The index and allocation information also needs to be checkpointed or rebuilt during recovery.

4 Implementation

This section describes Epic's GPU-based implementation of indexing, initialization and transaction execution phases.

4.1 Transaction Batching and Ordering

Currently, Epic batches transactions when they are generated and serially orders them by assigning a transaction ID to each transaction. In practice, the batching and ordering process can be performed without contention by batching transactions separately on each core and ordering them using a local counter. Before an epoch starts, transactions from all cores can be serialized based on the core ID and the local counter value. This method is similar to Calvin [35].

4.2 Indexing and Allocation

Epic is capable of executing tens of millions of transactions per second. Its index needs to handle hundreds of millions of operations per second, and so we use GPU-based indexing. Epic uses a hash table index to map keys to record IDs. When needed, range queries are performed in the read-write set identification phase using a range index to obtain all the keys for the read and write sets. The keys are then used to look up the record IDs in the hash table index. Epic implements indexing using CuCollection [23], a GPU-based concurrent hash table. Epic uses a modified version of a GPU B-tree [2,4] for the range index.

Since Epic's indexing operates in parallel, we ensure that read operations see all previously inserted records by performing insert operations before any indexing operations, which also prevents phantom reads. Epic does not distinguish between insert and write operations, and so it first indexes all write operations in an epoch to find the keys to be inserted (keys that are in the write set but are not found in the hash table). To allocate a record for each to-be-inserted key, Epic maintains a ring buffer of free record IDs on the GPU. To ease allocation, these keys are uniquified. Then, Epic allocates record IDs for them by removing the same number of record IDs from the ring buffer. The key-record ID mappings are then inserted in the hash table. Next, Epic indexes all read and write operations. For read operations, if a key is not found, Epic marks the read as invalid by returning a sentinel `invalid_read` value for the record ID. This value is treated as any other record ID during initialization, and then reads detect it during execution (Algorithm 5, lines 12–13). Since Epic performs inserts before read operations, a read of a non-existing record may see an index entry from a later write. A read operation detects this version as invalid during execution (see Section 3.3).

At the end of an epoch, Epic's execution phase returns the deleted record IDs (see Section 3.3). Epic garbage collects these records by appending them to the ring buffer. To free the index entries for these records, Epic also keeps a back-link array that maps record IDs to keys. The hash table and the back-link are stored in GPU memory and are only accessed by the GPU during indexing.

4.3 Multi-Version Initialization

Epic's multi-version concurrency control initialization is implemented using the CUB and Thrust parallel algorithms library. As shown in Algorithm 2, all operations, such as sorting and prefix sum, are highly parallelizable. Epic performs initialization for each table separately for ease of implementation. Each operation's record ID, transaction ID, operation ID and read-write type are stored in a 64 bit integer for efficient sorting. It is possible to prefix the record ID with a table ID and perform initialization for all tables together.

We implemented an optimized CPU-based initialization phase using Intel's TBB library but its performance was at least an order of magnitude slower than the GPU implementation, motivating our GPU-based approach.

4.4 Transaction Execution

After the concurrency control initialization phase, Epic executes the entire batch of transactions concurrently on the GPU using *warp-cooperative execution*, an approach motivated by previous work on GPU-based concurrent data structures [1, 3, 39]. Next, we provide some background on GPUs to motivate our execution approach.

GPUs provide an array of multi-threaded Streaming Multiprocessors (SMs), with each SM containing simple cores (typically 64–128 per SM). The GPU executes instructions from a group of threads, called a *warp*, in a Single Instruction, Multiple Threads (SIMT) lockstep manner on the cores of an SM, with threads executing the same instruction on different data elements. A warp typically consists of a fixed number of threads, such as 32 threads in Nvidia GPUs.

The warp-based execution model makes branch divergence an important aspect of GPU algorithm design. Branch divergence occurs when thread execution diverges due to control flow statements, such as branches, for threads within a warp. In this case, the GPU serializes the execution of the divergent paths, causing longer execution times per warp.

Instead of running a different transaction on each thread of a warp, Epic's warp-cooperative execution model uses all the threads in a warp to cooperatively execute a *single* transaction, which avoids branch divergence altogether. The threads in a warp read and write versions by accessing consecutive locations of a record. The GPU can coalesce (or combine) these contiguous memory accesses into a single request, which improves memory bandwidth utilization and is especially beneficial when transactions access large records. For example, 32 threads in a warp running the same instruction can access 128 contiguous bytes in parallel from global memory.

Although warp-cooperative execution can lead to reduced concurrency, the amount of parallelism available on modern GPUs is more than sufficient for Epic's transaction processing requirements. For example, Nvidia's A6000 GPU has 84 SMs, each capable of scheduling 1536 threads (48 warps) at a time. With the warp-cooperative execution scheme, Epic can execute $84 \times 48 = 4032$ transactions concurrently. We believe that transaction execution will not benefit from higher concurrency due to dependencies between transactions. Therefore, the benefits of avoiding branch divergence and coalesced memory access outweigh the reduced concurrency.

GPU Transaction Scheduling The GPU hardware scheduler dispatches threads on an SM at the granularity of a group of threads called a thread block. While the GPU does not provide control over the scheduling order of thread blocks (or threads within a thread block), it guarantees that an active thread runs to completion without being preempted.

Since Epic assigns a serial order to each transaction before execution, transactions must be scheduled based on their serial order. Otherwise, a later transaction may depend on an earlier transaction, which never gets to run because the later transaction holds the hardware resources. Epic schedules transactions in serial order by dynamically assigning transactions to threads when they become active. To do so, it uses a next-transaction global counter, that it increments once per block to allocate transactions for all warps within a block. Threads within the block then distribute the allocated transactions using a local counter.

4.5 Other Optimizations

Epic exploits parallelism within a transaction by splitting transactions, when possible, into multiple independent pieces. Due to its deterministic nature, these pieces can be executed concurrently while still ensuring isolation [12, 28].

Epic aims to overlap data transfer and computation on the GPU whenever possible by launching asynchronous tasks on different non-blocking CUDA streams. This approach effectively hides the latency associated with transferring transaction parameters and data. As shown in Figure 1, Epic transfers transaction parameters to the GPU. This transfer is overlapped with the execution of the previous batch of transactions. With CPU-side execution, Epic overlaps the transfer of the indexed transactions to the CPU with the initialization phase.

It is possible to pipeline Epic's CPU-side execution with GPU indexing and initialization. However, this approach complicates the index garbage collection mechanism. If a record is deleted in epoch N, its index information cannot be garbage collected until epoch $N+2$ because the indexing in epoch $N+1$ runs concurrently with the execution of epoch N. However, the same key may be re-inserted in epoch $N+1$. In this case, the index information for the record deleted in epoch N cannot be garbage collected. This issue can be resolved by tracking the epoch ID in an index entry when it is created. Epic currently does not implement this pipelined execution.

5 Evaluation

We compare the overall performance of Epic with several state-of-the-art in-memory transaction processing databases using the TPC-C, TPC-C NP and the YCSB benchmarks. Then, we provide a more detailed analysis of Epic's design.

All experiments are run on cloud server with a 32-core Epyc CPU and 512GB of memory. For all the CPU-based databases except Aria, we use 1 thread per core for a total of

32 threads. For Aria, we use the default 12 worker threads because this configuration achieves the highest throughput. We use the Nvidia A6000 GPU with 10752 CUDA cores and 48GB GDDR6 memory. The operating system is Ubuntu 22.04. All experiments are compiled with NVCC 12.0 with CUDA run time version 12.0.

5.1 Database Systems Comparison

We compare Epic against four state-of-the-art in-memory databases: STOv2 [14], Caracal [28], GaccO [6] and Aria [21]. We use the publicly available implementations of Caracal, STOv2 and Aria. Since GaccO's implementation is not publicly available, we implemented GaccO's GPU-side transaction execution based on the description in their paper. We use the default epoch sizes of 500 for Aria, 100K for Caracal, and 32768 for GaccO as specified in their papers for all experiments except for the latency experiment in Section 5.7. We use an epoch size of 100K transactions for Epic because throughput improvements become smaller beyond this epoch size, which balances throughput and latency.

STOv2 is a state-of-art in-memory CPU database. STOv2 implements and compares three concurrency control mechanisms: OCC-based Silo [36], timestamp-based TicToc [38], and a variant of MVCC-based Cicada [17]. These mechanisms are called OSTO, TSTO, and MSTO respectively. STOv2's implementations of TicToc and Cicada perform well thanks to careful attention to implementation choices. We enable both the timestamp splitting and deferred updates optimizations in STOv2. Timestamp splitting behaves similar to our field splitting optimization.

Caracal is a multi-versioned, deterministic CPU in-memory database. Similar to Epic, Caracal batches transactions and splits each epoch into an initialization phase and an execution phase. Caracal uses a version array to implement multi-version concurrency control (MVCC). Each record contains an array of versions that are created during the initialization phase and read during the execution phase. Caracal performs well under contention due to transaction batching and MVCC. However, Caracal's concurrency control mechanism keeps the version array sorted by the version ID, which imposes overhead during the initialization phase, and read operations need to perform a binary search through the version arrays. Additionally, the version array requires expensive garbage collection.

GaccO is a single-version, deterministic GPU database that uses lock-based concurrency control [6]. To support databases larger than GPU memory, GaccO proposes running transactions on both the GPU and the CPU. This CPU-GPU co-execution model requires keeping copies of CPU memory tables in GPU memory when the tables are accessed by GPU-side transactions, synchronizing updates to the tables at epoch boundaries, and delaying CPU-side transactions that conflict with GPU-side transactions.

We only compare with GaccO's GPU-based execution, so no synchronization with the CPU is needed. Similar to Epic, GaccO requires transactions' read-write sets in advance. GaccO initializes an epoch by creating a per-record lock table. For each record, all operations are sorted based on the serial ID of the transactions. The corresponding serial IDs are stored in the lock table, representing the order of lock acquisition. During the execution phase, transactions acquire locks on records deterministically by checking the lock table and waiting until the lock value matches the transaction's ID. Upon release, the lock value is advanced to match the next transaction that accesses the record. However, this lock-based concurrency control does not permit readers to share locks.

GaccO executes a transaction per thread and batches transactions by type (e.g., NewOrder in TPC-C) within an epoch to minimize warp divergence (see Section 4.4). This batching also enables GaccO to use a *commutative optimization* when highly-contended items are accessed commutatively. If an operation updates a data item commutatively then the order of performing such updates is flexible, provided the data item is not otherwise observed by its transaction and there are no other conflicting operations on the item. For instance, a transaction that increments a counter in the database row but never reads the value of the counter can implement the update using atomic instructions, without using the deterministic locking protocol. Since GaccO batches transactions by type, conflicts do not occur with other types of transactions.

However, due to this batching of transactions by type, we do not implement the full TPC-C benchmark for GaccO. For the OrderStatus and StockLevel transactions, batching by type would cause these transactions to execute on a snapshot of the database and return the same results within an epoch. Therefore, we only evaluate GaccO on the TPC-C NP and YCSB benchmarks.[1]

Aria is a deterministic database that does not require advance knowledge of read-write sets [21]. It achieves determinism by executing all transactions in a batch against a database snapshot from the previous epoch, while buffering writes and delaying commit until the end of the epoch. After all transactions have executed, Aria deterministically aborts transactions that conflict with an earlier transaction based on transaction ID ordering, and it uses a deterministic reordering optimization to reorder transactions in a batch to reduce the number of aborts. Aria assumes that the read-write sets of transactions are known after the execution phase, and uses Calvin's deterministic locking as a fallback strategy to rerun the aborted transactions after the execution phase.

Aria only implements TPC-C NP. We evaluate the variant with the fallback strategy since their paper reports that it performs better than without the fallback strategy under all contention levels on TPC-C NP.

[1] The GaccO paper also evaluates TPC-C NP on the GPU.

5.2 TPC-C

We use the TPC-C OLTP benchmark to evaluate Epic. The TPC-C benchmark simulates an OLTP workload for a warehouse management system. It consists of five transactions: NewOrder, Payment, OrderStatus, Delivery, and StockLevel.

The NewOrder transaction creates a new order for a customer by incrementing the nextOrderID field in the District table to obtain the order ID. This makes the write-set of NewOrder dependent on the execution-time value of the order ID. OrderStatus retrieves the status of the last order placed by a customer; StockLevel checks the stock level of items ordered in the last 20 transactions in a district; and Delivery processes the oldest undelivered order in a district.

To identify the read-set and write-set keys of these transactions, Epic runs the read-write set identification phase before the indexing phase. Initially, the order ID used by NewOrder is calculated using a per-district counter, which also helps determine the latest order ID for OrderStatus and StockLevel. Then, for each NewOrder transaction, the order information is inserted into a secondary index. The secondary index uses a range index keyed by the customer ID and the order ID. The secondary index also stores the items ordered in each order. OrderStatus performs a backward range scan using the customer ID and the latest order ID in the district as the key to find the last order ID for a customer. StockLevel uses the latest order ID to lookup the ordered item information to check for stock levels. Lastly, Delivery uses a per-warehouse counter to find the oldest undelivered order.

During execution, transactions can validate the read-write sets determined by the identification phase and abort transactions if they do not match the keys that would be accessed during the execution phase [35]. However, since Epic does not cause any concurrency-control related aborts, the read-write sets always match in TPC-C and so no aborts occur [11].

Furthermore, the Payment and OrderStatus transactions in the original TPC-C benchmark can be provided with a customer ID or the customer's last name. In the latter case, the customer ID is retrieved by scanning a read-only index of customers. Since existing GPU range indexes do not support variable length keys needed for scanning the last name, we simplified Payment and OrderStatus to only use the customer ID for all the databases. Other than this change, the behavior and contention level of Epic's TPC-C implementation conforms to the TPC-C specification.

TPC-C has low contention when each warehouse is assigned a separate CPU core. We vary the number of warehouses to evaluate performance under different contention levels. With a single warehouse, TPC-C becomes highly contended due to the per-warehouse Warehouse, District, and Stock tables.

STOv2 and Caracal implement the TPC-C benchmark and we compare Epic against them. Figure 4 shows the throughput of the systems. Epic outperforms the other systems under all contention levels. Under low contention, Epic benefits from the high memory bandwidth and parallelism offered by the GPU, enabling it to outperform all other systems. The two multi-versioned CPU systems, MSTO and Caracal, perform poorly under low contention due to the high overhead of MVCC. However, they perform better under high contention compared to the single version systems. As expected, Epic's performance degrades under high contention. However, due to the deterministic ordering of transactions and its efficient multi-versioning implementation, Epic outperforms the other systems under high contention as well.

5.3 TPC-C NP

The TPC-C NP benchmark is a subset of the TPC-C benchmark that consists of 50% NewOrder and 50% Payment transactions. We use this benchmark to compare with GaccO and Aria as well. The left graph in Figure 5 shows the throughput of the GPU and then the CPU systems for TPC-C NP.

The Epic, STOv2 and Caracal TPC-C NP results are qualitatively similar to TPC-C results. These databases have higher throughput on TPC-C NP under low contention because TPC-C NP has shorter transactions than TPC-C. However, they have lower throughput on TPC-C NP under high contention because TPC-C NP has higher contention than TPC-C. Caracal and Aria have lower throughput than other CPU based databases, but they also support distributed operation.

GaccO performs poorly under all contention levels because it batches transactions by type. For the Payment transaction, updates on the warehouse table require GaccO to serialize all transactions. Also, GaccO cannot run NewOrder transactions concurrently with Payment transactions, resulting in the GPU being underutilized. Additionally, GaccO's lock-based concurrency control has high overhead under contention.

Epic's performance under low contention for TPC-C NP is much higher than for TPC-C for two reasons. First, TPC-C NP does not require scanning for the latest order of a customer and lookup for ordered items and so the overhead of read-write identification is significantly lower. Second, and more importantly, TPC-C NP has short transactions that can be scheduled on GPU thread blocks (see Section 4.4) more efficiently. With TPC-C's mix of short and long transactions, a block needs to wait for the longest transaction to complete. We plan to explore scheduling strategies that co-locate long read-only transactions within blocks.

To implement GaccO's commutative optimization for TPC-C NP, we changed the NewOrder transaction to use atomic CAS instructions to update the District and Stock tables, and we changed the Payment transaction to use atomicAdd to increment the balances of the warehouse, district, and customers tables. Since the updated values are not used after the update or read by other transactions, the order of updates is flexible. The right graph in Figure 5 shows that GaccO with this optimization outperforms all systems. The throughput

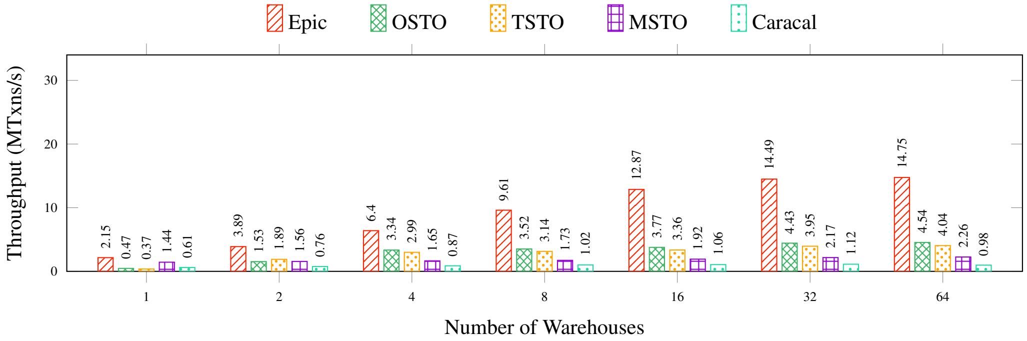

Figure 4: TPC-C Throughput

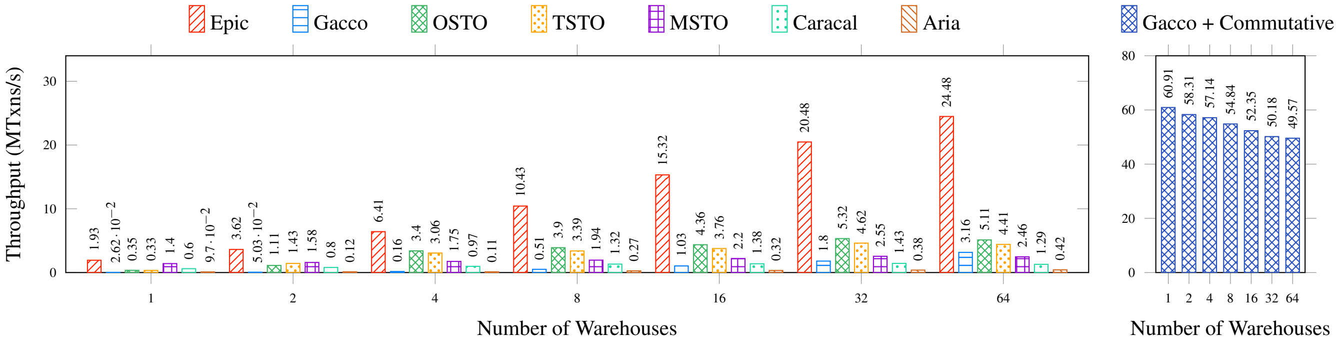

Figure 5: TPC-C NP Throughput

drops slightly with more warehouses due to decreased cache locality. This optimization eliminates concurrency control in TPC-C NP since both the NewOrder and the Payment transactions do not hold any locks. However, this optimization is not general-purpose, e.g., it doesn't allow reading the District table to validate the order ID in the NewOrder transaction.

5.4 YCSB

Next, we conduct experiments using the Yahoo! Cloud Serving Benchmark (YCSB) [9]. For the experimental setup, we use a single table consisting of 1,000,000 records. We used the standard record size in YCSB, where each record is 1000 bytes and consists of ten 100 byte fields. We performed experiments using four YCSB workloads, as shown in Figure 6. In all workloads, a read operation reads the entire record. An update operation replaces the value of one randomly chosen field. A read-modify-write (RMW) operation reads a record and updates a randomly chosen field. For our evaluation, we group 10 operations to form a transaction. We vary the Zipfian skew factor θ from 0 to 0.99 to vary contention levels.

Figure 7 shows the throughput of the six databases for the four YCSB workloads with increasing contention levels. Epic outperforms all other databases for all workloads. In YCSB-A, Epic's performance drops significantly under high contention. Epic performs a read-modify-write operation for each update operation. Even when an update only writes to a part of the record, the entire record needs to be copied from the previous version. As a result, the read-modify-write operations form long dependency chains under high contention. In the YCSB-B benchmark, where the write ratio is low, Epic's performance drops more gently under high contention. In the read-only YCSB-C benchmark, Epic achieves high throughput due to the high memory bandwidth of GPUs. Finally, in the YCSB-F benchmark, Epic shows a similar trend as YCSB-A, where performance drops significantly under high contention because Epic performs the same read-modify-write operations for both YCSB-A and YCSB-F. In some workloads, Epic's throughput increases slightly from low to medium contention level (skew factor 0.0 to 0.5) due to better cache locality that improves GPU indexing performance. The execution phase in Epic also benefits from this better cache locality, especially for read-only YCSB-C.

Workload	Description	Operations
YCSB-A	Update heavy	Read: 50%, Update: 50%
YCSB-B	Read heavy	Read: 95%, Update: 5%
YCSB-C	Read only	Read: 100%
YCSB-F	Read-modify-write	Read: 50%, RMW: 50%

Figure 6: YCSB Workload Configurations

We also evaluate the performance of Epic with field splitting, as described in Section 3.4. In this case, each record is divided into ten fields, and each field is treated as a separate

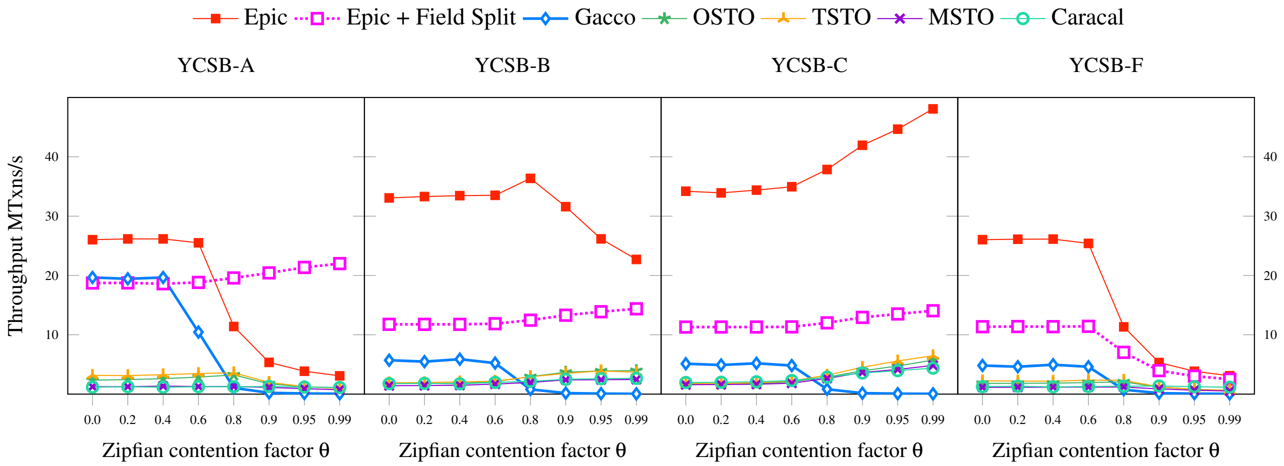

Figure 7: YCSB Throughput

data item from the perspective of concurrency control. As a result, each full-record read operation needs to perform 10 field reads, each requiring separate synchronization. As a result, the number of read operations in the initialization phase increases by 10x, and read performance decreases. On the other hand, since each field is treated separately, an update operation on a single field does not require copying the rest of the fields from the previous versions, improving update performance. As shown in Figure 7, Epic with field splitting performs better than default Epic under YCSB-A with high contention. However, Epic's performance is lower in YCSB-B, YCSB-C, and YCSB-F, where the read ratio is higher.

GaccO shows similar trends under all workloads, performing well under low contention, but its performance drops significantly under high contention due to its lock-based concurrency control. GaccO's initialization phase is simpler and faster than Epic's MVCC initialization but its lock-based concurrency control does not allow readers to share locks, causing its performance to drop significantly under contention, even under a read-only workload. GaccO's assigns each transaction to a single GPU thread, which causes non-coalesced memory accesses that reduce memory bandwidth utilization. As a result, GaccO's performance decreases when the ratio of read operations increases (YCSB-A and YCSB-B) because read operations retrieve the entire record. GaccO's commutative operation optimization cannot be applied to YCSB workloads (except YCSB-C) because other transactions read the values of the data items updated. Therefore, we did not implement this optimization for the YCSB workloads.

Both multi-versioned systems (MSTO and Caracal) suffer from the same extra dependency as Epic in YCSB-A. Therefore, they exhibit similar trends for YCSB-A and YCSB-F. OSTO and TSTO perform well under low contention, but their performance drops significantly under high contention with write-heavy workloads (YCSB-A and YCSB-F). This is due to increased aborts resulting from a high conflict rate. In read-heavy workloads (YCSB-B and YCSB-C), OSTO and TSTO outperform MSTO and Caracal due to their lightweight concurrency control mechanisms. However, Caracal achieves higher throughput than OSTO and TSTO in YCSB-A and YCSB-F under high contention because its MVCC-based concurrency control allows readers to run in parallel with writers.

5.5 CPU-side Execution

Next, we evaluate the performance of Epic's CPU-side execution using the same setup for the TPC-C, TPC-C NP and YCSB benchmarks. As mentioned in Section 3.3, the GPU performs indexing and initialization for the epoch and then transfers the execution plan to the CPU. This data transfer takes roughly 4 ms for the TPC-C NP and YCSB benchmarks and 6 ms for TPC-C, which contains long running queries with more operations. The transactions are then executed on the CPU. The throughput reported in Figure 8 includes the time for indexing, initialization, data transfer and execution because Epic currently does not implement pipelining.

With TPC-C and TPC-C NP, CPU-side execution achieves higher throughput than GPU-side execution with a single warehouse. We believe that the contended Payment transaction limits Epic from utilizing the parallelism of the GPU effectively. On the CPU, Epic's execution time synchronization is more efficient as the atomic flags can be directly communicated through the CPU cache. However, with more warehouses, GPU-side execution achieves higher throughput due to the higher parallelism and memory bandwidth of the GPU.

With CPU-side execution, Epic achieves lower throughput in TPC-C than TPC-C NP under low contention due to the longer data transfer time. However, Epic performs better for TPC-C with a single warehouse because TPC-C has lower contention than TPC-C NP.

With YCSB, each transaction reads several records, and so CPU-side execution is limited by memory bandwidth and la-

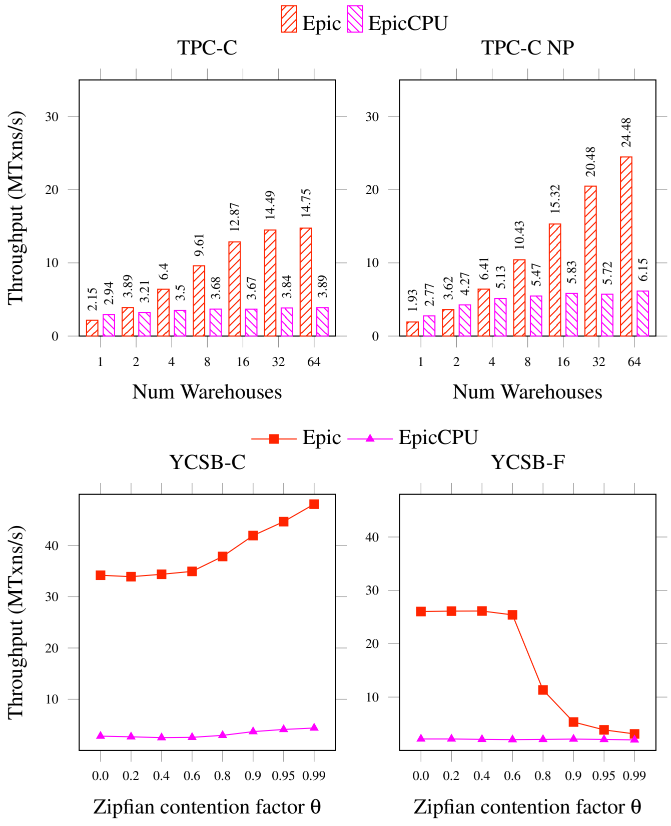

Figure 8: Throughput with CPU-side Execution

tency. For read-only YCSB-C, CPU-side execution has much lower throughput than GPU-side execution. Throughput increases slightly under contention due to cache locality. For YCSB-F, CPU-side execution throughput is bottlenecked by memory bandwidth at low contention and achieves similar throughput as GPU-side execution under high contention. YCSB-A and YCSB-B show similar trends so we omit them.

For all the three benchmarks, Epic's CPU-side execution achieves comparable throughput to OSTO and TSTO under low contention because Epic's GPU initialization is efficient. Under high contention, Epic outperforms OSTO by 6.2x and TSTO by 7.9x for TPC-C single warehouse and both by 3.2x for YCSB-F with a 0.99 skew factor due to its multi-versioning. Epic-CPU outperforms both multi-version systems, MSTO and Caracal, under all workloads because Epic's MVCC initialization is efficient and, unlike MSTO and Caracal, Epic's CPU-side execution runs without performing expensive version search.

5.6 Run Time Breakdown

Figure 9 shows the breakdown of per-epoch run time for Epic running TPC-C with the CPU- and GPU-execution model. The figure shows that the initialization time is similar for both low and high contention levels because Epic's initialization phase is unaffected by the contention level. The GPU execution time is significantly longer under high contention because transaction dependencies reduce GPU utilization.

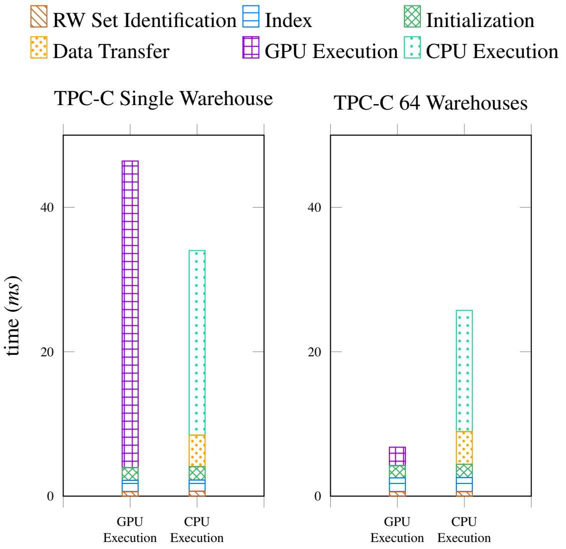

Figure 9: Epic Run Time Breakdown

For CPU execution, the indexed transactions and the transaction execution plans need to be transferred from the GPU to the CPU. Depending on the complexity of the transaction, the data transfer time can vary but is a significant portion of the total run time. Pipelining the GPU and CPU phases will help reduce the epoch run time.

5.7 Latency

In this experiment, we evaluate Epic's throughput and latency for different epoch sizes by comparing against the GaccO, Caracal, and Aria deterministic databases. We show TPC-C NP results because our GaccO implementation and Aria implement TPC-C NP. We also show YCSB-F results (but not for Aria, which doesn't implement it). For both workloads, we show results under low and high contention. Epic's results for TPC-C are not shown but they are similar to TPC-C NP.

We vary the epoch size from 500 to 200K transactions/epoch. Epic batches transactions during the previous epoch and the benchmarks do not cause aborts, so Epic's average transaction latency is 1.5× the epoch run time.

Figure 10 shows the throughput and average latency of the four systems. Each point on a line represents an epoch size. The lines start at 5000 for Caracal (which crashes at lower epoch sizes) and 500 for all other systems. The lines also show some key epoch sizes, e.g., at maximum throughput and at the knee of the curve. In all workloads, Epic achieves higher throughput with increasing epoch size. Intuitively, a larger epoch enables higher parallelism and amortizes overheads at the cost of transaction latency. Similarly, Caracal's throughput increases with larger epoch sizes.

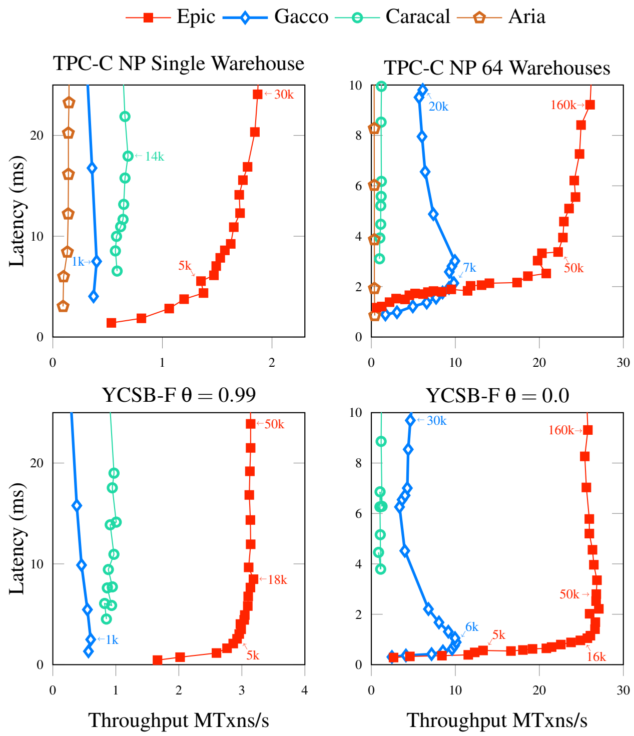

Figure 10: Latency vs. Throughput

GaccO's throughput increases with larger epoch sizes initially but then decreases. We believe that GaccO's lock-based scheduling performance degrades with increasing number of concurrent transactions. We plan to investigate this issue.

Aria's throughput decreases with larger epoch sizes under low contention because more transactions are deterministically aborted. However, Aria benefits from a larger epoch size under high contention. In this case, Aria's deterministic scheduling mechanism aborts a majority of transactions. The aborted transactions are rerun using the deterministic locking fallback strategy, which is more efficient at larger epoch sizes.

Overall, Epic achieves comparable latency to other systems at small epoch sizes. Epic has higher latency than GaccO at small epoch sizes because its multi-version initialization phase is slower and the small epoch size does not allow it to amortize this overhead. However, beyond roughly 2 ms average transaction latency, Epic outperforms all other systems.

5.8 Impact of Aborts

To evaluate the impact of aborts on Epic's performance, we run a micro-benchmark where each transaction reads and updates 10 records. The keys are generated using a Zipfian distribution with $\theta = 0.8$ for medium contention. Transactions abort when the read-set or the write-set is predicted incorrectly, and aborted transactions are rerun in the next epoch. We vary the abort rate for the experiments. We assume that the read-set and write-set are known after a transaction executes, and so an aborted transaction will not abort again when rerun, similar to Aria's assumption for its fallback strategy [21].

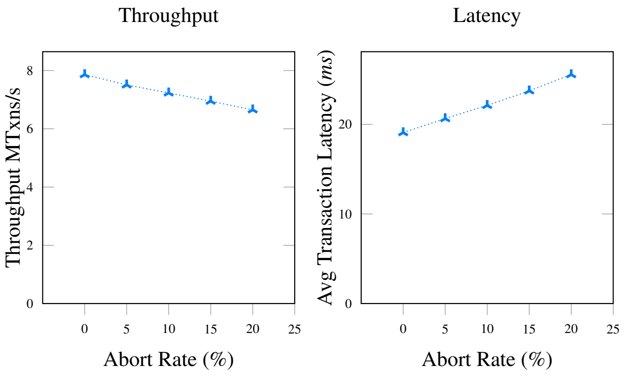

Figure 11: Impact of Abort Rate

Figure 11 shows Epic's throughput and average latency. As the abort rate increases, Epic's throughput decreases and latency increases roughly linearly. Aborted transactions are rerun in the next epoch, which increases their latency and requires additional work.

6 Conclusions

Multi-versioning schemes for transaction processing systems have traditionally been popular because they provide good performance for a range of workloads, including for long-running transactions and contended workloads. With in-memory databases increasingly being used for applications requiring high-throughput transaction processing, several multi-version schemes have been proposed for in-memory databases. However, these schemes have significant costs associated with version search and storage, garbage collection, index management.

This work proposes a novel design for multi-versioning that takes advantage of the predetermined ordering of transactions and known read-write sets in deterministic databases to eliminate version search by efficiently pre-calculating the version location of each read/write operation. Our batching design helps reduce version allocation, garbage collection and indexing overheads as well. Our design is parallelizable and so we explore accelerating transaction processing on GPUs. Our evaluation shows that our multi-versioned, GPU database performs well under both low and high contention workloads and significantly outperforms state-of-the-art systems.

A Artifact Appendix

Abstract

We implement Epic, the first multi-versioned GPU-based deterministic OLTP database. Epic batches transactions into epochs and establishes a serial ordering of transactions within a batch before transaction execution. Epic performs concurrency control initialization for a batch of transactions before execution, avoiding version search and reducing version allocation and garbage collection overheads. Epic runs on the GPU to accelerate concurrency control initialization and parallelize batched transaction execution. In addition, Epic supports larger datasets with a CPU execution model. We evaluate Epic using the TPC-C and YCSB benchmarks and compare it with state-of-the-art systems: STOv2, Caracal, Gacco, and Aria.

Scope

The artifact allows reproduction of the results of the paper, including the performance evaluation of Epic using the TPC-C and YCSB benchmarks, the latency and throughput comparison, and the performance evaluation of Epic with varying abort rates.

All the experiments except the runtime breakdown in Figure 9 can be reproduced using the artifact. The runtime breakdown is created by retrieving the runtime information manually, and we do not have a script to automate this process.

Additionally, the artifact cannot perform the performance evaluation for Aria due to the conflict of dependencies. Therefore, the Aria results in Figure 5 and Figure 7 are not reproducible using the artifact.

Contents

The artifact repository contains the source code of Epic, STOv2, and Caracal as separate submodules. We used our best-effort implementation of Gacco, and the source code is included in the Epic submodule. The repository contains scripts to run the experiments and generate the figures in the paper. The repository also contains scripts to install the necessary dependencies and set up the experiment environment. The README file in the repository provides detailed instructions on how to run the artifact.

Hosting

Our artifact repository is hosted on GitHub at `https://github.com/ShujianQian/epic-artifact/commit/9303f4d2b1fa8368de0dbdc24bcd798585ceb920`.

More details on how to set up the experiment environment, run the experiments, and reproduce the results are provided in the README file in the repository.

Requirements

Our experiments require running on servers equipped with GPUs. We used FluidStack to host on-demand virtual GPU servers. Our artifact repository contains instructions on how to set up the virtual servers and run the experiments.

Alternatively, the experiments can be run on machines with NVIDIA GPUs. The artifact repository is tested for machines with more than 32 CPU cores, 128GB of RAM, and NVIDIA GPUs of compute capability 8.6 and GPU memory of 48GB. The artifact repository contains scripts to install the necessary dependencies and run the experiments.

Burstable Cloud Block Storage with Data Processing Units

Abstract

Cloud block storage (CBS) is a key pillar of public clouds. Today's CBS distinguishes itself from physical counterparts (e.g., SSDs) by offering unique burst capability as well as enhanced throughput, capacity, and availability. We conduct an initial characterization of our CBS product, a globally deployed cloud block storage service at public cloud provider Alibaba Cloud. A key observation is that the storage agent (SA) running on a data processing unit (DPU) which connects user VMs to the backend storage is the major source of performance fluctuation with burst capability provided. In this paper, we propose a hardware-software co-designed I/O scheduling system BurstCBS to address load imbalance and tenant interference at SA. BurstCBS exploits high-performance queue scaling to achieve near-perfect load balancing at line rate. To mitigate tenant interference, we design a novel burstable I/O scheduler that prioritizes resource allocation for base-level usage while supporting bursts. We employ a vectorized I/O cost estimator for comprehensive measurements of the consumed resources of different types of I/Os. Our evaluation shows that BurstCBS reduces average latency by up to 85% and provides up to 5× throughput for base-level tenants under congestion with minimal overhead. We verify the benefits brought by BurstCBS with a database service that internally relies on CBS, and show that up to 83% latency reduction is observed on customer workloads.

1 Introduction

Cloud Block Storage (CBS) is a fundamental storage service on public clouds. It provides virtualized block-level storage volumes that can be dynamically provisioned and attached to compute instances. Beyond what an SSD can already offer, a CBS disk can provide additional benefits, including millions of IOPS, tens of terabytes capacity, higher durability with data replication, and out-of-box encryption support [1–4].

CBS adopts storage disaggregation to achieve better elasticity [5–9]. The disaggregated architecture of CBS empowers public clouds to independently scale storage and compute resources. Block storage volumes can be created, resized, and destroyed on demand without disrupting compute instances. Such agility and flexibility allow enterprises to right-size storage for different workloads in the cloud.

Due to the wide adoption of storage disaggregation, researchers have studied various technical aspects of it, including SSD co-optimization [10–12], kernel improvement [13, 14], kernel bypassing [7, 8, 10–12], storage-oriented network [5–8], performance analysis [15], and applications [16]. The performance of disaggregated storage is rapidly improving with the aforementioned system advances as well as the adoption of faster network/storage devices.

Through our analysis of the operational statistics of our production clusters and characterization of the storage agent (SA) which connects user VMs to the backend storage, we draw three key insights of CBS at Alibaba Cloud.

First, the bottleneck is shifted to compute nodes. Many existing systems target the bottleneck of SSDs [10, 11, 17]. We show that the distributed nature of cloud storage backend design and the over-provisioning tendency of cloud users result in relatively low utilization of storage servers and devices in terms of throughput. These characteristics of CBS have shifted performance bottleneck from the backend to the compute nodes. While backend traffic is well balanced by design and enjoys the benefit of the law of large numbers, compute nodes experience frequent traffic fluctuation due to unpredictable usage patterns of users.

Second, the burst capability of cloud block storage amplifies the chance of congestion. Cloud providers offer on-demand access to extra CPU and storage resources for running instances [18–20]. User VMs are provided with a *base-level* performance and the burst capability allows them to handle temporary traffic *bursts* above the base level. However, it can put a strain on the underlying server and cause performance degradation. When a single VM bursts to an extremely high throughput or multiple VMs on the same server burst concurrently, VMs compete for the limited available resources,

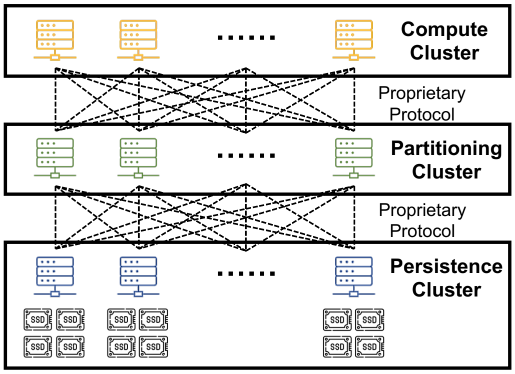

Figure 1: CBS architecture.

which leads to congestion. Moreover, heavy bursting VMs can crowd out other VMs running at a steady state.

Third, lack of resource scheduling at data processing units (DPUs) is the root cause of performance interference. Today, DPUs have become a standard component on compute nodes in the cloud [21–25]. A DPU runs hypervisor and network/storage functions freeing up host CPUs for customer usage. However, handling bursts on a DPU is extremely challenging for SA, as a DPU only possesses limited processing capability. Therefore, SA must strive for high resource utilization and provide performance isolation under congestion.

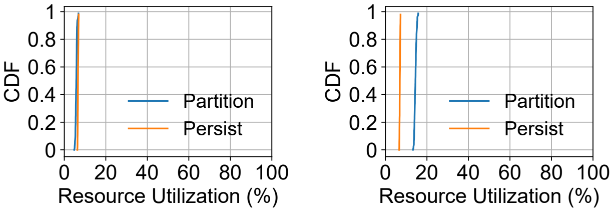
With a brief summary, there are two extra implicit requirements for CBS when supporting burst. (i) *Comprehensive resource utilization:* SA should fully leverage the available processing capacity of the DPU to support higher bursts and avoid congestion in the first place. (ii) *Base-level performance guarantee:* SLOs must not be violated for a tenant who does not exceed its base-level provisioning.

However, the existing SA meets neither of the goals by default. First, SA maps user queues statically to I/O threads running on DPU cores. An I/O thread can become congested while other threads are still idle when a certain user queue starts bursting. Second, an I/O thread serves I/Os in a First-Come-First-Serve (FCFS) manner as long as a VM is within its burst limit. VMs running at a steady state suffer high queuing delay as a result when other VMs are bursting.

In this paper, to overcome load imbalance and tenant interference induced by bursts, we present BurstCBS, a storage I/O scheduling system that leverages the hardware features of our custom xDPU and software characteristics of our SA. The design of BurstCBS offers a number of benefits. First, it equally distributes I/Os to all I/O threads. Second, it allows high bursts, while providing guarantees on base-level performance per VM. Third, it detects different types of bottlenecks on xDPU, avoiding triggering false congestion control. Finally, BurstCBS achieves the above benefits while keeping high resource utilization and minimal scheduling delay.

BurstCBS integrates three key techniques to realize the aforementioned benefits. First, considering the significant overhead introduced by inter-thread messaging, we leverage hardware capability and extensively optimize SA to implement I/O-granularity load balancing at line rate. With limited DPU memory, we design a two-tier memory pool that dynamically adjusts shared and queue-dedicated memory to achieve high I/O performance and memory efficiency. Second, we design a novel burstable I/O scheduler that is aware of the base-level/burst provisioning of each tenant. Rather than achieving high resource utilization with a work-conserving scheduler or guaranteeing strong performance isolation among multiple tenants, it dynamically attempts to provide burst capability to tenants that have excessive demand while monitoring and protecting base-level performance for other tenants in real time. Third, we design a vectorized I/O cost estimator that decouples potential resource bottlenecks that SA may encounter on xDPU. It vectorizes I/O cost and adjusts its estimation with a delay-based approach to allow the scheduling algorithm to react to resource contention effectively.

We implement BurstCBS as a standalone system package running on xDPU, and integrate it into the existing I/O workflow of SA. We conduct a comprehensive evaluation with various types of workloads and show that BurstCBS effectively protects base-level tenants while incurring a negligible overhead. Overall, BurstCBS reduces average latency by up to 85% and achieves up to 5× throughput for base-level tenants under congestion. A database service that internally relies on CBS reports that up to 83% reduction of SQL query average latency is observed with BurstCBS deployed.



(a) IOPS

(b) BPS

Figure 2: CDF of IOPS and BPS (bits per second) utilization in a production cluster. 100% IOPS utilization is defined as the maximum IOPS a node can saturate on a 4KB random I/O workload and 100% BPS utilization is defined as the maximum bandwidth that a node can saturate on a 128KB sequential I/O workload.

2 Background

CBS architecture. Figure 1 shows the three-layer architecture of CBS at Alibaba Cloud. User VMs are hosted in the compute cluster, and all I/Os generated by VMs are forwarded to the partitioning cluster for further processing. The partitioning cluster controls data placement and failover, hiding the complexity from the compute cluster [5, 9]. The persis-

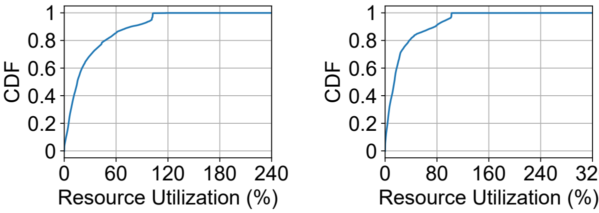
Burst support	✓	✓	✓
Credit-based burst	✓	✓	✓
Paid burst	✗	✓	✓
Max burst IOPS	3k	30k	1000k
Max burst BPS (MB/s)	N/A	1000	4096



(a) IOPS

(b) BPS

Figure 4: CDF of base-level throughput utilization in a production cluster.

tence cluster has tens of SSDs equipped on each node and is responsible for data persistence. Nodes in different layers are fully connected through a proprietary storage-optimized protocol to achieve load balancing at the backend clusters (i.e., partitioning cluster and persistence cluster).

CBS characteristics. A virtualized user disk is divided into multiple segments which are then distributed among all partitioning nodes. A partitioning node again divides each segment into smaller chunks which are evenly stored and replicated among persistence nodes. With this two-layer load-balancing design, storage I/Os are evenly distributed among all partitioning nodes and persistence nodes. An interesting phenomenon in the backend clusters is the asymmetry between IOPS/BPS utilization and disk capacity utilization. Figure 2 shows the distribution of IOPS/BPS per backend node in one of our most active production clusters in a peak hour. Storage accesses are balanced among all backend nodes resulting in low IOPS/BPS utilization on them while 78% disk capacity is utilized.

xDPU. At Alibaba Cloud, we design and build xDPU, an SoC that offloads infrastructure services from CPUs of compute nodes. It consists of its own compute resources (CPU, memory), programmable hardware accelerators (FPGA), network interfaces, and a DMA engine that can directly access guest VM memory over PCIe. The latest version of xDPU integrates eight 2.0GHz cores which are shared among storage, network, and administration functions. There are two 100Gbps network Ethernet ports available for use, and the DMA engine has about the same data movement throughput.

Storage agent. A storage agent (SA) is installed on an xDPU. It abstracts virtualized storage for VMs and connects the backend storage. SA consists of a control plane and a data plane. The SA control plane runs in wimpy cores of xDPU in user space. Among all cores, 2–4 of them are dedicated to SA control threads. The SA datapath logic is burned into FPGA, which moves data with the assistance of the DMA engine. A total of 100Gbps NIC/PCIe bandwidth is made available for SA. In Figure 3, we take NVMe WRITE operation as an example to explain how an I/O is processed by SA on xDPU. When a VM issues an NVMe WRITE command, the command is directly forwarded to FPGA on xDPU. The control threads of SA keep polling FPGA for new I/Os. When a control thread receives a new I/O, it splits the I/O into packets and constructs headers for them. Meanwhile, FPGA fetches the actual data via DMA. Once the header and body are ready, FPGA sends the packet to the backend via fabric.

We adopt an FPGA-CPU cooperative SA design instead of a fully FPGA-offloaded solution for three reasons. First, there is complex branching in I/O splitting and packet encapsulation for cloud block storage, which can hardly utilize the parallelism provided by FPGA. The wimpy CPU cores on xDPU yet have a much higher clock speed than FPGA, which makes CPU cores the right place to handle that part of logic. Second, SA must maintain a significant amount of states including thousands of connections to the distributed backend. The FPGA on xDPU does not have that much memory, while FPGA with more memory does not justify the cost. Third, from an engineering perspective, development and testing of FPGA code require much more effort which prevents us from rolling out new features quickly. We only consider offloading a software feature when it becomes mature enough.

3 Key Observations and Implications

We explain why the partitioning and persistence clusters are not the bottleneck in §2. In this section, we share two observations on the compute nodes of production CBS at Alibaba Cloud and reveal the corresponding challenges of providing predictable performance for cloud block storage.

Observation 1: The Burst capability of CBS makes compute nodes a common bottleneck. Conventionally, cloud providers provision VMs with fixed CPU, memory, and I/O resources to customers. However, a fixed amount of resources can barely match the dynamic workload faced by cloud users.

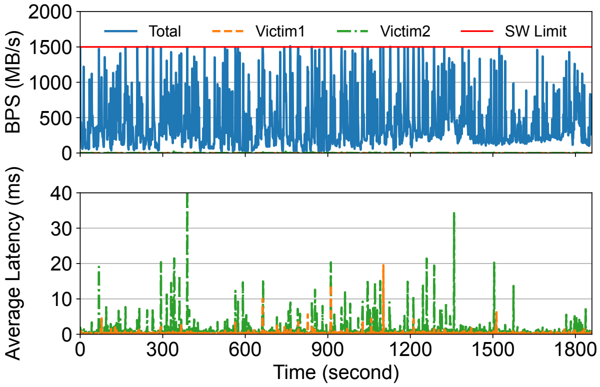


Figure 5: An incident of tenant interference under burst.

To bridge this gap, public clouds provide burstable VMs [26–29] as an option. Essentially, burstable VMs provide a base level of resources with the ability to burst above that when needed. Burstable VMs often come with a credit system. A VM accumulates credits when running below its base-level throughput while spending them to burst when it needs extra resources to saturate its demand.

Making block storage burstable is crucial for delivering burstable VMs because many workloads are bottlenecked on storage I/Os. In Table 1, we compare the burst capability of three widely used public clouds. All three cloud providers support credit-based burst which accumulates tokens for a user that does not use all of its base-level throughput. These tokens allow a user to burst when its desired throughput is beyond its provisioning. CloudB and Alibaba Cloud further allow users to burst on demand and pay for the extra throughput. What makes our case unique is that we allow a disk to burst up to 1 million IOPS and 4GB/s read/write BPS (subject to VM instance types and configurations).

We decide to allow this extreme burst capability for two reasons. First, it is a substantial requirement of our customers, as some of our CBS users have extremely bursty traffic. Figure 4 shows the distribution of base-level throughput utilization per disk in a production cluster. Some disk bursts over 300% of its base-level throughput. Second, fulfilling the burst requirement can further improve the overall resource utilization as well. The majority of our users over-provision their base-level throughput. In Figure 4, over 80% of disks use less than half of their base-level throughput. This is not a unique phenomenon at Alibaba Cloud. There is also previous work that reports the over-provisioning tendency of cloud users [30].

Although credit-based burst is attractive, it raises a strong challenge for us to provide predictable performance. Because users keep accumulating tokens as long as they are below base-level throughput, many VMs may possess tokens and start to burst at the same time. When it happens, every tenant on the impacted compute node observes higher latency and lower throughput due to congestion.

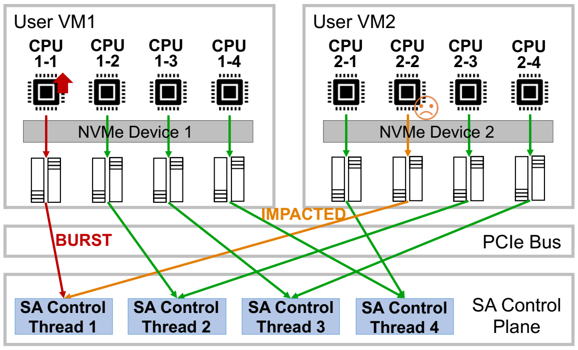

Figure 6: Impact of imbalanced load.

Our existing system addresses this problem by limiting the number of co-located VMs. Under a simplified model, assume a VM has the probability p to burst in a time interval, and we have N VMs on the compute node. We know that VMs will experience performance interference if k out of N VMs burst concurrently. The chance of performance interference is:

$$P(X \geq k) = 1 - \sum_{i=0}^{k-1} \binom{N}{i} (1-p)^{N-i} p^i \tag{1}$$

If we want to limit this probability to a small number, we have to limit the number of VMs that can co-locate on a compute node, which hurts the overall resource utilization. In production, over 95% of the compute nodes have 32 or fewer VMs allocated, which helps us maintain our SLA during 99% of the time. Indeed, although we have made this number small enough, we still observe performance interference occasionally. Figure 5 shows one such incident. During half an hour, multiple tenants were bursting and the software limit on xDPU was frequently triggered resulting in throttling. Although Victim1 and Victim2 ran below their base-level BPS steadily, they both observed many unexpected millisecond-scale average latency spikes during that time.

Observation 2: Inter-thread load imbalance and intra-thread resource contention are the major sources of performance interference on xDPU. In a VM, each vCPU corresponds to a queue pair. These queue pairs are mapped to an SA control thread in a round-robin manner by FPGA on xDPU. However, this mapping cannot adapt to dynamic workload in real time and is prone to cause load imbalance among SA control threads. Figure 6 gives an example. CPU 1-1 of VM 1 and CPU 2-2 of VM 2 are both mapped to SA control thread 1. When CPU 1-1 is creating a burst I/O stream, control thread 1 becomes congested. I/Os from CPU 2-2 experience a high queuing delay even if other control threads are idle. In short, uneven I/O intensity per vCPU created by users and static vCPU to SA control thread mapping through FPGA together lead to inter-thread load imbalance.

Bursting from a single thread in a VM is a common pattern of many I/O intensive applications because they are generally

Table 2: Parallel execution support of popular databases. Non-modifying ops refer to operations that do not change any database records.

	PE support	Enabled by default

SQLite	non-modifying ops	✗
Access	✗	✗

built under the assumption that host CPU is not the bottleneck. In Table 2, we surveyed parallel execution support of the top 10 database management systems in terms of popularity [31]. Relational databases either do not fully support parallel subqueries on multiple CPUs or do not enable parallel execution by default. Redis is also known for its single-threaded design.

Our online experience also confirms this phenomenon. Figure 7 shows the I/O intensity per vCPU for 1000 randomly sampled 4-core VMs in a minute in a production cluster. Over 80% of the total I/Os are from the most I/O-intensive core.

Besides inter-thread load imbalance, intra-thread resource contention is another cause of unexpected performance degradation. Processing an I/O consumes CPU cycles in the SA control plane to construct the packet header and interconnect bandwidth in the SA data plane to transmit the actual data. When there is a resource contention, an I/O has to wait in queues until the resources are available.

We observe there are two typical cases that an I/O stream is impacted as an undesired result. First, a burst tenant with a high I/O parallelism has a significantly better chance of acquiring the resources than a base-level tenant. In Figure 8a, when we increase the I/O parallelism of a burst tenant which creates a mixture of 4KB to 128KB I/Os in the background, serial write I/Os from the base-level tenant are also queued up and average latency increases sharply due to HoL blocking.

Second, various CBS product offerings are available to customers. Through our measurement and analysis, different CBS product offerings differ in their capability on competing SA resources since they have significantly different I/O processing pipelines. For example, in Figure 8b, we start a ProductA disk and let it burst in the background, and no matter how much I/O parallelism we add to the ProductB disk, it cannot reach a similar level of throughput to ProductA.

Summary of implications. Based on our observations, we draw a few important implications for designing BurstCBS:

- The performance bottleneck is generally on compute nodes rather than backend servers and devices.
- The burst capability of cloud block storage that we must support is a main trigger of this bottleneck.

- The root causes are load imbalance among control threads and resource competition within a thread.

4 BurstCBS Overview

BurstCBS is designed and implemented as a standalone system package on xDPU (Figure 9). BurstCBS consists of three key components: high-performance queue scaling, burstable I/O scheduler, and vectorized I/O cost estimator.

High-performance queue scaling (§5.1). We rely on xDPU hardware features to balance I/O distribution among SA control threads. However, it creates an extra challenge for SA control threads to achieve high-performance I/O processing. We propose a two-tier memory pool where BurstCBS moves free buffers between the shared pool and queue-dedicated pools for efficient use of the limited memory.

Burstable I/O scheduler (§5.2). Burst capability with performance isolation requires non-uniform and dynamic resource allocation among multiple co-located tenants. We design a burst-capable I/O scheduler that periodically runs on every SA control thread for resource allocation. It allows each tenant to burst when possible while keeping performance interference among tenants within an acceptable range.

Vectorized I/O cost estimator (§5.3). The key to allocating the right amount of resources to tenants is an accurate estimation of the resource consumption of each I/O. SA manages multiple resources including CPU cycles and interconnect bandwidth. Any of these resources can become the bottleneck under various I/O patterns. We design a vectorized I/O cost estimator that decouples the estimation of each resource.

Figure 10: 1 : 1 binding vs. 1 : N binding.

5 BurstCBS Design

The goal of BurstCBS is to address the two aforementioned issues: (i) lack of load balancing among control threads; (ii) lack of resource scheduling among tenants. In this section, we describe the design choices we make for each system module, as well as the considerations behind them.

5.1 High-Performance Queue Scaling

When we design the queue scaling mechanism among threads, there are two key requirements. First, load balancing must be achieved with low overhead to avoid hurting latency and throughput. Second, the mechanism should provide near-perfect load balancing to avoid further thread synchronization.

Today's DPUs are in the early stages and evolving fast. Unlike NICs supporting Receive Side Scaling (RSS) [32], there are no ASIC-based scaling solutions between host and DPU cores. Instead, DPUs provide programmable hardware on the datapath so that users can implement custom logic. For example, NVIDIA BlueField-3 consists of a set of embedded RISC-V cores named datapath accelerator (DPA) [23], and our xDPU has FPGA as the equivalent. FPGA is capable of performing lookup operations at a very high rate, which resembles a programmable switch that controls packets through match-action tables, making it an attractive candidate for offloading logic such as load balancing and rate control [33].

Evolution of load balancing on xDPU. Due to the limitation of FPGA resources on early versions of xDPU, it does not support load balancing by any means. We first make a compromise on the software side by creating one egress queue for every ingress queue, and equally assign the egress queues to all the SA control threads (Figure 10a). Assuming we have many ingress queues (one ingress queue per vCPU) and the throughput of each ingress queue only varies in a narrow range, we expect to see near-perfect load balancing.

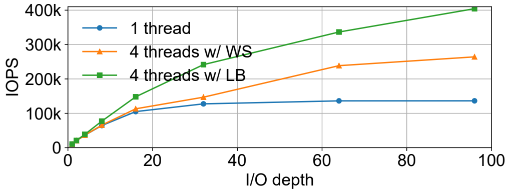

Figure 11: Throughput comparison of different approaches. WS refers to the work stealing prototype, and LB means that each thread receives an equal amount of load.

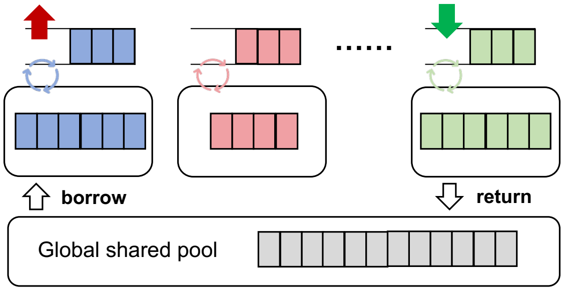

Figure 12: Two-tier memory pool.

This design works relatively well with our non-bursting CBS product types. After we launch burstable disks, we start to observe frequent load imbalance between control threads. Although we can dynamically adjust queue binding, it takes a few seconds to drain inflight I/Os and reconfigure I/O queues, making it impossible to handle transient bursts.

For early versions of xDPU, we have explored two potential software-based approaches to mitigate this issue: (i) designating a thread as a centralized dispatcher [34] and (ii) allowing idle threads to steal I/Os from others [14, 35]. However, both approaches create additional overhead that we cannot bear. They require intensive messaging between threads, which occupies a significant amount of time on wimpy cores. Figure 11 shows a 35% throughput loss if we switch to a work stealing prototype which we develop using DPDK's lockless ring buffer [36] with a reasonable level of batching.

The newest version of xDPU adds support for load balancing by allowing mapping one ingress queue to multiple egress queues (Figure 10b). We leverage this capability to realize queue scaling to multiple threads. Although no system assumptions are broken with multiple egress queues, it significantly changes how we manage DPU memory.

Two-tier memory pool for fast I/O processing. In the early years of SA development, we kept a shared pool of buffers for I/O processing because DPU memory was very limited. When an I/O arrives, I/O metadata which is required for packet header generation is written to a buffer retrieved from the memory pool. When we take the leap to support mil-

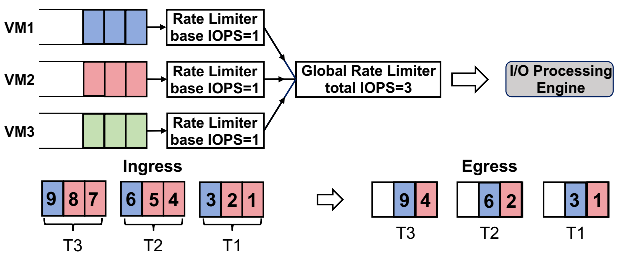

Figure 13: Lack of burst support for BaseCBS.

lions of IOPS per node, we discover that a lot of CPU cycles are wasted on writing disk/queue specific metadata into the buffers. To achieve the best I/O performance (i.e., latency and maximum IOPS), we make a design choice to let each queue maintain its own memory pool, so every memory buffer can be prefilled and will not be overwritten.

Adding extra queues makes each memory pool have even fewer buffers, which means that the number of inflight I/Os a queue can support becomes very limited. Not having enough buffers diminishes the burst maximum we can support for a disk. To remedy this loss, we move to a two-tier memory pool design (Figure 12). Each queue still keeps its own memory pool with a few dedicated buffers, but we add a global shared pool. When a queue experiences increased I/O depth, it acquires extra buffers on demand from the global pool and prefills them with its disk/queue specific metadata. It keeps the extra buffers in its own memory pool and only returns them when the burst terminates. With this design, we avoid slow I/Os caused by repetitive metadata filling to the buffers but keep memory allocation flexible enough.

5.2 Burstable I/O Scheduler

With load imbalance among threads addressed, we next focus on resource scheduling within a thread. There are two essential requirements guiding our design of the scheduler. First, a tenant should be able to use its base-level provisioning (i.e., base-level IOPS and BPS) with bounded latency no matter how other co-located tenants behave. Second, a tenant should be able to burst, but not exceed its burst provisioning. Every tenant should have an equal chance and ability to burst when they share the same burst provisioning and I/O pattern. Note that providing each tenant an equal fraction of the resources is a *non-requirement* for BurstCBS.

Base-level performance guarantee. Achieving base-level performance consists of two implications: (*i*) a tenant can achieve base-level IOPS/BPS with enough I/O parallelism; (*ii*) average read/write latency is bounded for a tenant if it is within its base-level IOPS/BPS. The latency guarantee is particularly important because it also determines the maximum throughput that an application can achieve if synchronous system calls are mostly used. In Figure 8a, we show that the latency of a victim tenant starts increasing dramatically with more parallelism of other tenants on a compute node. The reason is that a large amount of queuing delay is added when a hardware/software bottleneck is hit.

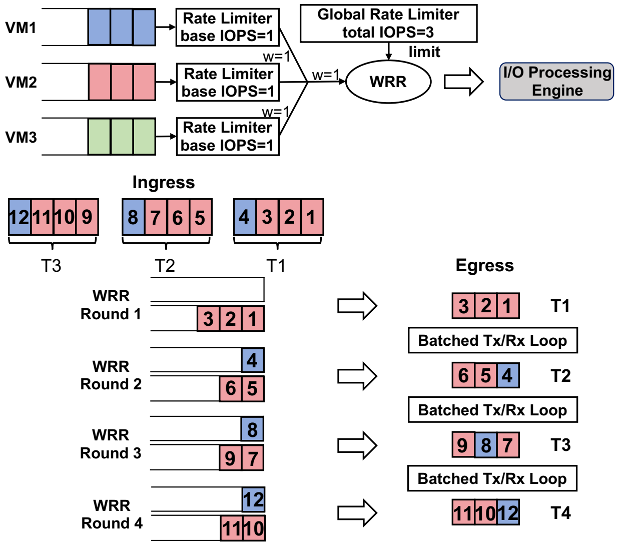

Figure 14: Queuing delay for WildCBS.

These two requirements intuitively translate to a group of rate controllers that limit the admission rate to prevent congestion, which resembles Gimbal [11]. We call this design BaseCBS, which provides performance isolation for base-level performance. There are two major differences between BaseCBS and Gimbal. First, Gimbal strives for black-box SSD congestion avoidance, so it limits the number of in-flight I/Os. On the contrary, we try to avoid congestion on DPU. When an inflight I/O is being processed by the backend servers and devices, it does not consume any resources on DPU. Therefore, BaseCBS limits the I/O admission rate instead. Second, Gimbal enforces strict fair sharing of resources among tenants to achieve absolute fairness while we need each tenant to get a share in proportion to its purchased base-level provisioning as a cloud provider.

Bounded burst support. Although BaseCBS provides a strong base-level performance guarantee, it does not provide burst support because each tenant has a static throughput limit. In Figure 13, even if VM3 is completely idle with no incoming I/O, and admitting an additional I/O will not result in congestion, VM2 is only allowed to process one I/O per window. To this end, BaseCBS is only applied to some of the legacy non-burstable CBS disks.

An easy modification that lets this design work is to assign only part of the total resource Res_{base} to BaseCBS while keeping the rest Res_{burst} in a shared pool for potential bursts. However, this design does not work out for CBS products. On the one hand, this design limits the burst capability we can provide on a compute node to Res_{burst}. On the other hand,

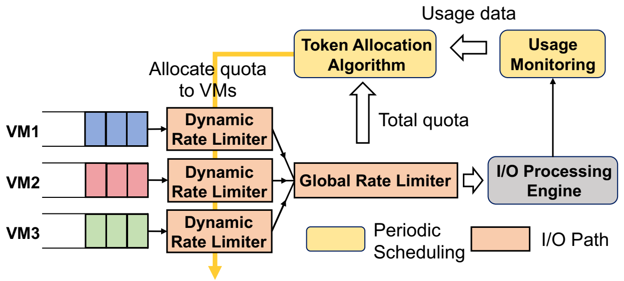

Figure 15: Burstable I/O scheduler workflow.

keeping separate and smaller resource pools directly leads to lower resource utilization, which would force us to provide CBS products at a higher price.

As Figure 4 shows, many of the tenants run way below their base-level IOPS/BPS. An ideal design is to harvest the idle base-level resources to support bursts and return the resources when they are needed. Therefore, bounded burst support essentially requires a work-conserving fair queuing scheduler with a per-tenant rate limiter which enforces provisioning limits (WildCBS). To this end, we use a weighted round-robin (WRR) scheduler, a classic work-conserving fair queuing scheduler that iterates through all ingress queues and processes requests in proportion to their weights.

Figure 14 shows an example of three tenants that are provisioned 1 base IOPS and 3 burst IOPS. 1 base IOPS per tenant is achieved by having a global rate limiter of 3 IOPS and each tenant is weighted equally in WRR scheduling. In this example, VM1 runs at base-level usage, VM2 tries to burst to 3 IOPS, and VM3 is completely idle. Due to the work-conserving nature of WRR, WildCBS is able to fully utilize idle resources from VM3, and the base-level IOPS of VM1 is still guaranteed. WildCBS is integrated into the existing version of SA to enable burst capability in production.

However, a side effect of WildCBS is that a VM that runs at or below base-level usage observes a significantly higher latency while the bursting VM is barely impacted. We observe that if some VMs dispatch I/Os at a much higher rate than others, they can quickly consume all the resource budget, leaving the rest of the VMs to wait until the next window. In Figure 14, VM2 causes all I/Os from a base-level tenant VM1 to delay by a time window. It becomes very common when the bursting VMs employ an extremely high I/O parallelism.

Burstable I/O scheduler. To remedy inadequacies of BaseCBS and WildCBS, we leverage resource usage history to instruct dynamic rate limiting. Figure 15 shows the design of our burstable I/O scheduler (BIOS). BIOS actively collects usage data and allocates resources in proportion to user demands. It provides strong protection on base-level performance by (i) enforcing the total resource allocation limit and (ii) resuming base-level provisioning as soon as it discovers insufficient resource allocation to under-utilizing tenants.

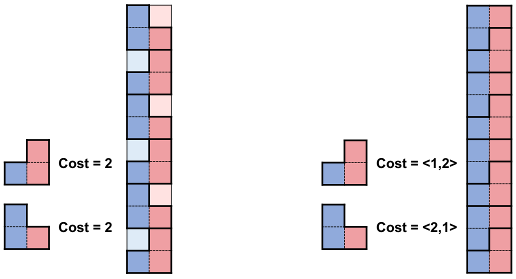
Algorithm 1 BIOS algorithm

```
 1: procedure RUN_SCHEDULING( )
 2:     $unused = total\_alloc - reserved$
 3:     for all tenants $i = 1..n$ do
 4:         if $status_i$ = burst or $throttle_i > 0$ then
 5:             $alloc_i \leftarrow res\_base_i$
 6:         else
 7:             $alloc_i \leftarrow alloc\_hist_i \times \alpha$
 8:         $unused \leftarrow unused - alloc_i$
 9:     for all tenants $i = 1..n$ do
10:         $w_i = \frac{usage_i + throttle_i \times weight\_throttle}{\sum usage_i + \sum throttle_i \times weight\_throttle}$
11:         $alloc_i \leftarrow min(alloc_i + unused \times w_i, res\_burst_i)$
12:         if $alloc_i > res\_base_i$ then
13:             burst_tenants.append(tenant$_i$)
14: function THROTTLE_IO(tenant$_k$, io)
15:     if $alloc_k \geq$cost(io) then
16:         $alloc_k \leftarrow alloc_k -$cost(io)
17:     else
18:         tenant$_b$ ←power_of_two_choices(burst_tenants)
19:         if $alloc_b \geq$cost(io) then
20:             $alloc_b \leftarrow alloc_b -$cost(io)
21:         else if reserved≥cost(io) then
22:             reserved←reserved−cost(io)
23:         else
24:             return true
25:     return false
```

Algorithm 1 depicts how resources are allocated. The algorithm first allocates base-level provisioning to all tenants unless they were below base-level and did not consume all resources in the last window (lines 4-5). Otherwise, the algorithm tries to lower their allocated resources to allow others to burst (line 7). In the second round of allocation, it allocates the remaining resources in proportion to the weighted sum of consumed and throttled I/Os in the last window, but it cannot exceed burst provisioning (lines 10-11). We add a higher weight to throttled I/Os because they may have more follow-up I/Os. The running time of this algorithm only increases linearly with the number of tenants. This is important because (i) there is not enough headroom on wimpy cores for a complex algorithm, and (ii) we may have hundreds of tenants running on the same compute node in extreme cases.

Fast base-level performance recovery. A scheduling algorithm that relies on historical statistics needs to tolerate bad predictions. The consequence of harvesting idle base-level resources is that if a tenant suddenly starts dispatching I/Os after being idle for a long time, it may observe high queuing delay and inadequate IOPS, which breaks our commitment on base-level performance guarantee.

A fast recovery mechanism is added as compensation before the algorithm catches its mis-prediction in the next scheduling cycle. As shown in Algorithm 1 lines 18-20, a base-level tenant that runs out of resources first tries to re-



(a) Scalar cost

(b) Vectorized cost

Figure 16: Scalar cost vs. vectorized cost.

claim the extra resources from bursting tenants. Ideally, we should reclaim resources from the tenant with the most remaining resources, which involves sorting all bursting tenants. However, applying sorting on a per-I/O basis hurts I/O performance significantly. We adopt power of two choices as an alternative to eliminate sorting on the I/O processing path.

This mechanism could fail to take effect if bursting tenants quickly consume all the allocated resources, leaving nothing left for a base-level tenant to reclaim. Therefore, we add another layer of protection of a shared resource pool (Algorithm 1 lines 21-22). The intuition behind this optimization is that, through our online measurements, it is unlikely multiple base-level tenants would resume their usage at the same time. So we reserve a small amount of pooled resources that are just enough for two tenants to resume base-level provisioning. It diminishes a little of burst maximum we can support, but greatly helps us guarantee base-level performance.

5.3 Vectorized I/O Cost Estimator

BIOS is a proper framework for serving a mixture of base-level and burst tenants. A key assumption of BIOS is that consumed resource per I/O is known. However, IOPS and BPS that an SA control thread on DPU can saturate are dynamic subject to hardware specification, software implementation, system configuration, and I/O pattern. To avoid overloading SA, it is necessary to estimate the I/O cost accurately. Previous storage systems focus on I/O cost estimation of SSDs [10, 11, 17]. Because manufacturers of SSDs reveal limited design details of their products, existing work estimates SSD I/O cost by profiling each device with synthetic workloads.

For CBS, the bottlenecks are on xDPU and SA, rather than SSDs. Based on our online measurement, we identify three major bottlenecks in xDPU and SA. (*i*) CPU: it takes a few microseconds to process an I/O on an SA control thread on average, so a control thread can handle a few hundreds of thousands of IOs per second at maximum. (*ii*) Interconnect: SA is able to use 100Gbps NIC bandwidth and ∼100Gbps DMA bandwidth. (*iii*) Software: the read/write bandwidth of SA is also constrained by a software rate limiter which protects other non-storage services from resource starvation.

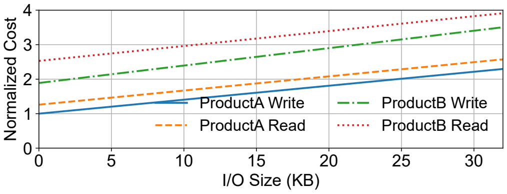


Figure 17: Normalized CPU cost estimation of four I/O types.

Table 3: Effectiveness of estimation adjustment.

	WildCBS	BurstCBS w/o adjustment	BurstCBS with adjustment
Read Lat (us)	1096.89	848.57	248.97
Write Lat (us)	868.79	749.57	270.49

Furthermore, the relative ratios across consumed resources are divergent on a per I/O basis. Our experiments show that a 4KB write I/O consumes 8× higher CPU time per byte compared to a 128KB write I/O, while they always consume the same egress bandwidth per byte. Therefore, the bottlenecks are CPU and egress bandwidth for 4KB and 128KB write I/Os respectively. This result implies that it is necessary to model the cost of different I/O types independently.

If we describe I/O cost as a scalar, it creates resource underutilization. In Figure 16, a scalar cost must be given the value of the most consumed resource, which unnecessarily leaves other resources idle, limiting our ability to burst. In contrast, if we decouple the costs of different resource types, higher resource utilization can be achieved without breaching the latency target. Therefore, we describe the cost of an I/O as a vector of 4 dimensions: *CPU time*, *ingress*, *egress*, and *software limit*. Ingress, egress, and software limits are shared among all threads. We simply divide the global limit by the number of threads to get the per-thread limit. Out of them, only CPU time requires profiling. We derive the CPU time of (product_type, rw, size) tuple from the maximum IOPS it can achieve. We only profile I/O sizes from 4KB to 16KB, because the bottleneck is no longer on CPU beyond 16KB. We fit the observed values into a linear model so that we can estimate CPU time for all sizes. Figure 17 shows the normalized estimation of different I/O types on the newest xDPU. ProductA and ProductB are both burstable CBS product classes. Compared to ProductB, ProductA is further optimized for higher throughput and lower latency by adopting advanced hardware features and optimized software implementation.

Unpredictable misestimation handling. Although vectorized cost estimator accurately reflects I/O cost in common cases, there are many circumstances that we cannot foresee and integrate into our cost model in advance. A typical misestimation happens when SA takes a different path for I/O processing when the FPGA of xDPU experiences transient hardware failures. During uncommon failures, SA enters a

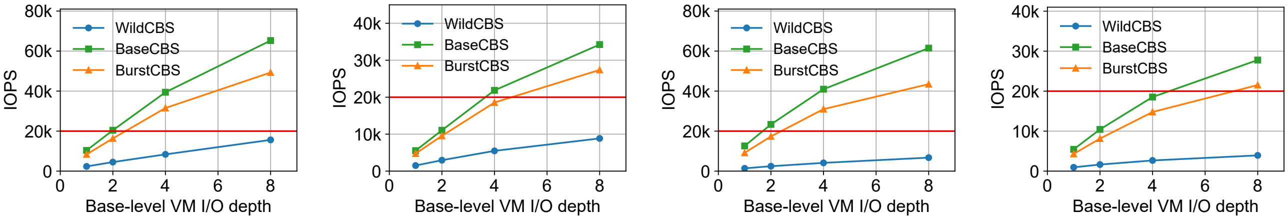
heavy error handling branch which retries failed I/Os multiple times until they reach the configured timeout and generates error logs for further investigation. Doing so at a per I/O basis consumes more CPU resources and bandwidth than a normal code path usually does. Based on our observation, the amortized cost per successful I/O can be doubled when SA experiences such unexpected failures.

To alleviate this impact, we introduce a delay-based cost adjustment mechanism. BurstCBS is anchored to a target delay. When the target delay is breached, we gradually increase the cost. And we reduce the cost when the delay drops below the target. Note that backend time is excluded from this delay. The reason is that SSD is notorious for its high tail latency [37–39], which may wrongly trigger the cost adjustment mechanism. To allow the cost adjustment mechanism to react quickly with only a few data points, irrelevant outliers should be avoided. In Table 3, we show a case that SA keeps detecting FPGA failures. BurstCBS without the cost adjustment mechanism mis-estimates I/O cost and admits more I/Os than its capacity, which results in high latency on the base-level tenant. Adding cost estimation adjustment significantly reduces the latency by admitting the right amount of I/Os.

6 Evaluation

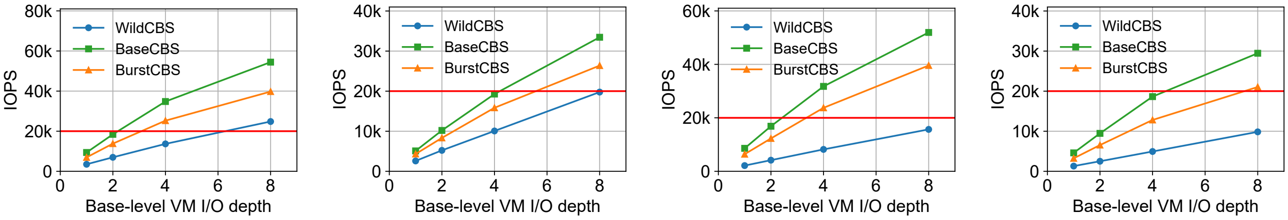
In this section, we evaluate the performance of BurstCBS. Our main baseline is WildCBS which combines WRR scheduling and per-tenant rate limiters. Currently, WildCBS is the most widely deployed version in our production clusters. We also compare BurstCBS with BaseCBS which is a variant of Gimbal and provides strong performance isolation between tenants. All of the experiments are conducted on a compute node with the newest version of xDPU.

Our experiments run two different FIO [40] workloads which we typically use at Alibaba Cloud to make sure our products can adapt to different usage patterns. One is IOPS-intensive and contains a mix of 4KB-16KB I/Os. This workload consists of small I/Os which resembles the I/O pattern of many transactional databases. The other is BPS-intensive



(a) ProductA write (b) ProductA read (c) ProductB write (d) ProductB read

Figure 21: IOPS with a BPS-intensive burst VM (I/O depth=64) in the background.



(a) ProductA write (b) ProductA read (c) ProductB write (d) ProductB read

Figure 22: IOPS with a IOPS-intensive burst VM (I/O depth=128) in the background.

and contains a mix of 4KB-128KB I/Os. Most of the I/Os are within this range in our production environment. We include both ProductA and ProductB I/Os in each workload.

We mainly evaluate three aspects of BurstCBS: thread load balancing with high-performance queue scaling (§6.1), latency (§6.2) and IOPS (§6.3) of base-level tenants with bursting neighbors, and overall resource utilization at burst (§6.4). We also evaluate effectiveness of the fast base-level throughput recovery mechanism (§6.5) and the scalability of BIOS (§6.6). At last, we perform a set of database experiments to evaluate how BurstCBS performs under real use cases (§6.7), and collect results from a node that serves an internal database service (§6.8).

6.1 Inter-thread Load Balancing

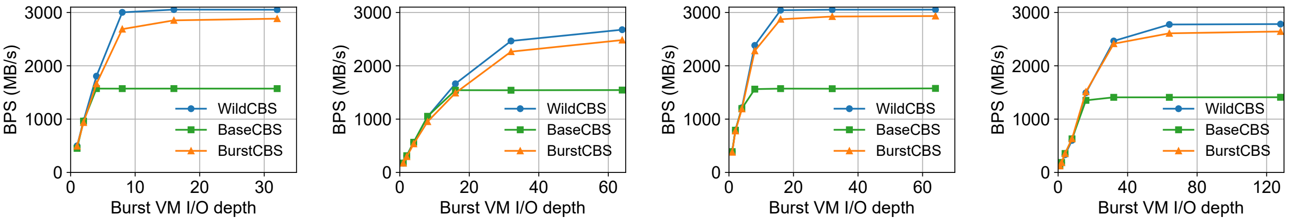
We first evaluate inter-thread load balancing to understand the effectiveness and overhead of FPGA-based load balancing with high-performance queue scaling. Figure 18a shows the maximum write IOPS that a tenant can achieve with one or two SA control threads behind the FPGA load balancer. We observe near-linear scaling on pure 4KB workload and IOPS-intensive workload because the bottleneck is on the SA control threads which run on CPU cores when a large amount of small I/Os are being processed. Scaling on BPS-intensive workload and pure 128KB workload is limited because the NIC is already congested while the SA control threads are not fully occupied. In Figure 18b, we repeat the experiment with I/O depth unchanged and compare average latency, from which we can draw a similar conclusion.

To show how well the load is balanced among multiple threads, in Figure 18c, we compare BurstCBS with the case that a user intentionally dispatches I/Os equally to each ingress queue (by using multiple vCPUs which are mapped to different queues) through FIO. We start six SA control threads in total and take the ratio of maximum to minimum values of throughput across threads to reflect uniformity. The results demonstrate that they are almost equivalent in terms of inter-thread load balancing.

6.2 Base-level Tenant Latency

A main goal of BurstCBS is to keep average latency under SLO for tenants running below their base-level IOPS/BPS. In this experiment, we run an I/O stream with different I/O depths from a background VM. While the background VM is running, we start a 4KB I/O stream of depth 1 on the victim VM and observe its average latency. In Figure 19, we use a read/write BPS-intensive I/O workload in the background VM with I/O depths from 1 to 64, and we record the average latency of four types of I/Os. We evaluate both read and write I/Os from two burstable CBS product classes, ProductA and ProductB. With the current implementation, ProductA is faster than ProductB, and write is faster than read. Overall, average latency is reduced by 68%–85% compared to WildCBS, and is very close to BaseCBS which shows the ideal latency we can possibly achieve with strong isolation.

Figure 20 shows the results on the IOPS-intensive workload in the background. The latency reduction ranges from 40% to 66% which is slightly less than that of the BPS-intensive workload. This difference is because the IOPS-intensive work-



(a) BPS-intensive, ProductA (b) IOPS-intensive, ProductA (c) BPS-intensive, ProductA+B (d) IOPS-intensive, ProductA+B

Figure 23: Overall resource utilization during a burst.

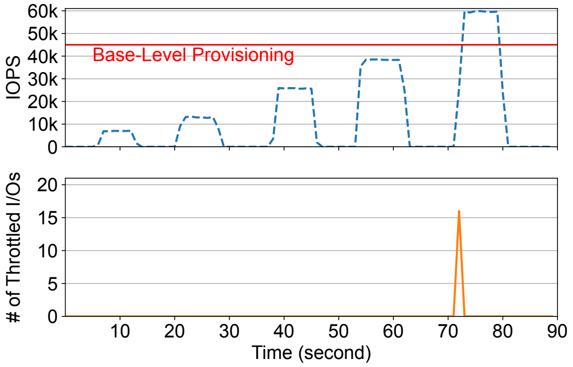


Figure 24: Responsiveness to sudden tenant activation.

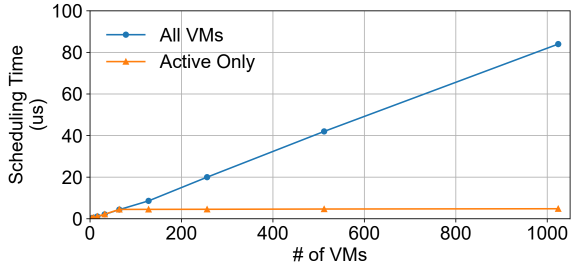

Figure 25: Scheduler scalability with number of VMs.

load shifts bottleneck to the CPU cores. When the CPU cores are congested, the performance gap between BaseCBS and WildCBS is not as significant.

6.3 Base-level Tenant Throughput

Another critical requirement for BurstCBS is that a tenant should be able to reach its base-level IOPS with a relatively small I/O depth. In this experiment, we set the base-level IOPS of the victim VM to 20k, and we expect it to reach that IOPS on a 4KB I/O stream within I/O depth 8. We again validate the effectiveness of BurstCBS on both BPS-intensive workload and IOPS-intensive workload with all four different I/O types. Figure 21 and Figure 22 show that BurstCBS can achieve the desired IOPS for all the cases, while WildCBS at I/O depth 8 fails to meet our goal for seven out of eight cases, and the IOPS is as low as 4,000. Similar to §6.2, there is a smaller performance gap between BaseCBS and WildCBS on the IOPS-intensive workload, which leaves limited space for us to optimize. And ProductB read I/O is the most costly operation out of the four I/O types, so BurstCBS barely reaches 20k IOPS in Figure 22d, which is the lowest.

6.4 Burst Resource Utilization

Although protecting base-level performance is our first priority, we also seek for high resource utilization during bursts. In this experiment, the available bandwidth is limited to 3GB/s, which is the maximum that an SA control thread can handle. We start two VMs and let one VM burst as much as possible while keeping the other VM running at I/O depth 2 which produces an I/O stream below its base-level provisioning. In Figure 23, the results demonstrate that BurstCBS loses about 5%–8% throughput compared to WildCBS, which meets our expectation because we keep 5% of the total resources in the shared pool for fast recovery. BaseCBS enforces fair resource distribution at all times, which limits the resources that the burst VM can use to half of the limit. Note that the maximum bandwidth cannot be achieved with the IOPS-intensive workload due to the extra CPU overhead incurred by small I/Os. And mixing ProductA and ProductB I/Os slightly improves resource utilization because ProductA and ProductB use different polling loops and idle loops waste CPU cycles.

6.5 Responsiveness to Sudden Activation

We next evaluate the fast base-level provisioning recovery mechanism. A tenant should be able to recover its base-level provisioning seamlessly even when the resources are lent to other tenants. In this experiment, we create a VM with base-level provisioning of 45k IOPS. We run I/O streams of depths 1-16 on this VM. Before we run each stream, we let the VM stay idle for a few seconds to make sure that its resource allocation drops to zero. When we run an I/O stream, the metric we record is the number of throttled I/Os. We expect to see no throttled I/Os when an I/O stream is within the base-level provisioning. In Figure 24, we do not observe any

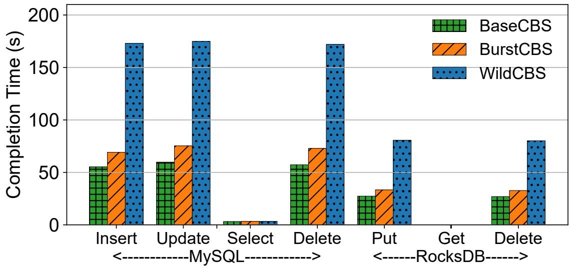

Figure 26: Completion time of 100k DB operations.

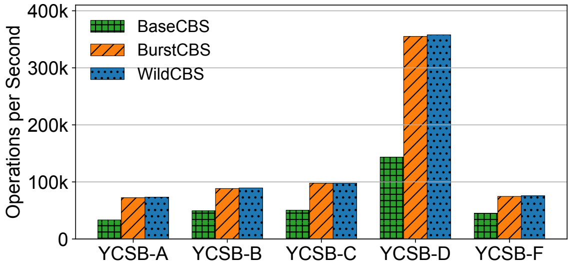

Figure 27: YCSB throughput.

throttled I/Os until we kick off a 60k IOPS stream which already makes the VM a burst tenant.

6.6 Scalability

Scalability of the scheduler is also our concern because if the periodic scheduler runs for too long, successive I/Os will experience high latency and it will also hurt overall throughput by occupying too many CPU cycles. In this experiment, we solely run the scheduler on xDPU and vary the number of VMs from 4 to 1024. 1024 is the theoretical maximum number of VMs on a compute node in any near future. In Figure 25, the scheduling time increases linearly with the number of VMs and is always below 100μs. We introduce an additional optimization that removes a VM from scheduling after it becomes idle for a while. We run the experiment again with 64 active VMs at maximum. It takes less than 5μs to run the scheduler once no matter how many VMs are there in total.

6.7 Application Performance

Transactional databases are one of the targeted use cases of burstable CBS. We evaluate both a SQL database (MySQL [41]) and a NoSQL database (RocksDB [42]) to validate its improvement on real-world use cases. Following our production specification, we provision 16 I/O-burstable VMs with 100k base-level IOPS and 200k burst IOPS on a compute node. The corresponding base-level BPS and burst BPS we provision are 1400MB/s and 2800MB/s respectively. Each VM has 8 vCPUs, 16GB memory, a 40GB ProductB virtual disk as the OS disk, and another 1TB ProductB virtual disk as the database data disk.

We first evaluate the latency of DB operations. For the MySQL experiment, we install MySQL 8.0 on one of the VMs. We develop a simple C program that connects to the MySQL database, executes each type of operation 100k times, and records the execution time. For RocksDB, we write a C++ program and again run put/get/delete 100k times with the sync flag enabled to force an immediate disk I/O per write request. When we execute the programs, we let the other 15 VMs burst by starting a BPS-intensive workload of I/O depth 32 on each of them. In Figure 26, for all write operations (insert, update, put, and delete), we observe about 60% latency reduction. Databases extensively use cache for read operations (select and get). Therefore, we do not observe significant improvement on read operations in this experiment.

We next evaluate the performance improvement brought by burst capability. In this experiment, we focus on YCSB [43] over RocksDB which creates higher throughput than MySQL with the same compute power. We leave the other 15 VMs idle and set up eight RocksDB instances to better leverage burst capability. For each DB instance, we create 10 million 1KB entries and execute 1 million operations. As shown in Figure 27, 2× burst on BurstCBS results in 1.7×-2.5× throughput improvement on various workloads over BaseCBS, and the results are close to those of WildCBS.

6.8 Practical Benefits

We last confirm that BurstCBS improves our database user experience. Here, we deploy BurstCBS to a production compute node that serves the internal Relational Database Service (RDS) and evaluate performance. RDS creates VM instances with CBS disks and manages databases on the VMs for users. A typical RDS VM instance comes with two data disks: one ProductB disk as the main storage, and one ProductA disk as a buffer pool extension. Previously, RDS has noticed neighbor interference and informed us.

In this experiment, an RDS VM instance is started and preloaded with 100 tables of 10 million rows. Another VM is used to connect to the RDS instance through a virtual private network and run single-threaded sysbench [44]. In Figure 28, 8 or 16 burst tenants of I/O depth 32 run in the background. The distribution of I/O sizes and the read/write ratio follow the same pattern in production [7]. The results show that average query latency is reduced by up to 83%. Note that RDS read operations can also trigger disk writes because the ProductA disk is used as a buffer pool extension.

This experiment is also run against a more fluctuant trace for 30 minutes. A 30-minute second-scale monitoring history of a burst disk in production is amplified to the scale of 10GB/s to generate the I/O trace. The trace is replayed in the background, and sysbench is used to record average query latency. In Figure 29, while WildCBS creates latency spikes of 20-50ms, BurstCBS is able to keep it under 10ms.

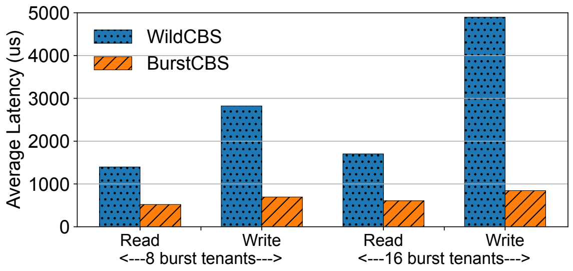

Figure 28: RDS query latency with burst neighbors.

7 Discussion

We discuss a number of future improvements on our roadmap that will further enhance BurstCBS.

Co-optimization with user OS kernel. Rate control at SA requires a significant amount of DPU memory to buffer the requests and may eventually cause out-of-memory. Limiting I/O rate on the user side can mitigate this issue. Furthermore, newer Linux kernel supports NVMe WRR [45], a feature that allows a user to prioritize certain I/Os, which helps protect the performance of critical I/Os when SA is congested.

Automated cost profiling. We currently maintain three different versions of xDPU and many more system configurations in our production environment. It brings a heavy operational burden if we need to manually profile I/O cost every time we make a software/configuration update. Instead, we are developing an automated I/O cost profiler which profiles I/O cost offline at system bootstrap and adjusts cost adaptively online.

Inter-server scheduling. The best way to handle congestion is always to avoid it in the first place. Once we detect multiple co-located VMs often burst at the same time, we can signal the control plane of VM instances to migrate them when possible. Because the time to migrate a VM ranges from a few seconds to several minutes and it causes temporary unavailability, we still rely on BurstCBS to handle short-term congestion.

8 Related Work

Cloud storage systems. There is a large body of work on cloud storage systems [5–9, 16, 17, 46–52]. Despite the different interfaces these systems expose (e.g., block store, object store), most of them are distributed systems to meet the scale of cloud. Existing research mainly focuses on the backend system design. Tectonic [51] and Pangu [52] provide unified backend storage for a large number of tenants and different use cases. To overcome the inefficiency of traditional in-kernel network stacks, RDMA [5, 6, 48] and other kernel bypassing network stacks [7, 8] are deployed. BurstCBS instead focuses on burst capability support of cloud block storage. We reveal and tackle the major challenges to achieve both extreme burst and base-level performance protection.

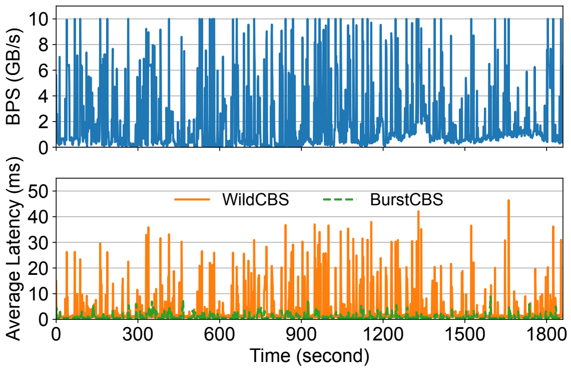

Figure 29: RDS query latency with replayed production background traffic.

Resource sharing for storage systems. Previous work has explored how to achieve work-conserving scheduling and/or fair sharing for storage systems [11,17,53–62]. Many of them also involve estimating per I/O cost for efficient resource scheduling. However, previous work mainly targets the bottleneck of storage media (e.g., HDD and SSD), while the bottleneck we encounter is on DPU. A highly related system is Gimbal [11] which designs a fair queuing scheduler for performance isolation on the server side of disaggregated storage with DPUs. BurstCBS distinguishes itself by supporting dynamic bursts and addressing unique challenges (i.e., load imbalance and cost estimation) on client-side DPUs.

9 Conclusion

This paper presents BurstCBS, a hardware-software co-designed storage I/O scheduling system that achieves inter-thread load balancing and intra-thread resource scheduling. BurstCBS applies three techniques: a high-performance queue scaling mechanism, a burstable I/O scheduler, and a vectorized I/O cost estimator. We implement and evaluate BurstCBS on xDPU-based servers. We show that BurstCBS provides base-level performance protection while allowing tenants to burst as much as possible.

Motor: Enabling Multi-Versioning for Distributed Transactions on Disaggregated Memory

Ming Zhang, Yu Hua*, Zhijun Yang

Abstract

In modern datacenters, memory disaggregation unpacks monolithic servers to build network-connected distributed compute and memory pools to improve resource utilization and deliver high performance. The compute pool leverages distributed transactions to access remote data in the memory pool to provide atomicity and strong consistency. Existing single-versioning designs have been constrained due to limited system concurrency and high logging overheads. Although the multi-versioning design in the conventional monolithic servers is promising to offer high concurrency and reduce logging overheads, which however fails to work in the disaggregated memory. In order to bridge the gap between the multi-versioning design and the disaggregated memory, we propose Motor that holistically redesigns the version structure and transaction protocol to enable **m**ulti-versi**o**ning for fast distributed **t**ransacti**o**n processing on the disagg**r**egated memory. To efficiently organize different versions of data in the memory pool, Motor leverages a new consecutive version tuple (CVT) structure to store the versions together in a continuous manner, which allows the compute pool to obtain the target version in a single network round trip. On top of CVT, Motor leverages a fully one-sided RDMA-based MVCC protocol to support fast distributed transactions with flexible isolation levels. Experimental results demonstrate that Motor improves the throughput by up to 98.1% and reduces the latency by up to 55.8% compared with state-of-the-art systems.

1 Introduction

Memory disaggregation in modern datacenters receives extensive attentions [2, 3, 35, 46, 53, 62]. Specifically, memory disaggregation decouples the compute and memory resources from traditional monolithic servers to build independent and scalable compute and memory pools. These pools are connected via fast network (e.g., RDMA [75] or CXL [7]). A compute pool contains many powerful compute units to run tasks and small DRAM-based memory to maintain metadata. Moreover, a memory pool consists of substantial memory modules to store application data and a small number of weak compute units only for memory allocations and network interconnections [84, 86]. With the aid of efficient resource pooling, memory disaggregation significantly improves the resource utilization, elasticity, and failure isolation [65, 72].

To provide atomicity and strong consistency guarantees for applications on the disaggregated memory, the compute pool leverages distributed transactions to access remote data in the memory pool. A recent design, i.e., FORD [84], is able to run distributed transactions on the disaggregated memory. To simplify the data store in the memory pool, FORD maintains one version of each data. However, this single-versioning design limits the concurrency since the reads need to wait for the writes to become visible during transaction commit. Moreover, to guarantee atomicity, FORD writes many undo logs to back up the old data, which consumes the network bandwidth and decreases throughput.

Enabling multi-versioning is expected to efficiently address the above limitations. By storing multiple versions of each data in the memory pool, the read requests are able to fetch existing versions of data rather than waiting for the writes to complete, thus improving the concurrency. Moreover, with multi-versioning, the old versions of data are retained to provide the atomicity, thus eliminating the need of writing undo logs. Prior multi-versioning based distributed transaction processing systems have been proposed in the traditional monolithic architecture [57, 64, 76]. Unfortunately, these systems are difficult to work on the new disaggregated memory architecture due to two challenges, as presented below.

1) Incompatible Transaction Protocol. Prior systems working on monolithic architecture assume that each server has strong CPUs to execute compute tasks in the transaction protocol, e.g., locking [64], validation [57], and timestamp calculation [76]. In general, a single task is not computationally expensive. However, when the number of requests increases, these tasks become substantial and frequent. The CPU in a memory pool is too weak to frequently poll massive tasks and execute them [45, 46, 66, 69, 75, 84, 86]. Therefore, legacy multi-versioning based transaction protocols are not compatible with the disaggregated memory pool.

2) Inefficient Version Structure. To store different versions of data, existing schemes leverage pointer-based structures to dynamically link the versions, called *linked chains* in this paper. In general, there are two types of the linked chains. (1) The old-to-new chain links the versions from the oldest to the newest version [10,25,38,76], as shown in Fig. 1a. (2) The new-to-old chain links the versions from the newest to the oldest version [9,32,57,64,81], as shown in Fig. 1b. To read a specific version, CPU performs *chain walking* that leverages the pointers to fetch the versions one by one until the target version. In fact, the linked chains work well in monolithic servers, since each server contains enough CPUs to quickly perform chain walking in its local memory. However, the linked chains become inefficient in disaggregated memory, since all the application data are stored in the remote memory pool, which does not contain powerful CPU to execute the chain walking. As a result, the compute pool has to perform the chain walking by consuming multiple network round trips to fetch remote versions one after another until the target version, leading to high overheads. Fig. 1c shows that when increasing the number of steps in the chain walking from 1 to 20, the RDMA read latency significantly increases by 24.8× in our testbed (§ 7.1). Moreover, to prevent long chains, the garbage collection (GC) is required to delete the obsolete versions that are no longer used by any transaction [16]. However, when using linked chains, GC is difficult to carry out on disaggregated memory, since the compute pool needs to frequently track the oldest transaction and reclaim the unused versions. Such tracking consumes many round trips for synchronizations and wastes the compute power.

To address the above challenges, we propose Motor, which holistically redesigns the version structure and transaction protocol to enable **m**ulti-versi**o**ning for distributed **t**ransacti**o**n processing on the disagg**r**egated memory. Instead of using linked chains, Motor leverages a new *consecutive version tuple* (CVT) structure to efficiently organize multiple versions of one data in the memory pool. CVT consecutively stores several versions together to fill in continuous address space. In this way, the compute pool is able to fetch all the versions of the same data by reading a CVT in a single round trip, instead of fetching the remote versions one by one, thus reducing the networking overheads to achieve low latency. When the CVT is filled up, Motor leverages a lightweight coordinator-active garbage collection (GC) scheme that reclaims the old versions in a preemptive manner without tracing transaction states. In the presence of GC, Motor also enables the applications to easily identify the consistency between the data value and its version in CVT to guarantee the correctness.

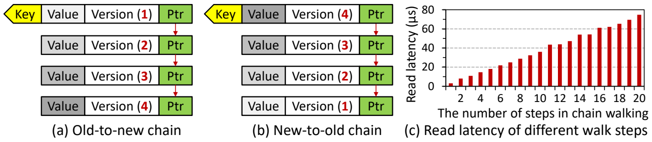

Figure 1: The linked chain based version structures (a, b), and the latency of using RDMA `READ` for chain walking (c).

On top of the CVT structure, Motor designs a fast multi-version concurrency control (MVCC) based transaction protocol. This protocol fully leverages one-sided RDMA to bypass the weak compute units in the memory pool. Our protocol allows the reads not to be blocked by writes, and avoids writing logs, thus improving the concurrency and saving network bandwidth. Moreover, our protocol supports various isolation levels (e.g., serializability and snapshot isolation) to flexibly meet the requirements of different OLTP applications.

In summary, this paper makes the following contributions:

- We propose Motor that enables multi-versioning for distributed transactions on the disaggregated memory.
- Motor designs a new consecutive version tuple (CVT) structure to efficiently organize multiple versions of data in the memory pool. CVT enables the compute pool to obtain the target version in one round trip, and provides lightweight garbage collection without the overhead of tracking (§ 4).
- Motor leverages a fast MVCC transaction protocol that fully exploits one-sided RDMA and CVT to meet the CPU-less memory pool with various isolation-level supports (§ 5).
- We implement[1] Motor and compare it with two state-of-the-art systems [64,84]. The experimental results demonstrate that Motor significantly improves the transaction throughput by up to 98.1% and reduces the latency by up to 55.8%.

2 Background and Motivation

2.1 Memory Disaggregation

Traditional datacenters consist of many monolithic servers, each of which contains a set of compute and memory units. However, this monolithic architecture suffers from low resource utilization and coarse failure domain [65,72]. Specifically, even if a user only needs more *compute* power, we have to add more entire servers in which the *memory* modules are wasted. Moreover, if a CPU is broken, the whole server becomes unusable, which expands the failure domain.

To improve resource utilization and failure isolation, memory disaggregation [20,35,46,50,51] becomes a promising solution, which decouples the compute and memory resources from a monolithic server to build separate resource pools. These pools are connected via fast network, e.g., RDMA [29] or CXL [7]. A compute pool contains many strong CPUs to intensively execute computing tasks. There are small amounts of DRAM in the compute pool to cache some metadata. Moreover, a memory pool consists of substantial memory modules to store the large-volume application data. The memory pool does not contain strong compute capability [46,65,69,72,75], but have some low-power compute units only for memory allocation and network interconnection [84,86]. By efficient resource pooling, datacenters are able to provide appropriate amounts of compute and memory units to meet the requirements of different applications in an on-demand manner, thus

[1] Source code is available at https://github.com/minghust/motor.

improving the resource utilization and reducing costs [48]. Moreover, even if a CPU fails in the compute pool, the decoupled memory modules in the memory pool are not affected due to the separate architecture, thus narrowing the failure domain. Therefore, memory disaggregation is a promising solution for modern datacenters and cloud providers. Without loss of generality, this paper considers that the compute pool leverages one-sided RDMA verbs (including `READ`, `WRITE`, and atomics such as `CAS` an `FAA`) to access the application data in the memory pool to bypass remote CPUs like existing studies [53, 66, 75, 84].

2.2 Transactions on Disaggregated Memory

System Model. To provide atomicity and strong consistency for applications on the disaggregated memory, the compute pool is required to employ distributed transactions to access remote data in the memory pool [84]. Specifically, the CPU threads in a compute pool run many ***coordinators***, which execute a transaction protocol to read data, handle conflicts, and commit updates. The compute pool does not store application data, but contains a small amount of DRAM to buffer some metadata (e.g., remote data addresses). The memory pool stores all the application data without running compute tasks. Each data is replicated into multiple replicas for high availability. In practice, the fail-stop failure [36] could occur at any time to cause the data in the memory pool inaccessible[2] [27]. To tolerate such failures, we adopt the $(f+1)$-way primary-backup replication [42] to generate 1 primary replica and f backup replicas for each data in the memory pool. Each replica can be accessed by multiple coordinators. During transaction processing, coordinators in compute pool read/write remote replicas via network at the byte granularity, and the compute units in memory pool are not involved. Since the coordinators and replicas are fully separated by network, all transactions become distributed in our system model.

Limitations of Single-Versioning. Recently, FORD [84] supports distributed transactions on the disaggregated memory and stores the latest version of each data in the memory pool. This *single-versioning* design simplifies the memory store but incurs two limitations. (1) *Low concurrency.* During transaction commit, the data being updated cannot be read. FORD makes these data invisible until completing the write, thus blocking the read operations; (2) *High logging overheads.* FORD writes the undo logs to all replicas to guarantee atomicity. These undo logs consume the network bandwidth, and the coordinator needs to wait for all ACKs of the logging requests before committing the updates to remote replicas.

2.3 Enabling Multi-Versioning

To address the limitations of single-versioning, we adopt a *multi-versioning* methodology to store multiple versions of each data in the memory pool. By doing so, the writes do not block reads, since the read request obtains an existing version of data, instead of waiting for the update operation, thus improving the concurrency. Moreover, the multi-versioning design does not need to additionally write logs to back up data in replicas, since the old versions naturally act as "undo logs" to guarantee atomicity. In this way, we eliminate the logging overheads to accelerate transaction commit.

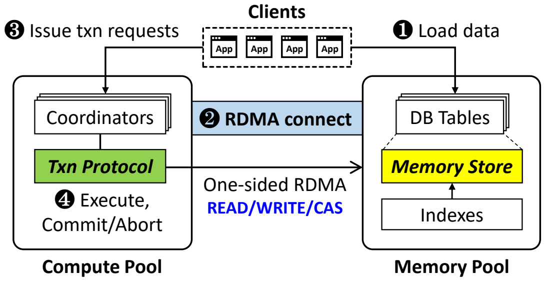

Figure 2: The system overview of Motor.

Challenges. Existing studies have adopted multi-versioning in transaction processing [16, 43, 57, 64, 76]. However, as analyzed in § 1, these studies do not fit the new disaggregated memory architecture due to two reasons. (1) Their transaction protocols target on traditional monolithic servers, which requires powerful CPUs in each server to execute substantial compute tasks [57, 64, 76]. However, in the disaggregated memory architecture, the compute units in the memory pool are too weak to frequently handle compute tasks [75, 84, 86]. (2) The version structures of new-to-old and old-to-new linked chains incur substantial RDMA round trips for chain walking and high overheads for garbage collection.

To address the above challenges, we propose Motor to efficiently enable multi-versioning for fast distributed transaction processing on the disaggregated memory.

3 Motor Overview

Fig. 2 illustrates the system overview of Motor, which contains two parts working in harmony. First, the *Motor memory store* (§ 4) efficiently organizes multiple versions of data in the memory pool. Second, the *Motor transaction protocol* (§ 5) handles multi-versioning based distributed transactions in the compute pool.

Workflow. We outline the workflow of Motor. ❶ The client initially leverages the CPUs in the memory pool to allocate memory to load the application data into relational database (DB) tables. These tables are organized by our consecutive version tuple (CVT) structure, as described in § 4.1. The CVTs can be quickly accessed using indexes, e.g., hash table [86] or B+tree [75]. ❷ We establish RDMA connections between the compute and memory pools. Moreover, the memory pool sends some metadata (e.g., the address of the RDMA memory region and descriptions of indexes) to the compute pool. These metadata help coordinators locate the remote data at runtime. ❸ The clients issue transactions to the compute pool to be executed. ❹ The compute pool uses CPU threads to simultaneously run many coordinators, which leverage our

[2] In line with existing studies [27, 38, 39, 64, 77, 84], we currently do not consider the byzantine failures [37].

transaction protocol to process transactions. In general, the coordinators fetch and lock remote data, and then execute the transaction logic. After execution, the coordinators validate that the data versions are not changed. Finally, the coordinators commit the updates to remote memory pool and unlock data. Our protocol enables coordinators to fully use one-sided RDMA to bypass the weak CPUs in memory pool during transaction processing.

4 Motor Memory Store

4.1 Consecutive Version Tuple

Key Idea. Motor proposes a *consecutive version tuple* (CVT) structure to maintain different versions of data in the memory pool. Unlike the linked chains using pointers to link versions, CVT consecutively stores the versions together to fill in continuous address space. By using CVT, the coordinator is able to fetch multiple versions in a single RDMA `READ`, instead of performing the chain walking to read remote versions one by one until the target version. After fetching the CVT, the coordinator locally searches for the target version, which is fast due to not involving any network I/O.

Structure. Fig. 3 shows the structure of the memory store in the memory pool, which is organized by CVTs. All the CVTs form a CVT region. A CVT consists of a header and several version cells (Vcells). In a header, `TableID` indicates the DB table this record belongs to. A record is a row of user data, containing the key and value, in a DB table. Moreover, `Key` is the unique identifier of this record, and `Lock` is used for concurrency control in transaction processing (§ 5.1). The `AttrBarPtr` points to an attribute bar in the value region. An attribute bar stores the modified attributes of different versions of a record's value, as described in § 4.2. The `VpkgPtr` points to a value package (Vpkg) in value region. A Vpkg contains the actual data value, which is wrapped by a `VpkgSA` and a `VpkgEA` to indicate whether the value is completely written, as explained in § 4.4. Moreover, in a Vcell, the `VcellSA` and `VcellEA` work with the `VpkgSA` and `VpkgEA` to check the consistency between a version and its value (§ 4.4). The `Valid` indicates whether this version of value is available, and the `Version` represents a version number. In addition, the `Bitmap` indicates the modified attributes at the current version, and the `StartOffset` represents the offset of attributes stored in the attribute bar (more details are presented in § 4.2).

Number of Versions in CVT. Motor needs to configure the number of versions (VNum) to hold in CVT. Considering that the memory pool does not contain powerful CPU to dynamically adjust VNum in transaction processing, Motor sets VNum to be fixed, i.e., a record has a fixed maximum number of versions. In fact, it is challenging to determine an efficient VNum due to the tradeoff among read latency, memory footprint, and transaction abort rate. Specifically, if VNum is too small, the CVT size becomes small, which decreases the RDMA transmission payload to decrease the read latency, and also reduces the memory footprint in memory pool. However, due to limited available versions in CVT, the garbage collection (§ 4.3) can be frequently triggered, and this may increase transaction aborts to hamper the throughput when the contention is high. In contrast, if VNum is too large, it helps mitigate transaction aborts, but would waste memory in read-intensive workloads that do not require many versions of data. Moreover, since an entire CVT is read at a time, a large CVT increases the payload to lengthen the RDMA read latency. We explore such tradeoff in § 7.2 and § 7.6, and observe that a suitable VNum significantly depends on the characteristics of workloads (e.g., the access contention and the number of records to read in a transaction). In general, setting VNum to 2 is sufficient for low-contention workloads with short-running transactions (e.g., TATP [1]). For high-contention workloads with long-running transactions (e.g., TPCC [13]), a slightly larger VNum (e.g., 4) efficiently reduces transaction aborts without heavy memory footprint and high read latency.

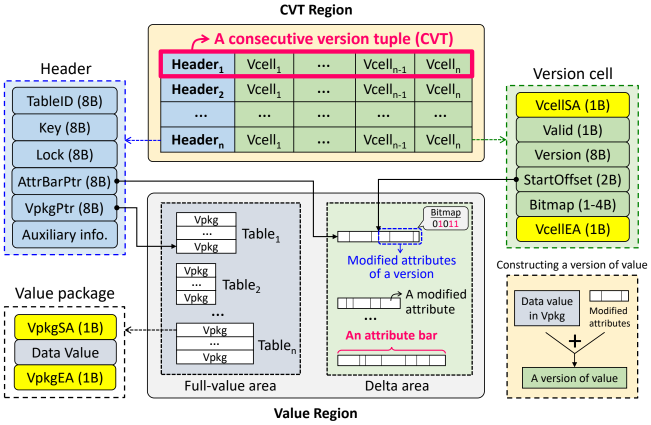

Figure 3: The structure of the Motor memory store, which is organized by CVTs in the disaggregated memory pool.

Indexes Supports. Motor provides unified interfaces for coordinators to quickly access remote CVTs by leveraging indexes (e.g., hash table [86] and B+tree [75]). Motor stores CVTs within the index. For example, when using B+tree indexes, CVTs are stored in leaf nodes, and the internal pointer nodes are cached in compute pool to reduce remote tree traverses. When using hashing indexes, CVTs are stored in hash tables by hashing `Key`s. Therefore, writing CVTs simultaneously modifies the index. Without loss of generality, our paper considers to use the hash table as a case in point to present the details of indexing remote data like existing studies [26, 78, 84]. To address hash collisions, Motor reserves multiple slots in a hash bucket [86]. Each slot stores one CVT. Given a key (e.g., `K0`) of a record, the coordinator hashes `K0` to obtain the ID of hash bucket and calculate the remote address of this bucket. The coordinator then reads the bucket and locally traverses slots to search for the target CVT whose `Key` is equal to `K0`.

CVT Address Cache. In practice, it is expensive to fetch an entire hash bucket each time when reading a CVT. To address this issue, Motor enables each coordinator to leverage a small private *CVT address cache* in the compute pool to store the remote addresses of CVTs. When reading the same CVTs next time, the coordinator can quickly use the cached addresses to directly read the CVTs instead of hash buckets. However, if the `Key` of fetched CVT mismatches the queried key, the cached address becomes stale. The coordinator addresses this issue by re-reading the hash bucket to confirm the existence of the target CVT, and then updates its address cache. To store millions of addresses (each one is 8B), an address cache only consumes several MBs of DRAM space, which is acceptable for the compute pool [65, 84].

4.2 Separate Value Region

Some prior studies like FORD [84] and Silo [71] store the value together with its version, so that coordinators can fetch the value and version in one read. However, this design becomes inefficient in our context, because storing the value together with its version significantly increases the CVT size, leading to high read latency and network bandwidth waste (all values are transmitted but only one is needed). Such drawbacks become even worse when the value size gets larger.

To tackle the above challenge, Motor separates the CVTs from data values in memory pool. The coordinator first reads a CVT to determine the target version, and then reads the corresponding value. In this way, the CVT size is not affected by the value size to achieve stable low read latency, and only one data value is transmitted to mitigate bandwidth wastes.

Reducing Memory Overhead. In the value region, storing a full-sized data value for each version simplifies the data store but wastes memory space. To alleviate the memory overhead, we have two observations. (1) The records in a relational DB table follow the same schema, which defines the number of attributes of the value and the size of each attribute. (2) When updating a record, a transaction can modify only one or several attributes. For example, in TPCC, the value of a record in `DISTRICT` table contains 9 attributes (100B in total), but in `NEW_ORDER` transaction only one attribute is modified, i.e., `D_NEXT_O_ID` (4B). Based on these observations, Motor stores the variable-sized modified attributes, instead of full-sized values, to maintain different versions of values for any record, thus reducing the memory overhead. Fig. 3 shows that the value region contains a full-value area plus a delta area. The full-value area stores the newest version of full-sized values, and the delta area stores old attributes being modified by transactions (like "undo logs"). Therefore, an updated record has only one full value and different versions of variable-sized attributes that are actually modified. To construct an old-version value, we only need to apply the attributes at the old target version into the newest full value.

Attribute Bar. In the delta area, Motor leverages a new structure, called *attribute bar*, to consecutively and compactly store the modified attributes of a record across transactions, as illustrated in Fig. 3. Motor uses the following metadata in CVT to efficiently manage attributes bars.

1) `AttrBarPtr` in Header. When a record is updated for the first time, the coordinator allocates an attribute bar in the delta area, and keeps the remote address of the attribute bar (i.e., `AttrBarPtr`) in the CVT's header.

2) `Bitmap` in Vcell. The coordinator uses a bitmap in Vcell to represent the modified attributes at the current version. For example, if a value has 8 attributes and the 1st, 2nd, and 4th attributes are modified by a transaction, the coordinator writes a bitmap of "00001011" (the rightmost bit represents the first attribute, i.e., the little-endian style) into the Vcell. The length of bitmap depends on the number of attributes.

3) `StartOffset` in Vcell. This is used to represent the offset of a group of modified attributes at the current version inside the attribute bar. The initial `StartOffset` is 0. The coordinator calculates a new `StartOffset` by using the last-written Vcell's `StartOffset` and `Bitmap`. Specifically, according to the positions of "1" in the last-written bitmap, the coordinator accumulates the total size of attributes in the last write, and adds this total size with the last-written `StartOffset` to obtain a new `StartOffset`.

Attribute Bar Size. A coordinator needs to allocate a proper-sized attribute bar to hold modified attributes to alleviate memory wastes. By sampling transaction execution, we observe that for records in a DB table, the total sizes of attributes being updated per transaction (called TotAttrSizes) are different but occur at specific frequencies. For example, in TPCC's `CUSTOMER` table, the TotAttrSize can be 512B, 12B, and 4B, respectively occurring at frequencies of 10%, 88%, and 2% across transactions. This is because in OLTP scenarios, the transaction logic specifies the attributes to update, and different transactions follow the standard execution ratio in the transaction mix [1, 4, 13]. According to the frequencies of different TotAttrSizes, Motor reserves corresponding proportions of space in the attribute bar to hold these attributes of VNum versions (i.e., if some attributes are more frequently updated, Motor reserves more space for these attributes). Hence, Motor approximately estimates the attribute bar size (ABS) = $\sum_{i=1}^{n}(\max(VNum \times Frequency_i, 1) \times TotAttrSize_i)$, where n is the number of TotAttrSizes. For example, when VNum = 4, the ABS of records in `CUSTOMER` table is: 1×512B + 3×12B + 1×4B = 552B, which is sufficient to hold modified attributes of different versions without wasting memory. Note that even if all attributes of a value are modified at some versions (i.e., TotAttrSize = full-value size), the attribute bar can still store all these attributes, since in this case the calculated ABS is guaranteed to be larger than the full-value size.

Mitigating Contentions on Allocating Attribute Bars. When coordinators simultaneously allocate attribute bars, they will compete for the free space in delta area, leading to high contentions. To avoid this, Motor pre-assigns a small MB-scale delta space with proper size (based on ABS) in the delta area to each coordinator. In this way, the coordinator allocates attribute bars in its own delta space without competing with others. The `AttrBarPtr` is globally visible to all coordinators after completing the update operation, so that a coordinator is able to append attributes to the attribute bars created by other coordinators. In rare cases the delta space is exhausted, the coordinator informs remote CPU to allocate larger space.

One RTT for Reading/Writing Values. Though the full value and attributes are separated, Motor consumes only one round-trip time (RTT) to read/write a value at target version. (1) *Read*. A coordinator selects the target version (e.g., $V0$) in a CVT. The selection scheme is presented in § 5.1. If $V0$ is the newest version, the coordinator reads the full value using RDMA `READ` in one RTT. Otherwise, the coordinator calculates remote addresses of the required old attributes by using `AttrBarPtr` in CVT header and `StartOffset` as well as `Bitmap` in the Vcells whose `Version` is larger than $V0$. The coordinator then uses batched RDMA `READ`s to read the full value and old attributes together in one RTT and locally constructs an old version of value. (2) *Write*. The coordinator uses batched RDMA `WRITE`s to update the full value and appends old attributes to the attribute bar together in one RTT.

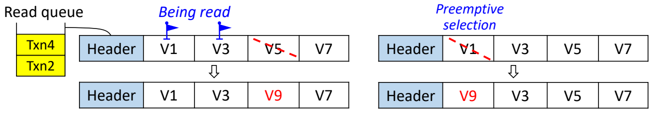
4.3 Coordinator-Active Garbage Collection

If there is no empty Vcell when updating data, we need a garbage collection (GC) mechanism to reclaim the obsolete versions. Legacy GC schemes track the oldest running transactions and delete the versions that are no longer used [16,64]. However, since the compute unit in the memory pool is not aware of transaction states, it is difficult to apply tracking in the memory pool. On the other hand, if the compute pool performs tracking, the coordinators need to confirm which versions are unused among all the in-flight transactions. This increases the network round trips for synchronizations and wastes the compute power.

In order to avoid the overhead of tracking, Motor proposes a *coordinator-active GC* scheme. The idea is that, if there is no empty Vcell, Motor allows the coordinator to actively select a victim version to be overwritten by the new version to complete GC. This scheme is lightweight due to eliminating the need of tracking the oldest running transaction.

To select the victim version, Fig. 4a shows a baseline scheme that skips the versions being read in a CVT, and selects the oldest version in the remaining versions. A read queue is reserved in each CVT to store the timestamps of transactions that are reading the CVT. Other coordinators check the read queue and skip the in-use versions. However, for read operations, since the coordinator does not know the current position of the queue's tail, it has to use RDMA `FetchAndAdd` to atomically move the tail, and then use RDMA `WRITE` to insert a timestamp to the read queue. Such extra RTTs in each read significantly increase the latency.

We observe that the oldest version in CVT has the smallest probability to be used, given that RDMA significantly accelerates transactions [26,78]. Hence, Motor enables coordinators to preemptively select the oldest version in CVT as the victim, as shown in Fig. 4b. This GC scheme avoids the RTT overhead in the baseline method. The tradeoff is that some long-running transactions would be aborted if their previously read data are quickly reclaimed. Nevertheless, the experimental results in § 7.2 show that reserving a proper number of versions in CVT efficiently mitigates such aborts. Overwriting old versions will make the versions in CVT unsorted, but the correctness is not affected, since the coordinator locally traverses all the versions in CVT to locate the target one.



(a) Skipping the versions being read (b) Overwriting the oldest version

Figure 4: Different garbage collection schemes for CVT.

Note that if the attribute bar does not have enough space, the coordinator reclaims old attributes from the start of the attribute bar to write newly modified attributes. In this procedure, the coordinator checks which Vcells correspond to the reclaimed attributes, and sets the `Valid` in these Vcells to 0 to delete these versions. Since Motor appropriately configures the size of attribute bar to store attributes of multiple versions, reclaiming the old attributes does not invalidate many Vcells.

4.4 Anchor-Assisted Read

To obtain a data value, the coordinator reads a CVT to select the target version, and then reads the full value and necessary attributes. As shown in Fig. 5a, coordinator `C1` reads a CVT and needs the value at version $V1$ (Value$_{V1}$). `C1` reads the full value (Value$_{V7}$) and old attributes to reconstruct Value$_{V1}$. At this point, another coordinator `C2` is performing GC to reclaim version $V1$ and write Value$_{V9}$. As a result, there are two incorrect results for `C1`. (1) `C1` reads a corrupted full value due to being partially updated by `C2`. (2) `C1` reads Value$_{V9}$ but mistakenly regards it as Value$_{V7}$, thus reconstructing an incorrect Value$_{V1}$. The root cause of this issue is that the version and data value are separately stored, which prevents coordinators from "atomically" reading a value and its version.

To address the above challenge, Motor proposes an *anchor-assisted read* scheme to help coordinators identify the consistency between the version and value. As shown in Fig. 5b, this scheme uses two anchors at the start and end of a Vcell, called VcellSA (i.e., Vcell's **S**tart **A**nchor) and VcellEA (i.e., Vcell's **E**nd **A**nchor). Similarly, in a Vpkg, two anchors (VpkgSA and VpkgEA) are used to wrap the full value. An anchor is 1 byte. A pair of SA and EA and the content they wrap are implemented in a C++ `struct`, allowing a coordinator to access them together using a single RDMA `READ` or `WRITE`.

To make anchors efficiently work, coordinators follow two rules. (1) *Write*. A coordinator increases the anchor value by 1 for all the four anchors (i.e., VpkgSA, VpkgEA, VcellSA, and VcellEA) to make them **equal**. The coordinator writes the Vpkg first, then the modified attributes, and finally the Vcell. (2) *Read*. A coordinator reads a CVT and then fetches the Vpkg and necessary attributes. Since the full value region stores the newest value, the VpkgSA and VpkgEA are also

(b) Using anchors to detect incorrectness

Figure 5: The anchor-assisted read scheme.

the newest. Hence, the coordinator checks whether the newest VcellSA and VcellEA in CVT are equal to VpkgSA and VpkgEA. If the four anchors are equal, the full value and attributes are not modified since the last read. The coordinator then safely reconstructs the target-version value by copying the fetched old attributes into the newest full value. However, if any of the two anchors are not equal, the coordinator aborts the transaction due to detecting partial updates or a conflicting in-flight GC procedure. In essence, the four anchors assist the coordinator to read a version and the corresponding value in an "atomic" manner. Unlike Silo [71] that reads the version twice to confirm consistency, our scheme only needs to read once and compares the four anchors to identify consistency.

Guaranteeing Write Order. The correctness of the anchor-assisted read scheme is based on that all the written data are installed into the memory pool in the correct order, which has two requirements. **[R1]** Vpkg → modified attributes → Vcell. **[R2]** Inside a Vpkg (or Vcell): start anchor → content → end anchor. In practice, the two requirements are satisfied in network and at remote RDMA NIC (RNIC), because (1) the *reliable connection* mode for one-sided RDMA guarantees that the transmitted messages are not lost or reordered [6], and (2) when the request reaches the remote RNIC, the RNIC ensures that the RDMA `WRITE`s are totally ordered with regard to each other [61], i.e., these write requests are sent to the on-chip integrated memory controller (iMC) in order. However, the two requirements can be then violated due to DDIO (i.e., Data Direct I/O [8]). If DDIO is enabled, iMC sends the written data to the L3 CPU cache. Due to unpredictable cache behavior, the data in L3 cache could be evicted to memory out of order to break **R1** and **R2**. In fact, DDIO aims to improve the cache locality, which benefits the CPU execution in traditional monolithic servers, but becomes useless in the disaggregated memory, since the weak CPU in memory pool is not involved during transaction processing. Hence, Motor disables DDIO in the memory pool, so that iMC directly sends writes from its internal first-come-first-serve write pending queue to the main memory. In this way, the writes are installed into remote memory in the correct order to satisfy **R1** and **R2**.

5 Motor Transaction Protocol

We present the Motor transaction protocol. Our protocol works in a widely-recognized transaction processing framework, which includes reading data, handling conflicts, and writing data back. The main difference from existing studies [27, 39, 64, 77, 78, 84] is that our protocol fully exploits the CVT structure and pure one-sided RDMA to support MVCC based distributed transactions on the disaggregated memory.

Timestamp Generation. Motor leverages sequential numbers as transaction timestamps (i.e., 1, 2, 3 ...), which are also adopted as data versions. In fact, the timestamp generation is orthogonal to our designs. Existing studies propose scalable timestamp generation schemes [24, 38, 64, 76], which can be applied to the compute pool as the timestamp service to assign strictly and monotonically increasing timestamps. Our paper does not focus on optimizing the timestamp generation, and we assume that a scalable timestamp service is efficiently leveraged in the compute pool to serve for all coordinators.

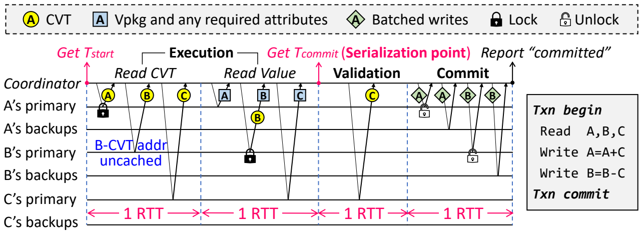
Overview. In the memory pool, each table is replicated to 1 primary and f backups, and the weak CPUs are not involved during transaction processing. In the compute pool, the coordinators leverage our protocol to execute transactions and access remote data through one-sided RDMA.

5.1 Processing Phases

Fig. 6 shows the procedure of handling a read-write transaction (e.g., `T0`) with serializability guarantee. All requests in the same RTT are issued in parallel. The read-write set is {`A`, `B`} and the read-only set is {`C`}. In Motor, the write set is included in the read set, since (1) for *Updates* and *Deletions*, the coordinator reads remote CVTs before writing data back, and (2) for *Insertions*, the coordinator reads remote buckets to obtain empty CVTs before inserting data. The detailed processing phases are presented below.

Phase 1. Execution. The coordinator obtains a start timestamp (T_{start}) from the timestamp service. For each read-only (RO) or read-write (RW) data, the coordinator looks up its local CVT address cache. (1) If the address has been cached (e.g., `A` and `C`), for the RO data (e.g., `C`), the coordinator uses RDMA `READ` to fetch their CVTs from the primaries; for the RW data (e.g., `A`), the coordinator uses doorbell-batched RDMA `CAS+READ` to respectively lock and read the CVTs from the primaries. The locking request prevents other conflicting transactions from modifying the same CVT at the same time. If the locking request fails, the coordinator aborts the transaction, instead of waiting, to avoid deadlocks. (2) If the address is not cached (e.g., `B`), the coordinator uses RDMA `READ` to fetch a hash bucket and then locally search for a `Key`-matched CVT. After obtaining the CVT, the coordinator selects a target version $V0$, which is the largest version among all the versions that are smaller than T_{start}.

Early Abort. If the coordinator observes a version (e.g., $V1$) larger than T_{start} in the CVT, it means that another transaction `T1`, has committed after `T0`'s T_{start}. In this case, the coordinator can *early abort* `T0` to guarantee serializability. The reason is that, even if using T_{start} to select $V0$ for execution, `T0` will be aborted in the next Validation phase, in which `T0` will obtain a larger commit timestamp than `T1`. That is, `T0` with a larger commit timestamp should have used `T1`'s update, i.e., $V1$, for execution, but `T0` used $V0$. Hence, the coordinator early aborts `T0`. Note that the early abort is unnecessary in the snapshot isolation, since it is sufficient for `T0` to read a snapshot at T_{start}, even if the snapshot becomes slightly stale [76].



```
Txn begin
 Read  A,B,C
 Write A=A+C
 Write B=B-C
Txn commit
```

Figure 6: The distributed transaction protocol of Motor.

After version selection, the coordinator uses batched RDMA `READ`s to read the Vpkgs and any required old attributes to construct the target-version value (§ 4.2). Note that for RW data that have not been locked (e.g., `B`), the coordinator additionally batches RDMA `CAS` with `READ`s to lock and re-read their CVTs when reading Vpkgs. After fetching all the data, the coordinator performs three checks for correctness: (1) if any locking fails, `T0` is aborted; (2) if a newer version larger than $V0$ occurs in the re-read CVT, `T0` is aborted, since another transaction has updated this data; (3) if the four anchors are not equal, `T0` is aborted, because the version and value are inconsistent. If passing all checks, the coordinator safely uses the data value inside the Vpkg to execute the transaction logic. Though Motor uses two RTTs to read the CVT and data value, the network payload is significantly reduced due to not transmitting unnecessary data values.

Phase 2. Validation. After all the remote CVTs of the RW data are successfully locked, the coordinator obtains a commit timestamp (T_{commit}) from the timestamp service. Note that if the read-write transaction does not contain any RO data, the following operations can be skipped to reduce latency, since all the RW data have been already locked. However, if the transaction contains RO data, the coordinator needs to validate that the versions of RO data are not changed from T_{start} to T_{commit} to provide serializability. To this end, the coordinator re-reads the CVT of each RO data from remote primaries and uses T_{commit} to select a version V', which is the largest version among all the versions that are smaller than T_{commit}. The coordinator checks whether any of the two cases occur: (1) the CVT is locked by another coordinator, or (2) $V' \neq V0$. In the first case, it is possible that another transaction with a lower T_{commit} is committing a new version. The second case means that another transaction with a lower T_{commit} has committed a new version. If either case occurs, the validation fails, because `T0` with a higher T_{commit} should read the new version but fails to do so in the Execution phase. As a result, `T0` is aborted to ensure serializability. In short, the validation succeeds only if the CVT is not locked and $V' = V0$.

Phase 3. Commit. When the validation succeeds, a coordinator commits the updates to all remote replicas together in a single RTT. The coordinator locally prepares the data to be written, which can be interpreted in three scenarios. **(1) Update.** If the record is updated for the first time, the coordinator allocates an attribute bar in its own pre-assigned delta space. The coordinator then finds an empty Vcell (i.e., `Valid` is 0) in the fetched CVT, sets the `Valid` to 1, fills the `Version` using T_{commit}, sets the `Bitmap` of the updated attributes, calculates the `StartOffset` inside the attribute bar, and configures both of VcellSA and VcellEA to be equal to a new number. If there is no empty Vcell or the `StartOffset` exceeds the length of attribute bar, the coordinator actively performs GC to reclaim old versions. Moreover, the coordinator collects the modified attributes that will be written to the attribute bar. The coordinator then prepares a new Vpkg by filling the new data value, and setting both of VpkgSA and VpkgEA to be equal to VcellSA. **(2) Insert.** Apart from preparing the Vpkg and Vcell like the Update operation, the coordinator prepares a new header and fills the `TableID`, `Key`, and `VpkgPtr`. The `TableID` and `Key` come from applications. The coordinator allocates the `VpkgPtr` in its delta space, i.e., Motor allows the newly inserted data to share the delta area with attribute bars to improve the space efficiency. **(3) Delete.** The coordinator sets the `Valid` of $V0$ to 0, so that subsequent transactions with larger timestamps cannot use the deleted version. The delete operation needs to set the full value in remote memory pool to an old-version value. To this end, the coordinator copies the old attributes fetched in Execution phase into the full value.

After these local preparations, the coordinator leverages doorbell-batched RDMA `WRITE`s to write the prepared data to all replicas and unlocks primaries in one RTT. When receiving *all* ACKs from *all* replicas, the coordinator reports “committed” to the application.

Processing Read-Only Transactions. A coordinator obtains a read timestamp (T_{start}) and reads the required CVTs from the primaries. The coordinator uses T_{start} to determine the target version, and then fetches the Vpkgs and any required old attributes from primaries to construct the value at the target version. If the four anchors are equal, the transaction commits, and otherwise aborts. Note that in single-versioning designs, the read-only transactions require validation [27, 39, 77, 84]. However, with multi-versioning, the read-only transactions do not require validation [57] due to obtaining a stable version snapshot at T_{start} (more details are discussed in § 5.2).

5.2 Flexible Support of Isolation Levels

By using our protocol, Motor supports two widely-used isolation levels, i.e., serializability (SR) [11] and snapshot isolation (SI) [12], to flexibly meet the requirements of different OLTP applications. With SR, the concurrent transactions appear to be executed one by one. Moreover, with SI, the transaction reads data from a snapshot at a time, which does not reflect changes made by other in-flight transactions.

Supporting SR. (1) For ***read-write*** transactions, they are serializable at the point of T_{commit} if guaranteeing that all the target versions selected at T_{start} are equal to those at T_{commit}. This property allows the transactions to be considered as executing at their T_{commit} one after another. Motor ensures this property by using locks and validations. i) If a transaction obtains all the locks of CVTs at T_{start}, the versions of read-write data cannot be changed by other transactions until T_{commit}. Hence, the versions of read-write data at T_{start} are equal to those at T_{commit}. ii) During validation, if a transaction detects that the remote CVT is locked or a new version appears at T_{commit}, the validation fails and the transaction aborts, since the previously fetched versions of read-only data become stale. If the validation succeeds, the versions of read-only data at T_{start} are equal to those at T_{commit}. (2) For ***read-only*** transactions, they do not have a commit timestamp due to not making data changes. In the multi-versioning design, since read-only transactions only observe a snapshot, the start time of read-only transactions can be considered to be "movable" in order to find a serializable execution order [57], i.e., the read-only transactions can be placed among other read-write transactions to make all the transactions appear to execute one by one. In summary, the write-write and read-write conflicts between transactions are respectively addressed by using locks and validations, which ensure that the precedence graphs [5] of all the transaction schedules do not contain cycles, thus guaranteeing serializability [68].

Supporting SI. To support SI, Motor disables the version validation for the read-only data in read-write transactions, i.e., these transactions are allowed to use a stale snapshot by using T_{start}. Note that the locking is still required to resolve the write-write conflicts. SI is weaker than SR, but achieves higher performance (as demonstrated in § 7.7) and has been adopted by multiple popular systems, e.g., MySQL [56], PostgreSQL [60], Oracle [59], and SQL Server [63].

ACID Guarantee. Motor guarantees ACID for transactions. (1) **A**tomicity. Motor maintains multiple versions of data, and the old versions act as "undo logs" to preserve the atomicity. (2) **C**onsistency. The data versions in memory pool are in a consistent state before a transaction starts and after it commits. (3) **I**solation. Motor supports serializability and snapshot isolation. (4) **D**urability. Motor stores $f+1$ replicas of each data against data loss, and can employ UPS-backed DRAM [27] or persistent memory [84] in the memory pool to durably store the committed updates even if a power failure occurs.

5.3 Fault Tolerance

Replica Failures in Memory Pool. By enabling data replication, Motor is able to tolerate replica failures in the memory pool. The replica failures can be quickly detected using RDMA [27]. If any replica fails before commit, the coordinator discards all the fetched data, unlocks remote locks, and aborts the transactions. If a primary fails during commit, Motor promotes a backup as the new primary to retain the committed updates, because the backups have the same updates as primary. The new primary is not visible to coordinators until the updates are installed into alive replicas. When the new primary becomes visible and subsequent coordinators can grab locks on the new primary, the updates of previous transactions have been already committed, thus guaranteeing serializability. Moreover, if a backup fails during commit, the coordinator selects another memory node to add a new backup. Adding a backup requires data migration, in which Motor enables memory nodes to use RDMA `WRITE` to quickly transmit application data. Subsequent transactions involving failed replicas hang up until the replicas are recovered. The $(f+1)$-way replication tolerates at most f replica failures.

Coordinator Failures in Compute Pool. In line with existing studies [27, 78], Motor supports to use leases [31] to detect coordinator failures. Motor enables the coordinators to write small-sized operation logs in local memory to record the operations (e.g., the keys that will be locked or committed) during execution. The operation logs are stored in UPS-backed memory and are not lost [27]. If a coordinator fails, Motor employs a new one to use the operation logs to resume the in-flight commit and unlock keys for recovery. For example, the new coordinator uses RDMA `CAS` to unlock the recorded keys, i.e., if the `CAS` succeeds, the previous lock is released to avoid starvation, and otherwise the key is actually not locked.

Network Failures. A network failure causes the network partition. In practice, it is hard to distinguish network failure from server failure. Like uKharon [34], we assume that the network partitions are discovered and resolved by datacenter administrators. If a network partition occurs, either availability or consistency cannot be fully guaranteed according to the CAP theorem [18, 30]. In the context of OLTP applications, offering consistency is more important to satisfy the ACID requirements. Hence, Motor weakens the availability by only allowing the major partition [17] to serve requests.

6 Implementations

We present some important implementation details including the transaction interfaces and execution framework.

Easy-to-Use Transaction Interfaces. Motor provides the following interfaces for applications to easily run MVCC based distributed transactions on the disaggregated memory.

- `TxnBegin()`: Start a transaction and record its ID.
- `GetTS()`: Get a timestamp from the timestamp service.
- `AddObject()`: Add a read-only (or read-write) object to the read-only (or read-write) set.
- `FetchAll()`: Obtain remote CVTs and target-version data values. The remote CVTs are simultaneously locked.
- `Validate()`: Validate the versions of read-only data.
- `TxnCommit()`: Commit the transaction by writing the updates back to remote replicas and unlocking the primaries.

Execution Framework. In the compute pool, Motor uses the CPU cores to spawn massive threads to execute transactions in parallel. However, if using a thread as a coordinator, the CPU core will become idle when waiting for RDMA ACKs, which decreases the throughput. To saturate the compute power of a CPU core, Motor generates multiple coroutines in a CPU thread to execute in a pipeline manner [39, 77, 84]. In a thread, one coroutine polls the RDMA ACKs, and each of the other coroutines acts as a transaction coordinator. Therefore, Motor enables substantial coordinators to concurrently execute transactions in the compute pool.

7 Performance Evaluation

7.1 Experimental Setup

Testbed. We configure four servers connected through a Mellanox SB7890 100Gbps InfiniBand (IB) Switch. Each server contains a 100Gbps Mellanox ConnectX-5 IB RNIC. One server containing Intel Xeon Gold 6330 CPUs is configured as the compute pool to run coordinators. Other three servers form the memory pool, and each server contains 192GB DRAM.

Benchmarks. We leverage a key-value store (`KVS`) as a microbenchmark. `KVS` stores 10M key-value pairs in one database (DB) table. The key is 8B and the value is 40B [39, 84]. In `KVS`, each transaction performs a read or an update operation to a 48B KV pair with skewed accesses following the Zipfian distribution [23]. We enable the skewness and the ratio of read-write transactions in the transaction mix of `KVS` to be configurable to facilitate comprehensive evaluation. Furthermore, we leverage three widely-used OLTP benchmarks, i.e., `TATP` [1], `SmallBank` [4], and `TPCC` [13], to evaluate the end-to-end transaction throughput and latency. Specifically, `TATP` shows a telecom application, which includes 4 DB tables and 80% of the transactions are read-only. `TATP` contains 2M subscribers and the record size is up to 48B. `SmallBank` models a banking application, which contains 2 DB tables and 85% of transactions are read-write. `SmallBank` has 10M accounts and the record size is 16B. `TPCC` models a complex ordering system, which contains 9 DB tables and 92% of transactions are read-write. `TPCC` contains 24 warehouses and the record size is up to 672B. Moreover, for all benchmarks, each DB table is replicated to three memory nodes to maintain a 3-way replication, i.e., 1 primary and 2 backups.

Comparisons. We compare our Motor with two state-of-the-art systems, i.e., FaRMv2 [64] and FORD [84]. FaRMv2 supports multi-versioning for transactions on monolithic servers, and uses the new-to-old chains to link versions [64]. To make FaRMv2 compatible with disaggregated memory (DM), we use one-sided RDMA to implement its transaction protocol, which is referred to as FaRMv2-DM in the rest of this paper. Moreover, FORD supports single-versioning for transactions on the disaggregated memory, and we run its open-source code. Though FORD leverages persistent memory, its one-sided RDMA designs on transaction protocol are also compatible with DRAM. Note that Motor targets on the disaggregated architecture, which is not comparable with the systems running on the monolithic architecture [39, 57, 76].

Performance Metrics. We report the transaction throughput by counting the number of committed transactions per second. Moreover, we report the 50th and 99th percentile latencies of committed transactions as the transaction latency.

7.2 Number of Versions in CVT

We explore how the number of versions (VNum) in CVT affects the performance of Motor. For each benchmark, we vary VNum from 2 to 15. The ratio of read-write transactions in `KVS` is 80%. Fig. 8 and 9 show that as VNum increases, the transaction throughput generally first increases and then decreases. The reason is that, when VNum gets larger, the abort rate of read-only transactions is reduced to increase the throughput. For example, in `TPCC`, the abort rate of a long-running read-only transaction `STOCK_LEVEL` decreases from 32.1% (VNum = 2) to 3.8% (VNum = 4). However, after reaching the peak transaction throughput, increasing VNum no longer significantly reduces aborts, but the CVT size continues to increase, which enlarges the payload size to increase RDMA read latency, as shown in Fig. 7. The increased read overhead overwhelms the benefit of reducing aborts, thus decreasing the performance. Besides, large VNums also consume more memory space, as presented in § 7.6. Fig. 8 shows that at skewness 0.7, `KVS` reaches the peak throughput earlier than 0.99, since a larger skewness incurs higher access contention and requires more versions to reduce aborts.

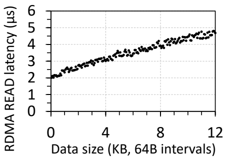


Figure 7: The latency of reading different sizes of data.

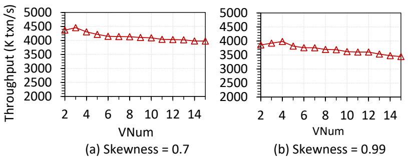
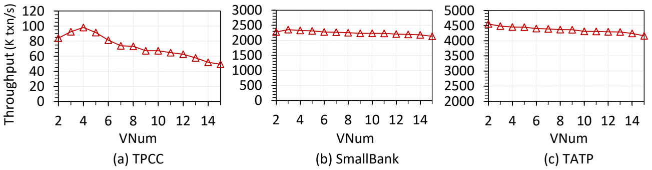


(a) Skewness = 0.7

(b) Skewness = 0.99

Figure 8: The transaction throughput on `KVS` benchmark when varying VNum with skewness 0.7 and 0.99.



(a) TPCC

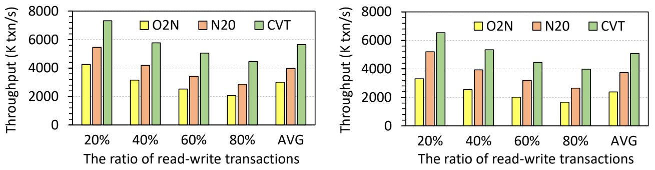
(b) SmallBank

(c) TATP

Figure 9: The transaction throughput on `TPCC`, `SmallBank`, and `TATP` benchmarks when varying VNum.

We observe that, as VNum increases after the peak throughput, the throughput degradation of `TPCC` (up to 49.6%) is heavier than other workloads. This is because one transaction in `TPCC` can access hundreds of records, which is much larger than other benchmarks, e.g., one transaction in `SmallBank` (or `TATP`) only accesses 1–3 (or 1–4) records. Therefore, the overall read overhead (considered as CVT size × number of records) of `TPCC` transactions is more sensitive to VNum, leading to sharper performance decrease. `SmallBank` is write-intensive, but its transactions are short, and maintaining 3 versions reaches the peak performance. `TATP` only requires 2 versions for a record to achieve the peak throughput, since 80% of transactions in `TATP` are read-only and short-running with low contentions. As VNum grows, the high read overhead leads to continuous throughput degradation in `TATP`.

In summary, determining a suitable VNum significantly depends on the characteristics of workloads, including the access contention and the number of accessed records in a transaction. When the contention is low (e.g., `TATP`), setting a small VNum is enough. If the contention is high, more versions are needed to allow higher concurrency, especially for the long-running transactions. We also need to consider



(a) VNum = 3, skewness = 0.7

(b) VNum = 4, skewness = 0.99

Figure 10: The transaction throughput of different version structures on KVS benchmark.

the number of records accessed per transaction to avoid large CVTs incurring high overall read overhead. According to these results, we respectively set the suitable VNum in TPCC, TATP, SmallBank, and KVS to 4, 2, 3, and 4.

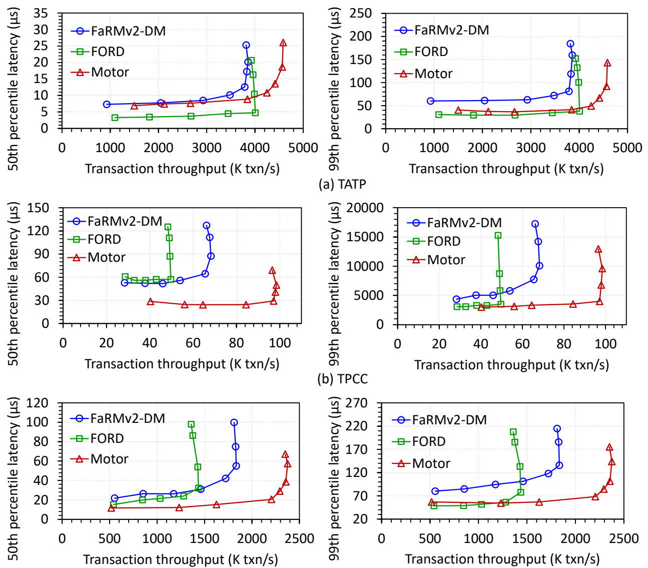
7.3 Performance of Version Structures

We compare the performance of our CVT and traditional linked-chain version structures, i.e., old-to-new (O2N) and new-to-old (N2O), upon the KVS benchmark. We configure the access skewness as 0.7 and 0.99, and vary the ratio of read-write transactions (RW-ratio) from 20% to 80% in the transaction mix of KVS. Based on the results in Fig. 8, we change the maximum number of versions to hold for all structures to 3 for skewness 0.7, and 4 for skewness 0.99.

Fig. 10 shows that CVT respectively improves the throughput by 1.7–2.4× and 1.3–1.6× compared with O2N and N2O. The reason is that, CVT enables the transaction to fetch the target version in a single round trip, while O2N and N2O require multiple round trips for chain walking. When increasing the RW-ratio, the throughputs of three structures decrease, since the write conflicts increase and read-write transactions require more round trips to commit. When the skewness is high (e.g., 0.99) and RW-ratio is low (e.g., 20%), the throughput gap between N2O and CVT becomes small, because the access is more concentrated and many read-only transactions quickly obtain new values from the chain head of N2O. However, such performance gap between O2N and CVT becomes larger at high skewness since the new versions in O2N are placed in the chain tail, which increases the read overhead. Moreover, CVT respectively reduces the 50th (and 99th) percentile latencies by 59.8%/30.8% (and 67.9%/47.7%) on average compared with O2N/N2O at skewness 0.99 due to the same reasons above. We have also examined that when further increasing the maximum number of versions to hold, CVT can deliver more performance benefits over O2N and N2O.

7.4 End-to-End Performance

We leverage TATP, TPCC, and SmallBank to evaluate the end-to-end performance of Motor, FORD, and FaRMv2-DM. All systems guarantee serializability. We configure the maximum number of versions in FaRMv2-DM's version chain to be the same as our CVT for fair comparisons. Fig. 11 illustrates the transaction throughput and latency. To plot a throughput-latency curve, we increase the request load by running 10–40 threads and 2–8 coroutines per thread, i.e., 10–280 concurrent coordinators. Each thread executes 1M transactions following the standard transaction mix of each benchmark [1,4,13].



(a) TATP

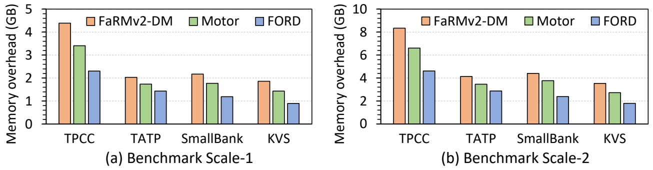
(b) TPCC

(c) SmallBank

Figure 11: The transaction throughput and latency of all the systems on TATP, TPCC, and SmallBank benchmarks.

Compared with FORD, Motor respectively improves the transaction throughput by 14.4% on TATP, 98.1% on TPCC, and 65.4% on SmallBank. FORD adopts the single-versioning design, which limits the throughput, since reads are blocked by writes during commit, and the undo logs consume network bandwidth. Unlike FORD, Motor allows to read existing versions in CVTs, and does not need to write undo logs to remote replicas by maintaining old versions of values. Hence, Motor improves the throughput over FORD. The improvements are higher in TPCC and SmallBank, because (1) they are write-intensive workloads in which Motor avoids many undo logs, and (2) Motor reserves multiple versions to reduces aborts for read-only transactions, especially long-running ones, e.g., STOCK_LEVEL in TPCC. FORD delivers the lowest 50th percentile latency in TATP, since the two transactions, i.e., GET_SUBSCRIBER_DATA and GET_ACCESS_DATA, occupy 70% of the transaction mix, and both of them only read one object. In this case, FORD only uses one RTT to read data, while Motor requires two RTTs to separately read the CVT and data value. However, the 99th percentile latency of Motor on TATP is close to FORD when the transaction becomes complex. Furthermore, Motor reduces the 50th percentile latency by 55.8%/26.2% on TPCC/SmallBank compared with FORD.

Compared with FaRMv2-DM, Motor respectively improves the transaction throughput by 18.9%/44.3%/29.5%, and reduces the 50th (99th) percentile latencies by 8.6% (39.1%) / 52.1% (35.6%) / 43.6% (34.5%), on TATP/TPCC/SmallBank. Motor achieves these improvements due to three reasons. (1) FaRMv2 uses the linked chain to store different versions, which increases network round trips to perform chain walking to obtain the target version. Unlike FaRMv2, Motor uses CVT to fetch the versions together in one round trip. Motor shows the highest improvement over FaRMv2-DM in TPCC, since TPCC requires more versions and the transactions read many



(a) Benchmark Scale-1 (b) Benchmark Scale-2

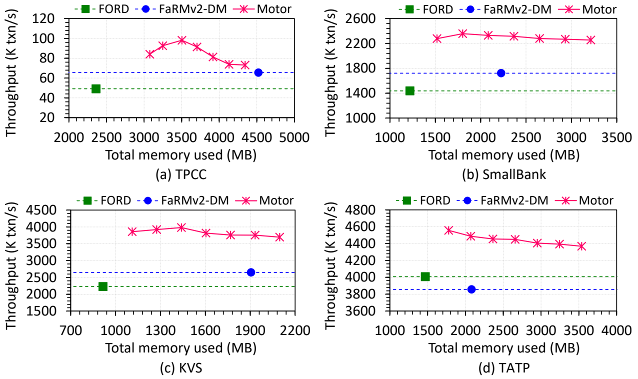
Figure 12: The space consumption in memory pool of all systems at two scales of benchmarks.

records, which exacerbates the chain walking in FaRMv2-DM to cause high overheads. (2) The design of FaRMv2 consumes a dedicated RTT to lock the read-write data, but Motor enables to batch the locking and CVT/value read requests to save RTTs. (3) The design of FaRMv2 uses two RTTs to commit the backups and primaries, while Motor updates all replicas together in one RTT. Moreover, FORD can also achieve lower latency than FaRMv2-DM by alleviating the read overhead, but FaRMv2-DM allows more concurrency in multi-versioning to improve the throughput.

7.5 Memory Overhead

We present the memory overheads of all systems in the memory pool using two different scales of benchmarks. Scale-1 (or Scale-2): TPCC contains 24 (or 48) warehouses; TATP has 2M (or 4M) subscribers; SmallBank has 10M (or 20M) accounts; KVS stores 10M (or 20M) KV pairs with skewness 0.99 and RW-ratio 80%. Scale-1 is the default configuration in § 7.1.

As shown in Fig. 12, FORD exhibits the lowest memory overhead by storing only one version of data. Due to supporting multi-versioning, Motor and FaRMv2-DM consume larger memory space than FORD. Nevertheless, Motor saves memory space in three aspects: (1) maintaining the actually modified attributes rather than full values for different versions; (2) appropriately estimating the size of attribute bar without wasting space; and (3) configuring suitable VNums for different workloads without storing unnecessary versions. For example, Motor supports 4 versions of data in TPCC, but only consumes 1.45×, instead of 4×, of memory space over FORD. Such memory saving is also shown in other benchmarks. In TATP, Motor only incurs 17.3% higher memory overhead than FORD, since only 16% of transactions perform updates and the modified attributes are small. In SmallBank and KVS, Motor respectively consumes 32.7% and 37.7% higher memory space than FORD, since SmallBank and KVS are write-intensive and require more versions than TATP. FaRMv2-DM suffers from 14.6%-22.8% higher memory overhead than Motor due to two reasons. First, FaRMv2 stores a full-sized value for each version, while Motor only stores the modified attributes of values. Second, FaRMv2 requires pointers to link old versions in its version chain, while Motor does not need such pointers since our CVT structure consecutively stores all the versions. Moreover, Fig. 12b shows that when the benchmark scale increases, the gap of space consumption between Motor and FORD generally keeps stable in all benchmarks. This demonstrates that our reduction of memory overhead still works even if the workload scale becomes larger. In summary, Motor trades some extra memory space to achieve better performance than the single-versioning design, while also reducing the memory overhead as much as possible.



(a) TPCC (b) SmallBank (c) KVS (d) TATP

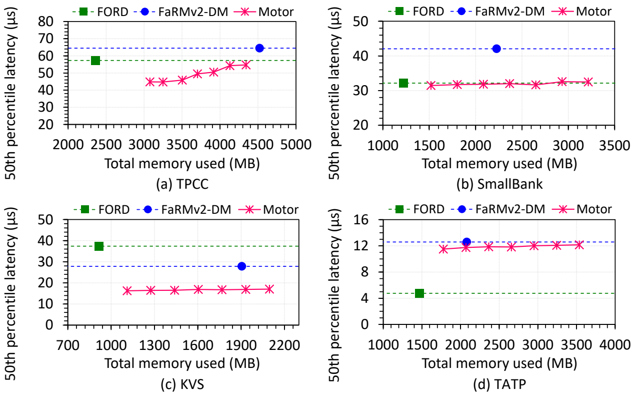
Figure 14: The transaction throughput of Motor when varying the memory footprint by changing ABS.

7.6 Varying Motor Memory Footprint

We study how Motor performs when varying the memory footprint based on the benchmark Scale-1 (§ 7.5). In the memory pool, since the full values always exist to provide complete user data, we vary Motor memory footprint by changing the number of versions (VNum) and the attribute bar size (ABS). As Motor has significantly reduced the memory overhead, the room to further decrease memory footprint is limited. For example, Motor only reserves 2 versions of data in TATP. This is the minimal number of versions for multi-versioning. Hence, in TATP, we increase VNum up to 8 to increase memory footprints. For other benchmarks, since their suitable VNums are larger than 2, we decrease (and increase) VNum from the suitable VNum to 2 (and 8) to vary memory footprints. When changing VNum (2–8), the corresponding ABS is estimated using the formula in § 4.2. Moreover, to vary ABS, we fix VNum to the suitable VNum in each benchmark, and (1) increase ABS to 2–6× of the estimated ABS using the suitable VNum, and (2) decrease ABS to 1× of the sum of different TotAttrSizes per transaction. Fig. 13–16 show the transaction throughput and latency of Motor when varying memory footprints. We also report the performance and memory footprints of FORD and FaRMv2-DM for comparisons.



(a) TPCC

(b) SmallBank

(c) KVS

(d) TATP

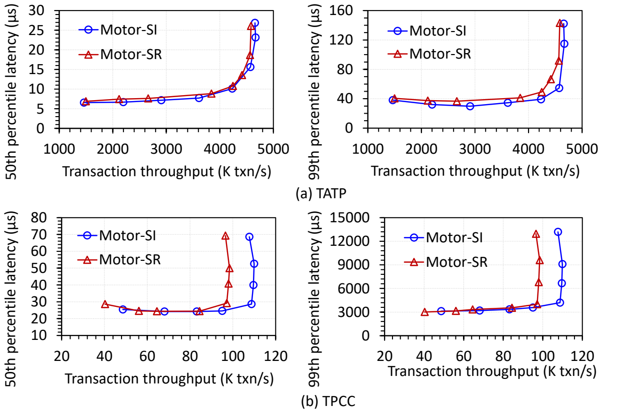
Figure 16: The comparisons of the 99th percentile latency when varying Motor memory footprint by changing VNum.

As shown in Fig. 13, when decreasing VNum from the suitable value, the memory footprints of Motor are reduced by up to 22.8% and are close to FORD on many workloads. Through reducing the memory footprint to contain less versions, Motor still achieves higher throughput than FORD and FaRMv2-DM. The reason is that compared with FORD, (1) Motor reserves more than one version to avoid blocking reads and reduce transaction aborts; (2) Motor does not need to additionally write undo logs and the read-only transactions do not need to validate versions with multi-versioning. Moreover, compared with FaRMv2-DM, (1) our CVT structure avoids chain walking to reduce latency; (2) our MVCC protocol saves RTTs via efficient request batching (§ 7.4). When slightly increasing VNum (e.g., from 4 to 6 in KVS), Motor still consumes less memory than FaRMv2-DM thanks to only storing necessary modifications in the delta area. Hence, compared with FaRMv2-DM, Motor can store more versions using a smaller amount of memory. In fact, when VNum increases from 2 to 8 (4×), the Motor memory footprint only increases by 1.4×/2.1×/2×/1.9× on TPCC/SmallBank/TATP/KVS. Fig. 14 shows that when fixing VNum and reducing ABS from the suitable ABS, the throughput decreases, since a small-sized attribute bar would result in more than one Vcells being invalidated in garbage collection to increase aborts. However, when increasing ABS from the suitable ABS, the throughput generally keeps stable, since the transaction aborts are hardly reduced. This demonstrates the efficiency of our estimation on ABS, i.e., reserving an exact and sufficient size for the attribute bar without wasting memory. Fig. 15 and 16 show that the latency of Motor grows when increasing VNum to enlarge the memory footprint, since large-sized CVTs increase the transmission latency. Nevertheless, Motor still exhibits lower latency than FaRMv2-DM by using the CVT to obtain all versions in a single read. In TATP, FORD achieves the lowest latency due to consuming less RTTs to fetch data, as analyzed in § 7.4. But in other benchmarks, Motor shows lower latency than FORD at suitable VNums due to eliminating the overheads of writing logs for read-write transactions and validating versions for read-only transactions. In summary, these results demonstrate the benefits of Motor over state-of-the-art systems when varying Motor memory footprint.



(a) TATP

(b) TPCC

Figure 17: The transaction throughput and latency on TATP and TPCC benchmarks when using different isolation levels.

7.7 Performance of Different Isolation Levels

Motor supports two isolation levels, i.e., serializability (SR) and snapshot isolation (SI). Fig. 17 show that Motor-SI generally achieves lower latency and higher throughput than Motor-SR on both read-intensive (TATP) and write-intensive (TPCC) workloads by eliminating the validation phase for read-write transactions. Compared with TATP, Motor-SI shows higher throughput improvement in TPCC, since TPCC accesses more read-only data per transaction and features higher read-write contentions, thus allowing more throughput improvement when relaxing the isolation requirement.

7.8 Using PM in Memory Pool

Both DRAM and persistent memory (PM) can be used in a memory pool [69, 86]. We leverage six 128GB Intel Optane PM modules in each memory node to evaluate the performance of Motor on TPCC. We use RDMA READ-after-WRITE to flush the written data from remote RNIC to PM for remote data persistency [84]. Fig. 18 shows that the throughput only decreases by 13.1% on PM due to the limited PM bandwidth [80, 84]. The results demonstrate that Motor efficiently works on both DRAM and PM, thus offering good portability for applications to run on different types of memory devices.

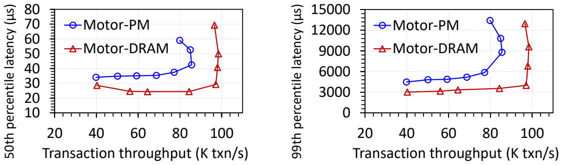


Figure 18: The transaction throughput and latency on TPCC benchmark when using DRAM and PM in the memory pool.

7.9 Fault Tolerance

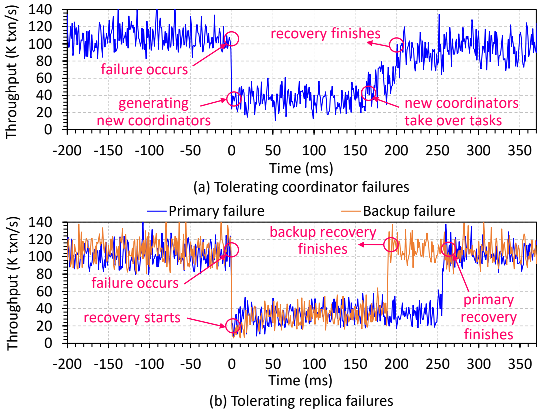
We leverage TPCC to show the resilience of Motor under coordinator failures in compute pool and replica failures in memory pool. We report the instantaneous transaction throughput in 1 ms interval over time (the crash occurs at time 0).

Fig. 19a shows the throughput timeline of recovering coordinators. We run 84 coordinators and 60 of them fail at the same time. Motor then generates 60 new coordinators and establishes network connections, which consumes about 170 ms. Afterwards, the new coordinators take over the remaining tasks. In Motor, each coordinator writes local operation logs to record the operations during execution. These operation logs consume very small space (up to 556B per transaction) and the log space can be reused across transactions. The new coordinators use the operation logs of failed ones to resume in-flight commits and unlock CVTs to avoid starvation. After recovery, Motor regains peak throughput.

Fig. 19b shows the results of recovering replicas. Considering that the CUSTOMER table is frequently used, we respectively allow the primary and one backup of CUSTOMER to fail, i.e., cannot be accessed. A small portion of transactions that do not access the failed replicas are normally executed, and hence the throughput does not become 0. Motor handles the primary failure by promoting a backup as the new primary and adding a backup. Motor tolerates the backup failure by adding a backup. Recovering the primary consumes more time, since Motor needs to change the view of primaries for coordinators, and the new primary is not visible until the updates are committed into alive replicas. Adding a backup requires data migration, during which Motor allows a memory node to use RDMA WRITE to transmit DB tables, CVTs, and attribute bars to another memory node. Write requests to the replicas involved in migration are blocked to guarantee the data consistency among replicas. Since the CUSTOMER table is large, the migration consumes nearly 200 ms. We also examine that if a small DISTRICT table fails, the migration consumes only 1.1 ms. Further optimization on migration is out of our scope. In practice, our ms-scale recovery is acceptable given that prior systems [27, 64, 66] also provide ms-scale recovery.

8 Related Work

Fast Distributed Transactions. Fast distributed transaction processing is a key pillar in distributed systems. Many systems use RDMA to process transactions [22, 26, 27, 39, 41, 58, 64, 77, 78]. Some studies transform a distributed transaction to a local one to reduce the communication overheads [19, 40, 52]. Some protocols on concurrency control [55, 74, 79, 82] and data replication [83] are proposed to improve the performance. The above systems work on the monolithic architecture, while our Motor targets on the disaggregated architecture.



(a) Tolerating coordinator failures

(b) Tolerating replica failures

Figure 19: The Motor's transaction throughput on TPCC over time under (a) coordinator failures and (b) replica failures.

Memory Disaggregation. Memory disaggregation improves the resource utilization. Existing studies explore memory disaggregation in many areas, such as hardware designs [35, 50, 51], operating systems [65], indexes [53, 75, 86], key-value stores [45, 49, 66, 69], networking [29, 67], erasure coding [47, 85], swapping [15, 20, 33, 62], and memory managements [14, 46, 48, 54, 70, 72, 73]. In fact, Motor focuses on transaction processing, which is orthogonal to the above systems. Though FORD [84] supports transactions on disaggregated memory, it adopts single-versioning, which limits the concurrency and incurs high logging overheads. Unlike FORD, Motor enables multi-versioning to address these limitations.

Multi-Versioning Schemes. Multi-versioning schemes have been adopted to support distributed transactions. They focus on high-performance MVCC protocols [28, 43, 57, 64], timestamp generations [38, 76, 81], garbage collections [16, 44], and verifications [21]. These systems are designed for traditional monolithic servers, which do not fit the disaggregated memory. Unlike these studies, our CVT structure and distributed transaction protocol efficiently support multi-versioning on the disaggregated memory.

9 Conclusion

This paper proposes Motor, an efficient distributed transaction processing system for multi-versioning in the context of disaggregated memory. Motor proposes a new consecutive version tuple structure to efficiently organize multiple versions of data in memory pool. On top of this, Motor designs a fully one-sided RDMA-oriented MVCC protocol to accelerate transactions. Extensive experimental results demonstrate that Motor significantly improves the transaction throughput and reduces the latency with moderate memory overhead.

Abstract

Database management systems (DBMSs) are crucial for storing and fetching data. To improve the reliability of such systems, approaches have been proposed to detect logic bugs that cause DBMSs to process data incorrectly. These approaches manipulate queries and check whether the query results produced by DBMSs follow the expectations. However, such *query-level manipulation* cannot handle complex query semantics and thus needs to limit the patterns of generated queries, degrading testing effectiveness.

In this paper, we tackle the problem using a fine-grained methodology—*expression-level manipulation*—which empowers the proposed approach to be applicable to arbitrary queries. To find logic bugs in DBMSs, we design a novel and general approach, *equivalent expression transformation (EET)*. Our core idea is that manipulating expressions of a query in a semantic-preserving manner also preserves the semantics of the entire query and is independent of query patterns. EET validates DBMSs by checking whether the transformed queries still produce the same results as the corresponding original queries. We realize our approach and evaluate it on 5 widely used and extensively tested DBMSs: MySQL, PostgreSQL, SQLite, ClickHouse, and TiDB. In total, EET found 66 unique bugs, 35 of which are logic bugs. We expect the generality and effectiveness of EET to inspire follow-up research and benefit the reliability of many DBMSs.

1 Introduction

Database management systems (DBMSs) are critical systems software and play important roles in modern data-driven applications and provide essential functionalities such as data storage and fetching [8, 12, 39]. Like other large-scale systems, DBMSs involve complicated code logic and various functionalities, and thus bugs are easily introduced during their development and maintenance [1, 13, 15]. One of the most critical kinds of bugs is *logic bugs*—the bugs silently cause DBMSs to produce incorrect query results [25–27]. To detect logic bugs, existing approaches generate SQL queries to test DBMSs and check whether the produced results follow the expectations [11, 25–27, 29, 35]. To do so, they either construct customized queries and validate the rows fetched by these queries [27], or transform the given queries and check whether the execution results of the transformed queries are consistent with the original ones [11, 25, 26, 29, 35].

However, all existing approaches have limited generality as they require the generated queries to follow specific patterns. Their generated queries cannot support SQL features that violate their designed query patterns, as shown in Figure 1. For example, PQS [27] requires that the results of the generated queries can be predicted by its manually implemented interpreter, and thus it is difficult for PQS to support advanced SQL features involving complicated calculations (*e.g.,* window functions). TLP [26] requires that the queries must contain predicates in **`WHERE`** or **`HAVING`** clauses for partitioning, while bug-triggering queries may not contain such clauses. In addition, TLP does not support advanced features like window functions and subqueries. DQE [29] limits its queries to only use common SQL features supported by **`SELECT`**, **`UPDATE`**, and **`DELETE`** statements, while any features (*e.g.*, **`JOIN`** operations and aggregate functions) supported by only one kind of statements are absent. Table 1 provides detailed information on whether existing approaches support specific SQL features. Except for our approach, none of the existing ones can encompass all the listed SQL features. Due to their limited support of general SQL queries, existing approaches miss many logic bugs (*e.g.*, the logic bug triggered by the query shown in Figure 2, which incorporate correlated subqueries and join operations).

The lack of generality in existing approaches is caused by the inherent limitations of their coarse-grained methodology, namely *query-level manipulation*. To construct customized queries or transform existing ones to other related queries, these approaches need to understand the semantics of the manipulated queries to guarantee the results produced by these queries follow their expectations. However, SQL queries are designed to be flexible [34], and can contain abundant and

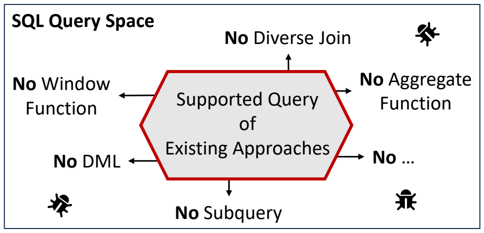

Figure 1: Limitations of existing approaches.

Table 1: Supported SQL features of existing approaches

Approach	Subquery	Join	Window	Group	DML
PQS	○	◐	○	●	○

TLP	○	●	○	●	○
TQS	◐	●	○	●	○
Pinolo	◐	◐	○	○	○
DQE	○	○	○	○	●
EET	●	●	●	●	●

Window: window functions; Group: **GROUP BY** clauses; DML: data manipulation language (*e.g.*, **UPDATE** statements); ◐: TQS [35] and Pinolo [11] support simple but not correlated subqueries. PQS [27] and Pinolo support only parts of join operations.

complex semantics [13, 14, 16, 28, 37] supported by DBMSs. Existing approaches cannot be applied to complex queries because it is difficult to fully understand the complicated semantics contained by such queries (*e.g.*, the queries in Figure 2). Due to these challenges, existing approaches have to limit the patterns of their generated queries to constrain the query semantics. Therefore, these approaches cannot utilize general queries that fall outside their expected query patterns.

To address the inherent limitations of existing approaches, we propose to approach the logic-bug-detection problem using a new and fine-grained methodology—*expression-level manipulation*. Expressions are the essential units of SQL queries. They can be functions, operations, column variables, constant values, or subqueries, *etc*. By manipulating expressions, we can focus on the fine-grained semantics of queries, *i.e.*, expression semantics, and correspondingly manipulate queries without the need to understand their overall query-level semantics. For example, we can easily construct a new query for oracle checking by manipulating the expressions `t2.c2` and `t2.c3` of the original query in Figure 2, even though the query is complex. In this way, we do not need to limit query patterns to ones with simple semantics.

Based on this fine-grained methodology, we propose a novel and general approach, *equivalent expression transformation (EET)*, which applies to arbitrary queries and can effectively find logic bugs in DBMSs. Given an arbitrary query, EET traverses its abstract syntax tree (AST) to iterate over the expressions used in this query. For each expression, EET transforms it to another semantically equivalent one based on logical equivalences [5, 19] and SQL branch structures [34]. In the end, EET compares the execution results of the transformed query (*i.e.*, the query whose expressions have been transformed) and the original query, and any observed discrepancy indicates a logic bug. For example, EET transforms expressions `t2.c2` and `t2.c3` of the original query in Figure 2 into two semantically equivalent **CASE WHEN** expressions of the transformed query, and validate the tested DBMS by checking whether the results of these two queries are identical. The key intuition of what makes this approach effective is that the transformed expressions can lead DBMSs to exercise different code logic for the manipulated queries. Such different query executions cross-check each other as they are expected to produce the same results.

```
--- Statements for database generation
CREATE TABLE t0 (c0 TEXT);
CREATE TABLE t1 (c0 TEXT);
CREATE TABLE t2 (c0 INT4, c1 INT4, c2 TEXT,
                 c3 TEXT, c4 TEXT, c5 TEXT);
INSERT INTO t0 values ('');
INSERT INTO t1 values ('');
INSERT INTO t2 values (1, 2, 'a', 'a', 'a', 'a'),
                      (0, 1, '', '', 'a', 'L');

--- Original query , result set: 0 ✓
SELECT t2.c0 FROM t2
WHERE (t2.c1 >= t2.c0) <> (t2.c5 = (
   SELECT t2.c4 AS c_0
   FROM (t1 AS ref_0 INNER JOIN t0 AS ref_1
      ON (ref_0.c0 = ref_1.c0))
   WHERE t2.c3 = t2.c2
   ORDER BY c_0 DESC LIMIT 1));

--- Transformed query , result set: empty
SELECT t2.c0 FROM t2
WHERE (t2.c1 >= t2.c0) <> (t2.c5 = (
   SELECT t2.c4 AS c_0
   FROM (t1 AS ref_0 INNER JOIN t0 AS ref_1
      ON (ref_0.c0 = ref_1.c0))
   WHERE (CASE WHEN (((ref_0.c0 LIKE 'z~%')
             AND (NOT (ref_0.c0 LIKE 'z~%')))
             AND ((ref_0.c0 LIKE 'z~%') IS NOT NULL))
          THEN t2.c3 ELSE t2.c3 END) =
      (CASE WHEN (((ref_1.c0 NOT LIKE '_%%')
          AND (NOT (ref_1.c0 NOT LIKE '_%%')))
          AND ((ref_1.c0 NOT LIKE '_%%') IS NOT NULL))
      THEN t2.c4 ELSE t2.c2 END)
   ORDER BY c_0 DESC LIMIT 1));
```

Figure 2: Queries exposing an ancient logic bug (20 years old) in PostgreSQL.

We implemented our approach as a practical DBMS testing tool and evaluate it on 5 widely-used and extensively-tested DBMSs, MySQL [20], SQLite [32], PostgreSQL [24], ClickHouse [3], and TiDB [36]. In total, EET found 66 unique bugs, including 16 in MySQL, 10 in SQLite, 9 in PostgreSQL, 21 in ClickHouse, and 10 in TiDB. Among these bugs, 65 are confirmed and 37 are fixed. 35 bugs are logic bugs, and many are long latent. These results demonstrate the effectiveness of EET in finding logic bugs in DBMSs.

Overall, we make the following contributions:

- We propose a fine-grained methodology, *expression-level manipulation*, which can operate on arbitrary queries without limiting query patterns.
- We propose a novel and general approach, *equivalent expression transformation (EET)*, which can effectively find logic bugs in DBMSs using transformation rules based on logical equivalences and SQL branch structures.
- We implement the approach as an automatic DBMS testing tool and evaluate it on 5 widely used DBMSs. In total, we found 66 bugs, 35 of which are logic bugs. To further facilitate research on DBMS testing, we open-source the tool at `https://github.com/JZuming/EET`.

2 Motivation

In this section, we illustrate queries that trigger an ancient logic bug, analyze the limitations of existing approaches, and present our solution based on a fine-grained methodology.

2.1 Illustrative Example

Figure 2 shows the queries that trigger a very ancient logic bug caused by incorrect hash-join mechanisms. The bug existed for 20 years in PostgreSQL until EET found it. The bug-triggering queries consist of three parts. The first part contains several statements (*e.g.*, **`CREATE`** and **`INSERT`**) for setting up a database for later querying. The second part is a randomly generated query, termed as *original query*, and the third part is the query transformed from the original query by our approach, term as *transformed query*. The expressions `t2.c3` and `t2.c2` in the original query are transformed into two semantically equivalent **`CASE WHEN`** expressions in the transformed query. The transformed query preserves the semantics of the original query, and thus these two queries should produce the same results. However, their results differed, indicating a logic bug had been triggered.

The bug-triggering queries have been minimized but are still very complex. Specifically, the transformed query contains a subquery in its **`WHERE`** clause. The subquery is a correlated subquery that references value (*i.e.*, the columns of table `t2`) from the outer query. The subquery uses **`INNER JOIN`** tables in its **`FROM`** clause and uses **`ORDER BY`** and **`LIMIT`** to constrain its returned value. PostgreSQL is expected to return a row `{0}` for the transformed query. However, it returns an empty set because the predicate inside the subquery triggers a logic bug. The detailed root cause is discussed in Section 5.3.

2.2 Limitations of Existing Approaches

Several approaches have been proposed to detect logic bugs in DBMSs [11,25–27,29,35]. PQS [27] synthesizes a query in a way that the query is expected to fetch a specific row. If the row is not fetched, a logic bug is triggered. TLP [26] partitions a given query into three separated queries by decomposing the predicate in the **`WHERE`** or **`HAVING`** clause. The union of the results of these three queries should be consistent with the original one, otherwise, a logic bug is found. Pinolo [11] manipulates the query predicate in its **`WHERE`** clause to construct a new query whose results are the superset or subset of the results of the original query.

All these approaches are trapped in *query-level manipulation*, which is a coarse-grained methodology for logic-bug detection in DBMSs. To guarantee the correct manipulation, this methodology inherently requires the approaches to understand the semantics of the manipulated queries. For example, PQS needs to interpret its synthesized queries to predict their expected results. However, SQL is a flexible query language, providing various features (*e.g.*, subquery, join) to manipulate data [34]. Under specific demands, SQL queries (*e.g.*, analytical queries) can be very complex [16,28,37]. In these cases, query-level manipulation cannot work effectively because it cannot handle the complicated semantics of these queries.

For the example query in Figure 2, PQS cannot infer its expected fetched row because it cannot predict the results of the complex predicates involving correlated subquery with join tables. TLP cannot partition the predicates inside the subqueries, because predicate effects propagating from subqueries to the outer query are implicit and complicated. Partitioning predicates in subqueries cannot guarantee the consistency between the results of its unioned queries and its original query. Similarly, Pinolo cannot guarantee the superset or subset relationships between the manipulated queries because the logical effects inside the subqueries are difficult to predict.

To avoid such inapplicable cases from happening in their generated queries, existing approaches limit the query patterns to constrain the semantics of their generated query. As a result, many important SQL features cannot be supported by existing approaches, as shown in Table 1. For example, PQS and Pinolo support only parts of join operations, and none of the existing approaches supports correlated subqueries, because their semantics are complex. Therefore, these approaches miss many logic bugs that are not covered by their limited query patterns, such as the 20-year-old logic bug of PostgreSQL in Figure 2.

2.3 Our Solution

To propose a general approach that is applicable to arbitrary queries, we need to tackle the logic-bug-detection problem using a new methodology instead of query-level manipulation. In this paper, we propose a fine-grained methodology—

expression-level manipulation, which shifts our focus from the semantics of a whole query to the semantics of a single expression of the query, empowering the potential and flexibility of manipulation. We can manipulate queries by processing their fine-grained elements, expressions, without the necessity to analyze the semantics of the whole query, and thus do not need to limit the query patterns to simplify query semantics.

Based on this methodology, we propose *equivalent expression transformation (EET)*, which is applicable to arbitrary queries to find logic bugs in DBMSs. Given a SQL query, EET iterates all expressions of the query and transforms them into semantically equivalent expressions. EET validates the DBMSs by checking whether the query with transformed expressions produces the same results as the original query. In this paper, we use logical equivalences [5,19] and SQL branch structures [34] to perform semantic-preserving transformation. For example, in Figure 2, EET transform the expressions `t2.c3` and `t2.c2` in the original query to two `CASE WHEN` expressions in the transformed query. `CASE WHEN` expressions are SQL-style conditional branch structures. Depending on the results of the conditional expressions following `WHEN` keywords, the returned values of the `CASE WHEN` expressions are determined by the expression following either the `THEN` keywords (*i.e.*, `TRUE` branches) or `ELSE` keywords (*i.e.*, `FALSE` branches). Both the branch conditions of the two `CASE WHEN` are unsatisfiable and can only be evaluated to `FALSE`. Therefore, these two `CASE WHEN` are semantically equivalent to `t2.c3` and `t2.c2`, respectively, which are the expressions used in the original query. Therefore, the original query and the transformed query should produce the same results. However, the original query outputs 1 row `{0}`, while the transformed query outputs empty, exposing a logic bug.

EET is effective because the transformed expression can result in different execution logic of the tested DBMSs. For the example in Figure 2, the transformed expressions (*i.e.*, the two `CASE WHEN`) lead the PostgreSQL server to invoke its buggy hash-join mechanism, while the original one does not. Such execution differences make PostgreSQL produce different results for the two queries and indicate at least one of the queries triggers bugs.

3 Equivalent Expression Transformation

In this section, we present the formalization and overview of EET, the two kinds of expression transformations that we propose in this paper, and the properties of this approach.

3.1 Overview

We formalize the core idea of *equivalent expression transformation (EET)* as the following formula, where Q represents an arbitrary query, E represents expressions contained in Q, and $DB(Q)$ is the result the tested DBMS produces for Q:

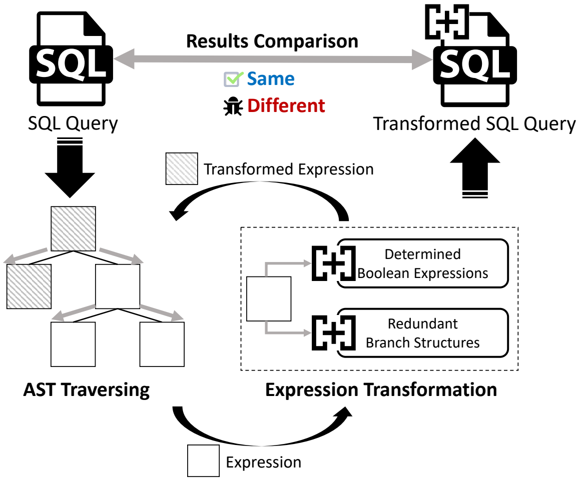

Figure 3: Approach overview of EET.

$$E \equiv E' \Rightarrow DB(Q) \equiv DB(Q'), \text{where } Q' = Q[\![E'/E]\!] \quad (1)$$

The idea is simple: given an arbitrary query Q with expressions E, construct a query $Q' = Q[\![E'/E]\!]$ by replacing all occurrences of E in Q with semantically equivalent expressions E'. Q' and Q are semantically equivalent by construction, and a DBMS should produce identical results on them.

Figure 3 shows the overview of EET. EET traverses the AST presentation of the query to iterate over expressions and transforms these expressions into semantically equivalent ones. After all the expressions have been transformed, the EET constructs a semantically equivalent query and validates the tested DBMS by comparing the results of the transformed query and the original query. In this paper, we propose *determined boolean expressions* (Section 3.2.1) and *redundant branch structures* (Section 3.2.2) to instantiate the expression transformations that satisfy $E \equiv E'$ in Eq. 1.

3.2 Expression Transformation

SQL queries contain various expressions, whose types can be categorized into two classes: boolean expressions and non-boolean expressions. For boolean expressions, we can transform them leveraging the logical equivalences [5,19] in mathematical logic, which have been well studied and generally recognized. For non-boolean expressions, it is difficult to propose general transformation, because these SQL expressions can be numeric (*e.g.*, integer, floating point), string, or timestamp, *etc*. Their execution rules are different. To generally support these types, we leverage SQL branch structures [34], which operate on expressions of various types and provide flexibility for transformation.

To this end, we propose two kinds of expression transformation, *determined boolean expressions* and *redundant branch* *structures*. Table 2 shows the details of each transformation, including its applied expressions and transformation rules. EET is extensible for additional expression transformations, and we expect that more kinds of effective transformation can be proposed in the future, as discussed in Section 3.3.

3.2.1 Determined Boolean Expressions

For each boolean expression, we can transform it using logical operations, such as **AND** and **OR**. We leverage 5 laws of logical equivalences [5, 19] for an arbitrary boolean expression p:

$$\top \vee p \equiv \top$$

$$\bot \wedge p \equiv \bot$$

$$\top \wedge p \equiv p$$

$$\bot \vee p \equiv p$$

$$p \vee q \equiv q \vee p, \quad p \wedge q \equiv q \wedge p$$

We interpret them to corresponding SQL equations:

$$\texttt{TRUE OR } p \equiv \texttt{TRUE} \tag{2}$$

$$\texttt{FALSE AND } p \equiv \texttt{FALSE} \tag{3}$$

$$\texttt{TRUE AND } p \equiv p \tag{4}$$

$$\texttt{FALSE OR } p \equiv p \tag{5}$$

$$p \texttt{ OR } q \equiv q \texttt{ OR } p, \quad p \texttt{ AND } q \equiv q \texttt{ AND } p \tag{6}$$

As the values of SQL boolean expressions can only be either **TRUE**, **FALSE**, or **NULL** [26], one of the expressions, p, **NOT** p, and p **IS NULL** must be **TRUE**, where p is an arbitrary boolean expression. Therefore, p **OR (NOT** p **) OR (** p **IS NULL)** must be **TRUE** according to Eq. 2. Similarly, one of the expressions, p, **NOT** p, and p **IS NOT NULL** must be **FALSE**, so p **AND (NOT** p **) AND (** p **IS NOT NULL)** must be **FALSE** according to Eq. 3. The equations are shown below:

$$p \texttt{ OR } (\texttt{NOT } p) \texttt{ OR } (p \texttt{ IS NULL}) \equiv \texttt{TRUE} \tag{7}$$

$$p \texttt{ AND } (\texttt{NOT } p) \texttt{ AND } (p \texttt{ IS NOT NULL}) \equiv \texttt{FALSE} \tag{8}$$

We use *true_expr* and *false_expr* to represent the expressions on the left-hand side of Eq. 7 and Eq. 8:

$$true\_expr(p) = p \texttt{ OR } (\texttt{NOT } p) \texttt{ OR } (p \texttt{ IS NULL}) \tag{9}$$

$$false\_expr(p) = p \texttt{ AND } (\texttt{NOT } p) \texttt{ AND } (p \texttt{ IS NOT NULL}) \tag{10}$$

Note that the operands of **OR**/**AND** can be randomly disordered according to Eq. 6 (*e.g.*, p and **NOT** p can switch their positions). Combining Eq. 4 with Eq. 7 and 9, Eq. 5 with Eq. 8 and 10, respectively, we get the following equations, where p and p' can be arbitrary boolean expressions:

$$true\_expr(p') \texttt{ AND } p \equiv p \tag{11}$$

$$false\_expr(p') \texttt{ OR } p \equiv p \tag{12}$$

Based on Eq. 11 and Eq. 12, we can transform an arbitrary boolean expression p by adding a structured expression containing a randomly generated boolean expression p'. We accordingly propose two transformation rules shown in rows No.1 and 2 in Table 2. Both of these transformation rules are guaranteed to preserve the semantics of original expressions. The queries shown in Figure 6 and Figure 7 (discussed in Section 5.3) are transformed by these rules.

3.2.2 Redundant Branch Structures

To transform non-boolean expressions, we propose to leverage **CASE WHEN** expressions, which are SQL-style conditional branch structures and support various SQL types. These expressions execute the following if-else logic:

$$C(p, expr_1, expr_2) = \texttt{CASE WHEN } p \texttt{ THEN } expr_1 \\ \texttt{ELSE } expr_2 \texttt{ END}$$

$$C(p, expr_1, expr_2) = \begin{cases} expr_1 & \text{if } p \text{ is } \texttt{TRUE} \\ expr_2 & \text{if } p \text{ is } \texttt{FALSE} \text{ or } \texttt{NULL} \end{cases} \tag{13}$$

We can determine the execution logic of **CASE WHEN** expressions by fixing the predicate p to be **TRUE** or **FALSE**. Furthermore, we can use Eq. 9 and Eq. 10 to replace the **TRUE** and **FALSE** values, making the transformed expression more complex. In the end, we get the following equations:

$$C(true\_expr(p), expr, expr') \equiv expr \tag{14}$$

$$C(false\_expr(p), expr', expr) \equiv expr \tag{15}$$

Based on Eq. 14 and Eq. 15, we can transform an expression to a designed **CASE WHEN** expression, which involves randomly generated expressions p and $expr'$ but still preserves the semantics of the original expression $expr$. We accordingly propose 2 transformation rules shown in rows No.3 and 4 of Table 2. Note that the type of $expr'$ should be the same as the type of $expr$, otherwise ambiguous behaviors may be triggered in some DBMSs [20, 24, 32]. The query shown in Figure 2 is transformed by these rules.

Besides fixing the predicate p to be **TRUE** or **FALSE** to determine the return value of a **CASE WHEN** expression, we can also manipulate the expression in **TRUE** or **FALSE** branch. If the expressions in the **TRUE** and **FALSE** branch are semantically equivalent to each other, the **CASE WHEN** expression is determined to be the expression in the **TRUE/FALSE** branch, no matter how the predicate p is evaluated. Formally, we get the following equation by making $expr_1 \equiv expr_2$ in Eq. 13:

$$expr_1 \equiv expr_2 \Rightarrow C(p, expr_1, expr_2) \equiv expr_1 \equiv expr_2 \tag{16}$$

Based on Eq. 16, we propose 2 transformation rules shown in rows No.5 and 6 of Table 2. In these rules, we deeply copy

Table 2: Transformation rules of EET

No.	Expression Transformation	Applied Expression	Transformation Rule
1	Determined Boolean Expressions	*bool_expr*: boolean	*bool_expr* → *false_expr*[3] **OR** *bool_expr*
2	Determined Boolean Expressions	*bool_expr*: boolean	*bool_expr* → *true_expr*[4] **AND** *bool_expr*

3	Redundant Branch Structures	*expr*: **CASE-WHEN** applicable	*expr* → **CASE WHEN** *false_expr*
			THEN *rand_expr(type(expr))*[1, 2]
			ELSE *expr* **END**

4	Redundant Branch Structures	*expr*: **CASE-WHEN** applicable	*expr* → **CASE WHEN** *true_expr*
			THEN *expr*
			ELSE *rand_expr(type(expr))* **END**

5	Redundant Branch Structures	*expr*: **CASE-WHEN** applicable	*expr* → **CASE WHEN** *rand_expr(boolean)*
			THEN *copy_expr(expr)*[5]
			ELSE *expr* **END**

6	Redundant Branch Structures	*expr*: **CASE-WHEN** applicable	*expr* → **CASE WHEN** *rand_expr(boolean)*
			THEN *expr*
			ELSE *copy_expr(expr)* **END**

7	Origin	*expr*: non boolean **CASE-WHEN** inapplicable	*expr* → *expr*

[1] *type(e)*: the type of the return value of expression *e*.

[2] *rand_expr(t)*: randomly generated expression that returns a value with type *t*.

[3] *false_expr* → *p* **AND (NOT** *p* **) AND (** *p* **IS NOT NULL)** | *p* → *rand_expr(boolean)*

[4] *true_expr* → *p* **OR (NOT** *p* **) OR (** *p* **IS NULL)** | *p* → *rand_expr(boolean)*

[5] *copy_expr(e)*: an expression deeply copied from expression *e*

the original expression *expr* (*i.e.*, the expression itself and its subexpressions) to another expression, namely *copy_expr*. The expressions *expr* and *copy_expr* are semantically equivalent because they are the same. We distribute these expressions in **TRUE** and **FALSE** branches of a **CASE WHEN** expression, and randomly generate a predicate. Eq. 16 guarantees that such a **CASE WHEN** expression is semantically equivalent to the original expression. The query shown in Figure 8 (discussed in Section 5.3) is transformed by these rules.

3.2.3 Choosing Transformation Rules

CASE WHEN expressions can be applied for the majority types of SQL expressions, including numeric types, string types, timestamp types, *e.t.c.* EET randomly chooses one of the rules No.3 to 6 to transform the expression belonging to these types. Boolean types also support **CASE WHEN**, so EET randomly applies one of the rules No.1 to 6 for each boolean expression. However, some types of expressions are **CASE-WHEN** inapplicable, and thus none of the rules No.1 to 6 are available. The table expressions `t0` and `t1` in Figure 2 are the examples. When we replace them with **CASE WHEN** expression, the query will trigger syntactic errors. To address this problem, EET conservatively transforms these expressions to themselves, as shown in rule No.7 of Table 2.

3.3 Properties

Soundness. EET follows the formally-proved equations in Section 3.2, and thus is guaranteed to preserve the semantics of the original queries. If the execution results of the original queries are determined (*i.e.*, excluding SQL features involving randomness), the transformed queries must produce the same execution results as the original ones, otherwise logic bugs are triggered. Therefore, EET is sound and produces no false positives in logic-bug detection.

Generality. EET can be generally applied to various SQL queries because it works at the expression level instead of the query level. Existing approaches, which work at the query level, inherently require the generated queries to follow specified query patterns. Otherwise, these approaches cannot infer the oracle results to validate the execution of their generated queries. Such limitations make existing approaches not general because they cannot be applied to arbitrary queries (*e.g.*, the queries violated their patterns). In contrast, EET can be applied to validate arbitrary queries because it works at the expression level. Given an arbitrary query that is not limited to any query patterns, EET can generally transform it by transforming its expressions, and use the results of the transformed query to validate the results of the given query. In this sense, EET is general in validating arbitrary SQL queries.

While the high-level idea of EET works generally, its im-

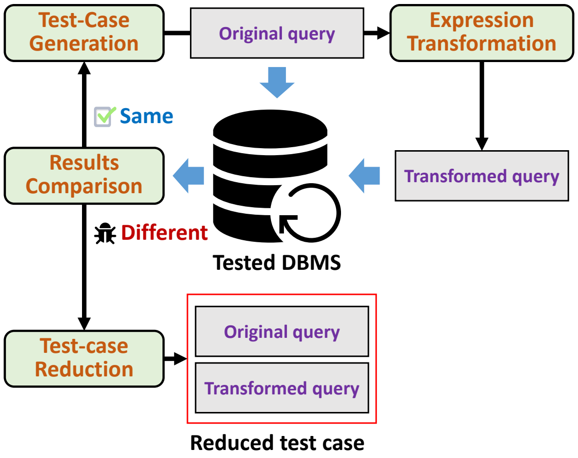

Figure 4: Implementation architecture of EET.

plementation for different SQL dialects can vary, depending on their branching structure syntax. For example, the function **DECODE** in Oracle [21] can return different values according to the comparison of its operands. This function can be implemented in the redundant branch structures of EET to transform queries written in Oracle-style SQL. In this paper, for redundant branch structures, we use only **CASE WHEN** expressions, which are supported by all the tested DBMSs.

Extensibility. In this paper, we propose two kinds of expression transformations for finding logic bugs to demonstrate the effectiveness of EET. Besides these two, we expect that more transformations are possible to enhance the approach. For example, a new transformation can be proposed to process table expressions (*e.g.*, **t0** and **t1** in Figure 2) by joining the original table with other tables while keeping the join results the same as the original one. EET can be easily extended to support new transformations as we only need to specify the transformation rules and the applied expression types. In our implementation, we used less than 200 lines of code for the proposed two kinds of expression transformations.

Black-Box Testing. EET is a pure black-box technique, which does not rely on the internal implementation of the tested DBMSs. Such a property makes our approach portable and can be easily deployed for testing various DBMSs, even the ones whose source code is unavailable.

4 Implementation

We implemented EET into a fully automatic tool on top of SQLsmith [33], which we mainly use for generating databases and complex queries. The overall codebase of the tool is 14k lines of C/C++ code, 2k of which is used to implement our approach. Figure 4 shows its architecture. The following describes the important implementation details.

Test-Case Generation. EET generates databases and queries randomly. To generate a query, the tool incrementally builds an AST tree according to the grammar of SQL [27, 34, 38]. When constructing a node of the AST, EET updates and records the available variables (*e.g.*, relations, columns), and fills the node with a randomly generated expression referencing the available variables. After the AST tree is completed, a new query is generated and can be fed to the tested DBMS.

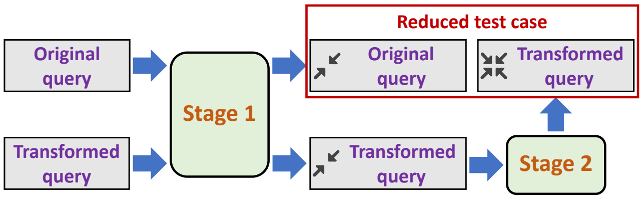

Figure 5: Two-stage reduction of EET.

Expression Transformation. EET leverages the AST representation of the query to iterate each expression. For each expression, EET checks its type and randomly chooses one of the suitable transformation rules, as discussed in Section 3.2.3. During transformation, EET may need to generate additional expressions (*e.g.*, an additional boolean expression is required in rules No.1 to 6 in Table 2). In this case, EET reuses the information (*e.g.*, available variables in corresponding AST nodes) used in test-case generation to randomly generate additional expressions with specific types.

Result Comparison. EET compares the execution results of the transformed query and the original query, including their query output and database changes caused by these queries. Any discrepancy indicates that logic bugs are triggered.

Test-case Reduction. To trigger a logic bug, EET may perform transformations on a large query (*e.g.*, hundreds of lines of SQL), and all its expressions are transformed. However, the same bug might be triggered using parts of the large query and couples of transformed expressions. To ease the burden of developers, we need to reduce the bug-triggering queries before reporting the bugs. We customize *two-stage reduction* for EET to reduce the bug-triggering queries automatically. Figure 5 shows the workflow of this reduction procedure.

In the first stage, EET reduces both the original query and the transformed query. Each time the parts (*e.g.*, an expression) of an original query are reduced, the corresponding parts (*e.g.*, the transformed expression) in the transformed query are also reduced to make these two queries consistent. For example, in Figure 2, when the expression **t2.c3** of the original query is reduced to a constant value **NULL**, the corresponding **CASE WHEN** expression in the transformed query should also be replaced by **NULL**. EET checks whether these two queries still produce different results. If so, the bug still exists and the reduction is effective. Otherwise, EET recovers the reduced parts and tries to reduce other parts of these two queries. When no part can be reduced, EET enters the second stage.

In the second stage, EET tries to incrementally disable the transformation for each expression in the transformed queries. After one transformation for an expression is disabled, if the execution results of the transformed queries are still different from the original, EET keeps this expression not transformed. Otherwise, EET recovers the expression to the transformed version. When no transformation can be disabled in the transformed query, this stage ends.

5 Evaluation

Our evaluation aims to answer the following questions to demonstrate the effectiveness of EET:

Q1 Can EET find real logic bugs in widely used and extensively tested DBMSs? (Section 5.2)

Q2 How diverse are the logic bugs found by EET? (Section 5.3)

Q3 Can EET find logic bugs that are missed by existing approaches? (Section 5.4)

5.1 Experimental Setup

We focused on testing open-source DBMSs for transparent and convenient bug reporting. We chose MySQL [20], PostgreSQL [24], SQLite [32], ClickHouse [3], and TiDB [36] because they are popular and extensively tested. At the time of paper writing, MySQL, PostgreSQL, and SQLite rank 1st, 2nd, and 6th, respectively, among the open-source DBMSs according to their popularity in DB-Engines Ranking [6]. ClickHouse and TiDB are relatively new DBMSs but very popular on GitHub [10]. They have gained over 31K and 35K stars, respectively, demonstrating their popularity. All of these DBMSs have been extensively tested by existing approaches for finding logic bugs [4, 11, 25–27, 29, 35] and crash bugs [13, 33, 38]. Finding new bugs in these DBMSs is very challenging and can demonstrate the effectiveness of EET.

We use EET to test the latest version of each DBMS. When the code of a DBMS is updated, we start a new test for the updated version. Specifically, we started to test MySQL from version 8.0.34, PostgreSQL from commit `3f1aaaa`, SQLite from commit `20e09ba`, ClickHouse from commit `30464b9`, and TiDB from commit `f5ca27e`. All the DBMS code is cloned from their official GitHub repositories. We intermittently deployed EET to test these DBMSs. We stopped and restarted the testing when we implemented new features in EET. The overall testing duration is three months. We evaluate EET on Ubuntu 20.04 with a 64-core AMD Epyc 7742 CPU at 2.25G Hz and 256GB RAM.

5.2 Bug Detection

As shown in Table 3, we reported 66 unique DBMS bugs found by EET, including 16 in MySQL, 9 in PostgreSQL, 10 in SQLite, 21 in ClickHouse, and 10 in TiDB. 65 of these bugs have been confirmed, and 37 have been fixed. None of these bugs are marked as duplicates by developers.

Table 3: Status of the bugs found by EET

DBMS	**Reported**	**Confirmed**	**Fixed**
MySQL	16	16	2
PostgreSQL	9	9	8
SQLite	10	10	10
ClickHouse	21	20	15
TiDB	10	10	2
Total	66	65	37

Table 4: Bug classification

DBMS	**Logic**	**Crash**	**Error**
MySQL	10	6	0
PostgreSQL	3	3	3
SQLite	9	0	1
ClickHouse	11	3	7
TiDB	2	7	1
Total	35	19	12

Bug Classification. We classify the bugs EET found into the three following types:

Logic bugs. The tested DBMSs incorrectly execute the SQL queries and produce wrong results (*e.g.*, select or update incorrect rows). These bugs were exposed because they incurred discrepancies between the results of the original queries and the transformed queries generated by EET.

Crash bugs. These bugs cause the tested DBMSs to crash or panic when specific queries are processed. Their root causes may be (1) memory corruption like null-pointer dereference; (2) assertion failures and (3) unexpected memory exhaustion.

Abnormal errors. The tested DBMSs report unexpected errors (*e.g.*, "database disk image is malformed" in SQLite) when processing syntactically and semantically valid queries.

As shown in Table 4, 35 bugs (52% of the bugs EET found) are logic bugs, which are the most interesting and hard-to-find bugs. The three logic bugs in PostgreSQL are exciting because PostgreSQL is a well-known hard nut for DBMS testing [13, 25, 27], where SQLancer [30], the DBMS testing tool integrating three logic bug detection techniques [25–27], found only one logic bug [31]. EET also found 19 crash bugs and 11 abnormal errors. These results demonstrate that EET is effective in finding bugs in DBMSs, especially logic bugs.

Bug Importance. We collect the severity information of the bugs we reported to MySQL and TiDB. PostgreSQL, SQLite, and ClickHouse do not provide the severity of each reported bug. All the crash bugs we reported to MySQL were identified as *confidential*, among which 2 have been assigned CVEs.

Among the 10 logic bugs in MySQL, 7 were recognized as *serious* bugs, and 3 were *non-critical*. Among the 10 bugs reported to TiDB, developers marked 6 as *major*, 1 as *minor*, and 3 as *moderate*.

The developers appreciated our effort in finding real bugs in their DBMSs. Particularly, PostgreSQL developers recognized our contribution to the reliability of PostgreSQL and sent us their commemorative coin [23]. ClickHouse and PostgreSQL developers provided their testimonials:

> ***ClickHouse:*** This tool has proven its value, and we want to integrate it into our CI and use it continuously. Thanks to @xxx for running it and reporting the findings!

> ***PostgreSQL:*** Thanks for your efforts! I thought about the generation of self-join tests for about a year, and it would be interesting to read about your approach. Could you send me a copy of the paper after release? Or the name of the conference to participate and see it offline.

Throughput. We count the number of tests (each one consists of one original query and one transformed query) performed by EET per second during testing the 5 DBMSs. On average, a single EET instance performs 3.39 tests per second (293k tests per day), which is lower than existing approaches. It is reasonable because EET supports complex queries, and DBMSs spend much more time executing complex queries than simple queries [13], making most CPU time spent on query execution (94.18% in our statistic results). We believe this throughput is practical considering (1) DBMS testing typically persists for several months [25–27, 29], and thus a sufficient number of tests can be executed and (2) setting up multiple testing instances can significantly improve the test efficiency of EET.

5.3 Bug Diversity

For the 35 logic bugs, we investigate their diversity from three aspects: (1) the diversity of bug-triggering queries involving multiple SQL features, (2) the diversity of the root causes of why DBMS produces incorrect results, and (3) the diversity of bug manifestation during testing DBMSs.

SQL Features. Table 5 lists the SQL features used in the 35 queries triggering logic bugs. The columns *Subquery*, *Join*, *Window*, and *Group* show whether the queries contain subqueries, join operations, window functions, and **`GROUP BY`** clauses, respectively. The column *DML* shows whether the bug-triggering queries are DML statements (*e.g.*, **`UPDATE`** and **`DELETE`**) instead of DQL (*e.g.*, **`SELECT`**).

Among the 35 bug-triggering queries, 18 contain subqueries (8 of them involve correlated subqueries), 18 use join operations (*e.g.*, inner join, outer join, and cross join), 4 invoke window functions (*e.g.*, **`DENSE_RANK`**, **`FIRST_VALUE`**), 3 involve **`GROUP BY`** clauses, and 2 are DML statements. We investigated the 10 bugs not involving these 5 features and found that all of them used SQL functions (*e.g.*, **`ACOS`**, **`HEX`**, and **`UNIX_TIMESTAMP`**) to perform complicated value calculations, string manipulation, and timestamp controlling. These results indicate that EET can find logic bugs triggered by various SQL queries.

The combined results in Table 1 and Table 5 demonstrate that EET can find many logic bugs missed by existing approaches because EET can support more various SQL features. For example, PQS [27], TLP [26], and NoREC [25] cannot find the 18 logic bugs related to subqueries, which are not supported by these approaches. Lacking support for join operations, DQE [29] cannot find the 18 join-related logic

```
--- Statements for database generation
CREATE TABLE t0 (c0 INT , c1 INT, c2 INT);
INSERT INTO t0 VALUES(2,1,-20);
INSERT INTO t0 VALUES(2,2,NULL);
INSERT INTO t0 VALUES(2,3,0);
INSERT INTO t0 VALUES(8,4,95);
--- Original query , delete 4 rows ✓
DELETE FROM t0 WHERE TRUE;
--- Transformed query , delete 3 rows 🐞
DELETE FROM t0 WHERE
((((t0.c0 <= t0.c2) AND
    (t0.c0 <> (SELECT c0 FROM t0 ORDER BY c0 LIMIT 1
    OFFSET 2))) IS NULL) OR
((t0.c0 <= t0.c2) AND
    (t0.c0 <> (SELECT c0 FROM t0 ORDER BY c0 LIMIT 1
    OFFSET 2))) OR
NOT ((t0.c0 <= t0.c2) AND
    (t0.c0 <> (SELECT c0 FROM t0 ORDER BY c0 LIMIT 1
    OFFSET 2))))AND TRUE;
```

Figure 6: Queries triggering a logic bug in the one-pass optimization of SQLite.

bugs. Notably, none of the existing approaches could find the 8 logic bugs related to correlated subqueries, as they cannot support semantically complex features. EET, benefiting from expression-level manipulation, is not limited to specific query patterns and can generally support all the listed features. Therefore, EET can find many bugs beyond the capabilities of existing approaches.

Root Cause Analysis. We investigated the 19 fixed logic bugs, whose patches and developer feedback are visible. They consist of 9 bugs in SQLite, 3 in PostgreSQL, and 7 in ClickHouse. We found that 12 bugs are caused by incorrect optimization. It is expected because EET supports logic bug detection for complex queries, which has huge potential to be optimized and thus can cover many optimization mechanisms in the tested DBMSs. 11 bugs are related to **JOIN** operations. Indeed, existing approaches could not systematically test the DBMS components related to **JOIN** operations until TQS was proposed [35], and thus many bugs remain unexposed. These results indicate that EET can also be used to effectively test the **JOIN** mechanism implemented in the tested DBMSs (*e.g.*, the hash-join bug shown in Figure 2). Different from TQS, EET can also detect bugs in other DBMS components, such as a bug in the JIT components used for expression compilation in ClickHouse. The following shows three interesting bug examples caused by different root causes.

Example 1: Optimization bug in SQLite. Figure 6 shows the queries triggering a logic bug in the one-pass optimization of SQLite. The original query is a simple **DELETE** statement with a predicate **TRUE**, which removes 4 rows in the table **t0**. EET transforms this query by applying rule No.2 in Table 2 to the predicate **TRUE**, which is semantic preserving. The transformed query should also remove 4 rows in **t0**, but only 3 rows are removed, indicating a logic bug triggered. The root cause is that the transformed query triggered the one-pass optimization in SQLite, which passes the target table only one time. For each row, SQLite evaluates whether it satisfies the predicate. If so, SQLite deletes the row. Because the subquery in the **WHERE** clause is behind a short-circuit operator (*i.e.*, **AND** operation), SQLite evaluates it after one or more rows have already been deleted, and SQLite thus produces a wrong result for the subquery, which at the end makes a row in table **t0** not deleted. SQLite developers fix this bug by disabling the one-pass optimization when the processed query contains a subquery in its **WHERE** clause.

```
--- Statements for database generation
CREATE TABLE t0 (c0 UInt32, c1 UInt32,
        PRIMARY KEY (c0)) ENGINE = MergeTree;
INSERT INTO t0 VALUES (2, 2);
--- Original query , result set: {FALSE} ✓
SELECT FALSE FROM t0;
--- Transformed query , result set: {TRUE} 🐞
SELECT (acos(c0) <> atan(c1)) AND
         (NOT (acos(c0) <> atan(c1))) AND
         ((acos(c0) <> atan(c1)) IS NOT NULL)
     OR FALSE from t0;
```

Figure 7: Queries triggering a logic bug in the JIT compilation of ClickHouse.

Example 2: JOIN bug in PostgreSQL. Figure 2 shows the query triggering an ancient logic bug in the hash-join implementation of PostgreSQL. Specifically, PostgreSQL built a hash table for the **INNER JOIN** tables (*i.e.*, **t1** and **t0**) in the **FROM** clause. Their hash table was affected by a PostgreSQL data structure, *Param*, a parameter used for passing values into and out of subqueries or from nested loop joins to their inner scans. PostgreSQL must rebuild the hash table when specific Param values are updated. However, in some cases, the inner hash-key expressions for the hash table reference some Params whose changes are unexpectedly missed by PostgreSQL. The transformed query in Figure 2 updated such Params while PostgreSQL did not perceive the changes of these Params, as a result of which PostgreSQL incorrectly reused the outdated hash table and produced wrong results. PostgreSQL developers fixed this bug by invoking specific functions to take the missed Params into account.

Example 3: JIT bug in ClickHouse. Figure 7 shows the query triggering a logic bug in the JIT compilation of ClickHouse. The original query is a simple **SELECT** statement. EET transforms the **FALSE** expression in the **SELECT** clause, applying rule No.1 in Table 2. The transformed query trigger the JIT compilation of ClickHouse because the query repeatedly uses the expression **acos(c0)<> atan(c1)**. To speed up the query execution, ClickHouse compiles this expression into machine code that can be executed by CPUs directly. However, the JIT compiler incorrectly compiled the non-equal operation (*i.e.*, **<>**), and thus the machine code produced wrong

```
--- Statements for database generation
CREATE TABLE t0 (c0 INT, c1 INT);
CREATE TABLE t1 (c0 INT, c1 INT, c2 REAL,
                 c3 REAL, c4 INT);
INSERT INTO t0 VALUES(14, 24000);
INSERT INTO t1 VALUES(85, 95000, 97.87, 0.0, 0);
--- Original query , result set: {1}  🐞
SELECT DISTINCT 1 AS c1
FROM ((t1 AS ref_0 RIGHT OUTER JOIN t0 AS ref_1
        ON ref_0.c4 = ref_1.c0)
   LEFT OUTER JOIN
      (t1 AS ref_2 LEFT OUTER JOIN t0 AS ref_3
        ON ref_2.c1 = ref_3.c0)
   ON (((SELECT c1 FROM t0 ORDER BY c1 LIMIT 1) IN (
     SELECT ref_4.c0 AS c0 FROM t1 AS ref_4)) IS TRUE))
WHERE ref_2.c3 <= ref_2.c2;
--- Transformed query , result set: empty ✓
SELECT DISTINCT 1 AS c1
FROM ((t1 AS ref_0 RIGHT OUTER JOIN t0 AS ref_1
        ON ref_0.c4 = ref_1.c0)
   LEFT OUTER JOIN
      (t1 AS ref_2 LEFT OUTER JOIN t0 AS ref_3
        ON ref_2.c1 = ref_3.c0)
   ON (((SELECT c1 FROM t0 ORDER BY c1 LIMIT 1) IN (
     SELECT ref_4.c0 AS c0 FROM t1 AS ref_4)) IS TRUE))
WHERE CASE WHEN TRUE THEN ref_2.c3 <= ref_2.c2
            ELSE ref_2.c3 <= ref_2.c2 END;
```

Figure 8: SQLite logic bug triggered by the original query.

results when comparing the **NaN** value returned from **acos (c0)**. Therefore, the transformed query produces an unreasonable result. The developers fix this bug by repairing the function responsible for compiling the non-equal operation.

Bug Manifestations. While analyzing the 19 fixed logic bugs, we found another interesting phenomenon: a logic bug can be triggered by either the transformed query, the original query, or both of them. Specifically, 10 of the 19 bugs are triggered by the transformed queries (*e.g.*, Example 1-3), while 8 bugs are triggered by the original queries (*e.g.*, Example 4). Interestingly, EET found a logic bug triggered by both the transformed query and the original query (*i.e.*, Example 5), whose results are different. These results demonstrate that EET can catch a logic bug if any discrepancy is incurred between their result, independently of which query is the culprit.

Example 4: Bug triggered in the original queries. Figure 8 shows a case where the original query triggers a bug in SQLite. The original query contains the **DISTINCT** keyword, and its **FROM** clause consists of multiple join tables with many join conditions specified in the corresponding **ON** clauses, while the predicate in the **WHERE** clause is a simple comparison expression. In this case, SQLite applies the omit-outer-join optimization, which can reduce the useless join tables (*e.g.*, **ref_3**) that are not referenced outside their **JOIN** expressions. However, this optimization did not work well when SQLite also flattened the subqueries in the **JOIN** expressions (*e.g.*, the two subqueries in the last **ON** clause). As a result, SQLite incorrectly reduced the tables consisting of the flattened subqueries and thus produced wrong results for the original query. EET transforms the predicate in the **WHERE** clause of the original query to a **CASE WHEN** expression. Such transformation makes the predicate complex and blocks the buggy omit-outer-join optimization, and thus SQLite produced correct results for the transformed query. SQLite developers fix this bug by adding restrictions for applying omit-outer-join optimization.

```
--- Statements for database generation
CREATE TABLE t0 (c0 TEXT);
CREATE TABLE t1 (c0 INT4, c1 INT4, c2 TEXT,
                 c3 INT4, c4 FLOAT8, c5 INT4);
CREATE TABLE t2 (c0 TEXT, c1 TIMESTAMP);
CREATE VIEW t3 AS
 SELECT '1' AS c_0
   FROM ((SELECT ref_0.c0 AS c_0 FROM t0 ref_0
          GROUP BY ref_0.c0) subq_0
     FULL JOIN t2 ref_1 ON (subq_0.c_0 = ref_1.c0))
  WHERE ref_1.c1 > ref_1.c1;
CREATE VIEW t4 AS
 SELECT ref_1.c5 AS c_2, ref_1.c4 AS c_3,
           ref_1.c1 AS c_4, 1 AS c_6, ref_1.c3 AS c_9
   FROM (t3 ref_0 RIGHT JOIN t1 ref_1
           ON (ref_0.c_0 = ref_1.c2));
INSERT INTO t1 VALUES (11000, 0, null, 0, 0.0, 15);
--- Original query , result set: {0}  🐞
SELECT COUNT(*) AS c_6
FROM (t1 AS ref_0 LEFT OUTER JOIN t4 AS ref_1
        ON (ref_0.c0 = ref_1.c_2))
WHERE ref_1.c_3 =
    DCBRT(CASE WHEN ref_0.c2 LIKE '7%z'
            THEN ref_1.c_6 ELSE ref_0.c4 END);
--- Transformed query , result set: {1}  🐞
SELECT COUNT(*) AS c_6
FROM (t1 AS ref_0 LEFT OUTER JOIN t4 AS ref_1
        ON (ref_0.c0 = ref_1.c_2))
WHERE (CASE WHEN ((ref_1.c_9 >= ref_1.c_4)
           OR (NOT (ref_1.c_9 >= ref_1.c_4))
           OR ((ref_1.c_9 >= ref_1.c_4) IS NULL))
      THEN ref_1.c_3 ELSE ref_1.c_3 END) =
    DCBRT(CASE WHEN ref_0.c2 LIKE '7%z'
            THEN ref_1.c_6 ELSE ref_0.c4 END);
```

Figure 9: PostgreSQL logic bug triggered by both the original query and the transformed query.

Example 5: Bug triggered in both two queries. Figure 9 shows the test case where both the original query and the transformed query trigger the same logic bug in PostgreSQL. EET transforms the expression **ref_1.c_3** in the **WHERE** clause of the original query to a **CASE WHEN** expression, which unexpectedly makes the transformed query return different results. We reported the test case to PostgreSQL developers, who confirmed that both the two queries in the test case triggered a bug according to their query plans. Figure 10 shows their query plans. Their query plans are nearly the same, and the only difference is that the original query used a hash join, while the transformed query used a hash right join. Both query plans are problematic because they lose join filters, which are responsible for filtering the rows that satisfy the

```
QUERY PLAN: Original Query / Transformed Query
Aggregate
|-- Hash Join / Hash Right Join
      Hash Cond: (ref_1.c5 = ref_0.c0)
MISSING: Join Filter: (ref_1.c4 / CASE... = dcbrt(...))
   |-- Nested Loop Left Join
         Join Filter: ('1'::text = ref_1.c2)
      |-- Seq Scan on t1 ref_1
      |-- Materialize
         |-- Seq Scan on t2 ref_1_1
               Filter: (c1 > c1)
   |-- Hash
      |-- Seq Scan on t1 ref_0
```

Figure 10: Query plans of the original query (using hash join) and the transformed query (using hash right join) in Figure 9.

predicate in the **WHERE** clauses. The root cause of this logic bug is that PostgreSQL removed some unnecessary **LEFT JOIN** tables that are underneath other **LEFT JOIN** but failed to clean the data structures referencing the removed tables, causing PostgreSQL to consider that the join filters affected by such data structures are unreasonable and drop them. After the bug is fixed, the query plans of both the origin query and the transformed query contain their corresponding join filters.

5.4 Comparative Study

To check whether EET can find logic bugs missed by existing approaches, we investigate the earliest bug-inducing versions of the 35 logic bugs EET found and check whether these versions are before the existing approaches got published. We would conclude that EET can find logic bugs missed by existing approaches if some long-latent bugs are found by EET. This comparison is reasonable and objective because: (1) all logic bugs found by EET are not marked as duplicates by developers, meaning that no approach found these bugs until EET found them; (2) all the 5 DBMSs in our evaluation have been extensively tested by existing approaches [4,11,25–27,29,35], meaning that the existing approaches did not find the long-latent bugs found by EET during their evaluation.

We classify the existing approaches according to the years they got published, resulting in 2 classes: 2020 (PQS [27], TLP [26], NoREC [25]) and 2023 (TQS [35], Pinolo [11], DQE [29]). Therefore, we check whether the versions inducing the logic bugs found by EET are before 2020 and 2023. Table 6 shows the results.

Among 35 logic bugs found by EET, 13 already existed before 2020 (*i.e.*, bugs were involved in 2019 or earlier), indicating that all the existing approaches miss these 13 logic bugs in their extensive evaluation, as all these approaches are proposed in or after 2020. In addition, 11 logic bugs can be triggered between 2020 and 2022, while none of the three approaches (*i.e.*, TQS, Pinolo, and DQE) published in 2023 found these bugs. These results indicate that existing approaches indeed miss many long-latent logic bugs. Due to the inherent limitations of query-level manipulation, these approaches have to limit the patterns of their generated queries and thus cannot be applied to complex queries (*e.g.*, the bug-triggering queries in Figure 2), while many DBMS bugs can be triggered only by complex queries [13]. Empowered by expression-level manipulation, EET can be easily applied to complex queries and thus successfully found many logic bugs missed by existing approaches.

Table 6: Latency of the logic bugs found by EET

DBMS	Found	Bug-involved year		Longest latency
		< 2023	< 2020	
MySQL	10	9	6	6 years
PostgreSQL	3	1	1	20 years
SQLite	9	5	4	8 years
ClickHouse	11	7	2	4 years
TiDB	2	2	0	3 years
Total	35	24	13	20 years

We investigate the longest latency of the logic bugs found by EET for each tested DBMS. The result is shown in Table 6. Interestingly, for each tested DBMS, EET can find at least one bug whose latency is longer than 3 years. The bug with the longest latency, *i.e.*, 20 years, is found in PostgreSQL, which is shown in Figure 2. These results demonstrate that EET can effectively find long-latent bugs.

While EET can find many logic bugs missed by existing approaches, it may inherently miss some bugs that can be found by existing approaches. For example, if a logic bug makes both the original query and the transformed query produce the same incorrect results, EET will miss this bug. However, approaches like PQS [27] can help detect such missed bugs by inferring the expected query results. One interesting future work is to integrate EET and existing approaches into a testing framework that can efficiently schedule these approaches during testing DBMSs.

6 Related Work

Logic Bug Detection in DBMSs. Several approaches have been proposed to detect logic bugs in DBMSs [11,25–27,29,35]. PQS [27] synthesizes a query that guarantees to return a specific row using its manually implemented interpreter. If the tested DBMS fails to fetch the row, PQS identifies a logic bug. NoREC [25] generates a query with a predicate and transforms this query by moving its predicates from its **WHERE** clause to its **SELECT** clause. NoREC identifies a logic bug if the moved predicate produces different results. TLP [26] partitions an original query into three separated queries by decomposing its predicate. The union of the results of these separated queries should be consistent with the result of the original one, otherwise, a logic bug is triggered. SQLancer [30] integrates the above three techniques and has been deployed to test various DBMSs. In addition, DQE [29] generates different types of queries (*e.g.*, **SELECT**, **UPDATE**, and **DELETE**) with the same predicates. These different queries should operate the same rows, otherwise, a logic bug is triggered. Pinolo [11] modifies the predicate of a query, making its constraints looser/stricter. Therefore, the modified query should return a superset/subset of the results of the original query, otherwise, Pinolo identifies a logic bug. TQS [35] applies schema normalization [7, 22] to slit a wide table into multiple tables and construct a customized query using join tables, whose ground truth results can be inferred from the original wide table. Based on these ground truth results, TQS finds many logic bugs related to **JOIN** operations.

As discussed in Section 1 and 2, all these approaches are based on *query-level manipulation*, which requires the approaches to understand the semantics of the manipulated queries. Therefore, existing approaches cannot be applied to complex queries whose semantics are complicated. Different from existing approaches, EET is based on *expression-level manipulation*, which operates on expressions and has no necessity to understand the query semantics. Therefore, EET does not need to limit the query patterns and thus can be applied to various queries.

DBMS Test-Case Generation. Without focusing on logic bugs, some approaches [9, 13, 17, 33, 38] are proposed to generate more diverse test cases for DBMSs. SQLsmith [33] is a grammar-based DBMS fuzzer, which embeds the AST rules of SQL language and can generate complex SQL statements. SQUIRREL [38] proposes a new intermediate representation to model SQL queries and infers the dependencies between statements. In this way, SQUIRREL can generate queries that contain multiple SQL statements. Griffin [9] performs grammar-free mutation to test DBMSs by summarizing the DBMS state information into its metadata graph and mutating SQL queries according to the graph to prevent semantic errors. DynSQL [13] performs dynamic query interaction to capture the latest DBMS state information and incrementally generate complex and valid queries. In addition, some approaches [2, 18] are proposed to improve the test-case generation for logic bug detection. SQLRight [18] enables code coverage feedback, which gives the supported test oracles more chance to find logic bugs in rarely executed DBMS code. QPG [2] records the covered query plans during testing DBMSs and prioritizes mutating the queries that trigger new query plans, which is more likely to expose a new logic bug.

These approaches and EET can complement each other. On one hand, the high-quality and diverse queries generated by these approaches can help EET find more logic bugs hidden in the corner logic of DBMSs. On the other hand, the general test oracle provided by EET can enable these approaches to catch more various bugs.

7 Conclusion

In this paper, we propose a new and fine-grained methodology, *expression-level manipulation*, for approaching logic-bug-detection problems in DBMSs without limiting the query patterns. Based on this methodology, we propose a novel and general approach, *equivalent expression transformation (EET)*, which can effectively find logic bugs using two transformations: determined boolean expressions and redundant branch structures. We evaluate EET on 5 widely used DBMSs. In total, EET found 66 bugs, 35 of which are logic bugs. Many of these logic bugs have long latency and are missed by existing approaches. We believe the generality and effectiveness of EET can inspire more follow-up research on DBMS testing.

Abstract

Proving the correctness of a distributed protocol is a challenging endeavor. Central to this task is finding an *inductive invariant* for the protocol. Currently, automated invariant inference algorithms require developers to describe protocols using a restricted logic. If the developer wants to prove a protocol expressed without these restrictions, they must devise an inductive invariant manually.

We propose an approach that simplifies and partially automates finding the inductive invariant of a distributed protocol, as well as proving that it really is an invariant. The key insight is to identify an *invariant taxonomy* that divides invariants into Regular Invariants, which have one of a few simple low-level structures, and Protocol Invariants, which capture the higher-level host relationships that make the protocol work.

Building on the insight of this taxonomy, we describe the Kondo methodology for proving the correctness of a distributed protocol modeled as a state machine. The developer first manually devises the Protocol Invariants by proving a *synchronous* version of the protocol correct. In this simpler version, sends and receives are replaced with atomic variable assignments. The Kondo tool then automatically generates the asynchronous protocol description, Regular Invariants, and proofs that the Regular Invariants are inductive on their own. Finally, Kondo combines these with the synchronous proof into a *draft* proof of the asynchronous protocol, which may then require a small amount of user effort to complete. Our evaluation shows that Kondo reduces developer effort for a wide variety of distributed protocols.

1 Introduction

Distributed protocols are notoriously difficult to reason about. Because they underpin critical applications and infrastructure, any bugs can have severe consequences. Hence, in recent years, both researchers [14,20,25,37,38,41,45] and practitioners [2,30,46] have turned to formal verification to rigorously prove the correctness of distributed systems and protocols.

At the core of a formal distributed protocol safety proof is an *inductive invariant*, which implies that a desired safety property holds throughout a system's execution. As argued in previous work [13,26,43,44], manually deriving inductive invariants is a creative challenge. For example, the IronFleet [14,15] authors reported spending months to identify and prove an inductive invariant for Paxos [22,23].

Unsurprisingly, this challenge spurred a new category of algorithms and tools to automatically find the inductive invariants of distributed protocols [10,13,17–19,26,33,43,44]. For instance, DuoAI [43] finds an inductive invariant for Paxos in minutes, without any user guidance.

However, automated invariant inference has its own Achilles' heel—it limits how developers may express their protocols. State-of-the-art tools like DuoAI only work when the problem of checking the correctness of inductive invariants is a decidable one. Thus, they apply only to protocols that operate within the confines of a first-order logic fragment known as *effectively propositional reasoning* (EPR [34]). As an example of its limited expressivity, EPR does not permit arithmetic, requiring developers to use creative abstractions to encode common systems primitives such as epoch numbers and vote counting. As detailed by Padon et al. [31], expressing a protocol such as Paxos in EPR is quite challenging.

In summary, the current state of the art is a landscape of two extremes: the developer has to choose between 1) expressing the protocol naturally using standard programming primitives such as arithmetic, but manually find the inductive invariant, or 2) abstracting the protocol into the restrictive confines of EPR so as to apply automated invariant finding tools.

In this work, we present a new approach to bridge this gap. Our key insight is that there is an *invariant taxonomy* in the clauses within an inductive invariant. This taxonomy can be used to modularize invariants and proofs into strata of varying difficulty. Furthermore, we observe that all but the most difficult stratum can be derived almost fully automatically, even in a non-EPR setting that permits intuitive programming constructs such as arithmetic. Interestingly, proving the top-most stratum is often equivalent to proving the safety of a simpler, synchronous version of the protocol.

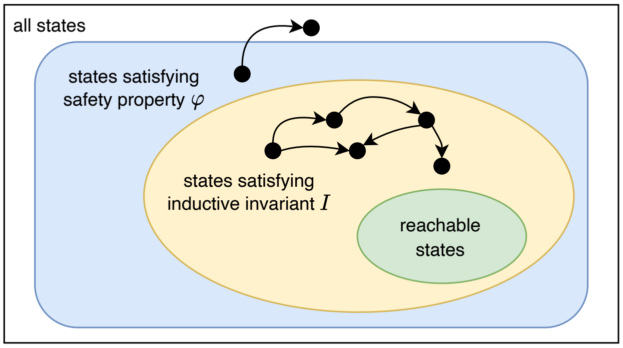
In this taxonomy, we identify a class of **Regular Invariants** with simple, regular structure that stem from recurring features and patterns in asynchronous message-passing systems. These invariants relate messages to their sending or receiving hosts (dubbed *Message Invariants*), assert the monotonic nature of common data structures (*Monotonicity Invariants*), and govern the ownership of unique resources (*Ownership Invariants*). As we will detail in subsequent sections, these invariants are not only easy to derive, but also easy to prove.

On the other hand, there is a separate class of **Protocol Invariants** that deal with the global relationships between hosts in the system. These capture the macro-level operation of the particular protocol, reflecting the structure of its design, and thus may require careful developer thought. Such invariants might state, for example, that a decision is made only when a majority of the nodes agree on it, or that all replicas of a log must have agreeing entries.

This taxonomy is not merely conceptual, but has significant practical implications. First, it enables a streamlined, systematic approach to finding and proving inductive invariants. The developer can easily dispatch Regular Invariants, before using them as building blocks for proving Protocol Invariants. Such an approach modularizes the derivation and proof of invariants into distinct components, with the most challenging part, Protocol Invariants, neatly contained. This is in contrast to monolithic proofs of the past, where developers have written invariants that intertwine complex protocol logic with simple local-level reasoning, thereby proliferating the difficulty of Protocol Invariants across the entire proof.

More importantly, Regular Invariants are sufficiently systematic that they can be derived from the protocol description with a few hints from the user, and then proven automatically, even in a general purpose verification tool such as Dafny [24]. Although our proposed taxonomy does not cover the space of all possible invariants, we observe that these derived Regular Invariants, in conjunction with a set of user crafted Protocol Invariants, often suffice to prove a wide variety of distributed protocols. In fact, these Protocol Invariants are typically (although not always) the same set needed to prove a *synchronous* version of the protocol; i.e., in a model without a network, where a sender sends a message and the receiver receives it in one atomic step.

Leveraging these insights, we design Kondo, a methodology and tool that lets developers harness the structure afforded by the invariant taxonomy. Using Kondo, the developer focuses their efforts on proving the correctness of a simpler, synchronous version of the protocol. Kondo then generates the asynchronous protocol from the synchronous description, and automatically devises and proves Regular Invariants for the asynchronous protocol with a few simple hints from the user. In addition, Kondo carries over Protocol Invariants from the synchronous proof, and combines them with Regular Invariants to create a *draft* proof of the asynchronous protocol. Sometimes, this draft proof is complete and constitutes the final proof; otherwise, the user helps complete the proof by adding some proof annotations to the draft.



all states
states satisfying safety property φ
states satisfying inductive invariant I
reachable states

Figure 1: Venn diagram of states in a distributed system. The dots and arrows represent example states and transitions.

Overall, we make the following contributions.

1. We identify an invariant taxonomy that distinguishes between Regular Invariants and Protocol Invariants, and define three sub-classes of Regular Invariants (Section 3).
2. We propose the Kondo approach to help developers leverage the structure afforded by the invariant taxonomy, and implement the Kondo tool [1] as a new feature in the Dafny compiler. The user begins by proving a simpler, synchronous protocol. Kondo then aids in lifting that proof to a fully asynchronous setting (Sections 4 and 5).
3. We evaluate the effectiveness of Kondo on a range of distributed protocols that span different application domains, from consensus to mutual exclusion. We show that Kondo can simplify finding and proving the inductive invariants of these protocols, and identify areas in which Kondo may be less effective (Section 6).

2 The Challenge of Inductive Invariants

Manually proving the correctness of an asynchronous distributed protocol is widely regarded as a challenging task. Its difficulty is compounded by the lack of principled techniques for structuring the invariants that a developer must derive for the proof. This results in invariants that entangle complex protocol logic with otherwise standard network semantics. Such invariants are hard to reason about and can complicate the entire proof.

Background. A correctness proof of a protocol involves showing that a desired safety property φ is an *invariant* that is true in all reachable states of the system. However, φ itself is usually too weak to support an inductive argument; i.e., there exist states satisfying φ that can transition to an unsafe state (Figure 1). As a result, the developer must devise an *inductive*

```
datatype Vote = Yes | No
datatype Decision = Abort | Commit
datatype Message =
      VoteReqMsg
      | VoteMsg(v: Vote, src: nat)
      | DecideMsg(d: Decision)
datatype Option<T> = None | Some(v: T)
datatype Coordinator = Variables(
      numParticipants: nat,              // some constant N
      decision: Option<Decision>,        // initially None
      yesVotes: set<nat>,                // initially empty
      noVotes: set<nat>                  // initially empty
)
datatype Participant = Variables(
      hostId: nat,                // unique identifier ∈ [0,N)
      preference: Vote,           // non-deterministic constant
      decision: Option<Decision>,        // initially None
)
```

Figure 2: Hosts and message states of the Two-Phase Commit protocol, written in Dafny. Note that Vote, Decision and Message are sum types.

invariant $I = I_1 \wedge \cdots \wedge I_n$, composed of several individual invariants I_k. I needs to both imply φ and be *inductive*, i.e., it should hold in all initial states of the system, and be closed under system transitions—if I holds for a state s, it also holds for the next state s' after any transition from s. If an individual conjunct I_k is itself inductive (even if it does not imply φ) we refer to it as *self-inductive*.

Coming up with an inductive invariant is a creative challenge because it must be strong enough to be inductive, yet weak enough to encompass all the reachable states of the system. For distributed protocols, this challenge is exacerbated by the presence of an asynchronous network that may arbitrarily delay, drop, duplicate, or re-order messages. In addition to considering the local states of each host, the developer must also contend with the state of the network and its interaction with hosts. As a result, proofs of distributed protocols require complex inductive invariants involving many clauses that simultaneously juggle host and network states [14, 28, 31].

2.1 Case Study: Two-Phase Commit

To highlight the challenge in finding inductive invariants, we use the classic Two-Phase Commit protocol. It is parameterized by an arbitrary number of participants, and it has a single coordinator (Figure 2). Participants are initialized with some preference of Yes or No that they communicate to the coordinator, which then makes a decision, using the protocol listed in Figure 3. The safety specification we target in this example is that if any participant reaches a Commit decision, then every participant's local *preference* must be Yes:

1. Coordinator broadcasts VoteReqMsg.
2. Upon receiving VoteReqMsg, a participant p replies VoteMsg(p.preference, p.hostId).
3. Upon receiving VoteMsg(v, src), the coordinator adds src to its *yesVotes* or *noVotes* set based on v.
4. The coordinator waits to receive votes from every participant. Then, if the coordinator has $|noVotes| > 0$, it sets its local decision to Abort and broadcasts DecideMsg(Abort). Otherwise, if $|yesVotes| = numParticipants$, it sets its decision to Commit and broadcasts DecideMsg(Commit).
5. Upon receiving DecideMsg(d), a participant sets its local decision to d.

Figure 3: Two-Phase Commit protocol description.

$$\forall id : \; participants[id].\mathrm{decision} = \mathrm{Some(Commit)} \\ \implies \big(\forall id' : \; participants[id'].\mathrm{preference} = \mathrm{Yes}\big) \quad \text{(2PC-Safety)}$$

Unfortunately, outside the context of EPR, there is no established methodology one can follow in finding an inductive invariant for this specification. Instead, they must rely solely on wit and will, in a journey of intuition-guided trial and error. In particular, the developer devises a candidate list of other protocol properties that when taken in conjunction with 2PC-Safety, they suspect, will form an inductive invariant.

An example of an invariant one may come up with is:

> "*if there is a* DecideMsg(Commit) *in the network, then every* VoteMsg *from each participant must contain* Yes."

Despite its apparent correctness, proving this invariant requires non-trivial supporting invariants. The developer will find that the proof requires host-level reasoning about how the coordinator processes votes, how it decides based on its local vote tally, and how it avoids sending conflicting messages. Overall, this leads to a proof that tightly intertwines host and network reasoning.

In this work, we argue that such monolithic invariants need not be the norm. Rather, they can be structured into forms that are more tractable. The idea of using simple invariants as building blocks for proving more complex ones is not a new one [3, 4]. However, we propose a systematic way of applying this idea to distributed protocols and derive invariants in layers of increasing complexity.

3 The Invariant Taxonomy

We present an invariant taxonomy designed to help developers tease apart host-level invariants from low-level invariants (e.g.,

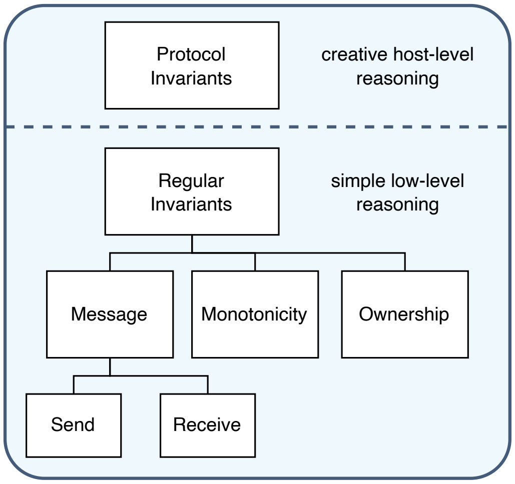


Figure 4: The invariant taxonomy.

invariants about the network). This taxonomy has two distinct categories—an upper stratum of Protocol Invariants, and a lower stratum of Regular Invariants, illustrated in Figure 4. Regular Invariants are easy to devise mechanically, and thus they can be assumed while discovering Protocol Invariants (which we show in Section 4 can even be discovered while completely ignoring the network). Using this taxonomy, the developer can contain host-level Protocol Invariants—the portion that demands user creativity—inside a well-demarcated portion of the proof. In turn, the Regular Invariants supporting those invariants are uncontaminated by host-level logic.

Note that these categories do not cover the space of all invariants. For a given protocol, there can exist invariants that are neither Regular Invariants nor Protocol Invariants. However, we find that our categorization is comprehensive enough to encompass all the invariants needed to prove a wide variety of distributed protocols (Section 6).

3.1 Regular Invariants

Regular Invariants are structurally simple and can be derived without requiring an understanding of why the protocol works. They concern low-level properties that follow from network semantics, the monotonicity of data like certain counters and sets, and the syntactic structure of protocol steps. They are also often self-inductive, which makes them easy to prove, and are even amenable to automation (Sections 4 and 5).

We identify three subcategories of Regular Invariants, namely Message Invariants, Monotonicity Invariants and Ownership Invariants, depicted by the hierarchy in Figure 4.

Message Invariants. These relate the state of the network to the state of hosts. In this way, they act as the logical bridge for proving invariants about relationships between host states when the hosts are separated by a network medium. Message Invariants come in two flavors:

1. **Send Invariants** assert that a message m is in the network only if it was sent by a host. They also describe, for each message variant, some relationship p between the message contents and the state of its sender:

$$\forall m \in \mathit{network} : p(m, \mathit{hosts}[m.\mathrm{src}])$$

2. **Receive Invariants** assert that if some condition q is met at some host h, then there must exist some message m in the network that was received by that host and has some relationship r with the host:

$$\forall h :\ q(\mathit{hosts}[h]) \implies \big(\exists m :\ m \in \mathit{network} \wedge h = m.\mathrm{dst} \wedge r(\mathit{hosts}[h], m)\big)$$

Monotonicity Invariants. Monotonic data types are a common primitive in distributed protocols [38]. Widely-used structures include grow-only epoch counters to filter stale messages, and add-only sets to collect votes from participant nodes. Monotonicity Invariants capture the monotonic properties of these data types, by asserting how the state of individual hosts may evolve as the system transitions:

$$\forall \sigma, \sigma' :\ \mathit{lteq}(\sigma, \sigma')$$

Here, σ and σ' are respectively the prior and current states of a host, and *lteq* represents some ordering relation on the values of local variables between the states.

Monotonicity Invariants require referencing the past states of hosts, which are typically not part of the distributed system model. In Section 4.2, we describe our history-preservation technique that enables us to systematically transform a protocol into one that preserves information about state histories. The protocol augmented with history information supports stating and proving Monotonicity Invariants, and using them in the proofs of higher-level Protocol Invariants.

Ownership Invariants. Many distributed protocols also require reasoning about uniquely owned resources. For example, at most one client can hold a unique lock in a distributed lock system, or at most one host can hold a unique key in a sharded key-value store.

Ownership Invariants capture the semantics of such resources. Specifically, they say that for each unique resource γ, at most one node can 'own' γ at any point in time, and if γ is in transit in the network, then no nodes can have ownership of γ. These properties are common to protocols that deal with resource ownership.

3.2 Protocol Invariants

Protocol Invariants describe a relationship ℓ among hosts, and do not mention the network. That is, they have the form

$$\forall h_1, \ldots, h_n :\ \ell(\mathit{hosts}[h_1], \ldots, \mathit{hosts}[h_n])$$

As such, Protocol Invariants are ignorant of the complications arising from network asynchrony. Instead, they focus on the higher-level reasoning of how host behaviors culminate in the overall correctness of the protocol, thus capturing properties that require insight into *why* the protocol is correct.

In addition, observe that given an asynchronous distributed protocol $\mathcal{P}$, any Protocol Invariant in $\mathcal{P}$ must also be an invariant in the *synchronous* version of the protocol $\mathcal{P}_{sync}$. This version, $\mathcal{P}_{sync}$, is one in which messages are delivered instantaneously between hosts—a sender sending a message and the receiver receiving it occurs as one atomic step, without a network delay. In practice, we observe that invariants used in proving the safety property in $\mathcal{P}_{sync}$ tend to be helpful Protocol Invariants in $\mathcal{P}$. Moreover, in all the protocols we evaluated, these Protocol Invariants, in conjunction with a set of automatically derived Regular Invariants, are all that is needed to prove $\mathcal{P}$ (Section 6.2).

3.3 Streamlining Proofs Using the Taxonomy

The invariant taxonomy mirrors the unique roles played by the network and the protocol logic. The network, while an inevitable part of reasoning about distributed systems, does not contribute to the underlying logic of the protocol—it simply serves as a medium to carry information between hosts. Instead, it is the interplay of host actions that affects the outcome of the protocol.

Respecting this natural division is key to writing a modular and efficient proof. By confining creativity-demanding invariants to exclusively describe hosts, Protocol Invariants ensure that user creativity is called upon only when needed, while the remaining mundane Regular Invariants are dispatched with minimal effort.

Two-Phase Commit Revisited. We revisit the Two-Phase Commit example from Section 2.1 to demonstrate how one can use the invariant taxonomy to bring order and simplicity to their proof. Figure 5 lists a set of invariants for Two-Phase Commit. The conjunction of these invariants and 2PC-Safety forms an inductive invariant that proves 2PC-Safety.

Of the six invariants, only *A*5 and *A*6 are Protocol Invariants. Discovering them involves protocol-level insight about how the states of different hosts are related. On the other hand, the remaining invariants are Regular Invariants. They arise from the individual steps where messages are sent or received, and describe what that particular step says about the network. For instance, *A*3 stems directly from protocol step 4. Likewise, *A*4 follows from step 5. They are also self-inductive—each invariant is preserved by the step that it directly relates to and is trivially preserved by other steps. For example, *A*1 relates directly to protocol step 2, which is the only step that adds a VoteMsg to the network.

Armed with this insight, the developer can employ the following proof strategy. They can first write down the Regular Invariants *A*1, *A*2, *A*3 and *A*4 without any thought about overall protocol correctness. This is easy because these invariants are apparent just from looking at individual, local protocol steps. Their self-inductive nature also allows the developer to quickly check if the invariants they wrote are correct. Finally, with these Regular Invariants effortlessly in place, the developer then devises the crowning jewels *A*5 and *A*6 as Protocol Invariants, the one part of the proof that requires creativity.

*A*1 For each VoteMsg(v, *src*) in the network, *src* is a valid participant identifier.

*A*2 For each VoteMsg(v, *src*) in the network, v reflects the *preference* of the participant identified by *src*.

*A*3 For each DecideMsg(d) in the network, d reflects the local *decision* at the coordinator.

*A*4 For each participant that decided Commit, DecideMsg(Commit) must be a message in the network.

*A*5 For each *id* in *yesVotes* at the coordinator, the participant identified by *id* must have the corresponding *preference*.

*A*6 If the coordinator decided Commit, then every participant's preference must be Yes.

Figure 5: Two-Phase Commit protocol invariants structured using the invariant taxonomy. The conjunction of these, together with 2PC-Safety, forms the inductive invariant of the protocol. *A*5 and *A*6 are Protocol Invariants, while the rest are Message Invariants.

4 Finding Invariants the Kondo Way

We now present the Kondo methodology and tool to help developers leverage the regularity afforded by the invariant taxonomy. In contrast to EPR-based approaches, Kondo targets general protocol models where determining the inductiveness of an invariant is an undecidable problem.

Kondo is based on two core observations. First, the systematic structure of Regular Invariants makes both *deriving and proving* these invariants amenable to automation, even in an undecidable setting that permits higher-order logic.

More surprisingly, we observe that Protocol Invariants can be devised and proven in a synchronous version of the protocol $\mathcal{P}_{sync}$ and used directly in the asynchronous protocol. Because messages are delivered instantaneously between hosts in $\mathcal{P}_{sync}$, it is much easier to iteratively devise an invariant and prove inductiveness. In all the distributed protocols in our evaluation (Section 6.2), the Protocol Invariants taken from $\mathcal{P}_{sync}$, in conjunction with the set of derived Regular Invariants for the asynchronous protocol, are sufficient to form an inductive invariant for each protocol's safety property (although this may not always be the case; see Section 6.5).

Final proof of $\mathcal{P}_{hist}$

Figure 6: Kondo workflow. Shaded bubbles represent artifacts that the user writes. Boxes represent artifacts that Kondo generates. Sometimes, the draft proof from ❺ may constitute the final proof, and the user need not perform step ❻ in such cases.

These observations inform the Kondo methodology. Using Kondo, the developer first writes and proves a synchronous version of the protocol. Then, Kondo automatically generates

1. a *history-preserving* asynchronous protocol $\mathcal{P}_{hist}$. In addition to modeling an asynchronous network, $\mathcal{P}_{hist}$ maintains a history of host states that aid in expressing Message and Monotonicity Invariants;
2. a set of Regular Invariants (sometimes with the help of user-supplied hints), along with their proofs of inductiveness; and
3. a *draft* proof of correctness of $\mathcal{P}_{hist}$. This draft may constitute the final proof, or may require modest effort from the developer to complete.

4.1 Overview

Figure 6 shows an overview of how a developer uses the Kondo methodology and tool to prove the safety of a protocol.

Step ❶: The user begins by writing a synchronous version of the protocol, denoted as $\mathcal{P}_{sync}$, together with a safety specification φ. This synchronous execution model does not have a network component. Instead, the overall system is simply a collection of host states that communicate atomically.

Step ❷: The user proves that $\mathcal{P}_{sync}$ satisfies φ by devising an *inductive invariant* I_{sync} that implies φ. Because we operate in a general setting in which checking the inductiveness of I_{sync} is undecidable, the user may also need to write a set of lemmas to convince the verifier that I_{sync} is indeed inductive.

Step ❸: Given $\mathcal{P}_{sync}$, the Kondo tool automatically generates a history-preserving asynchronous protocol $\mathcal{P}_{hist}$. It shares the same safety property φ as $\mathcal{P}_{sync}$.

Step ❹: Kondo generates a set of Regular Invariants for $\mathcal{P}_{hist}$, together with lemmas that prove their inductiveness. We denote the conjunction of all Regular Invariants as R. Note that to generate Receive, Monotonicity and Ownership Invariants, Kondo requires small hints from the user. The nature of these hints is detailed in Section 5.1.

Step ❺: From the user-written proof of $\mathcal{P}_{sync}$, Kondo generates a draft proof of $\mathcal{P}_{hist}$. This draft uses the conjunction $I_{\text{sync}} \wedge R$ as the inductive invariant. It lifts lemmas written for the $\mathcal{P}_{sync}$ proof to the new asynchronous context, while leaving gaps in places where the translation fails. Section 5.2 describes this process. Notably, code generated by Kondo is human-readable.

Step ❻: The user runs the verifier on the draft proof. In some cases, the draft suffices as the final proof. Otherwise, particular lemmas in the draft may be incomplete. The user then manually completes the proof of $\mathcal{P}_{hist}$ by filling in gaps in the bodies of these lemmas. Notably, *no new lemmas* need to be constructed, and the logical line of reasoning is identical to $\mathcal{P}_{sync}$. However, the user may need to write additional proof annotations to convince the verifier that the lemmas still hold in the asynchronous protocol.

4.2 Protocol Models

Like prior work [13, 14, 26, 43, 44], we use the temporal logic of actions (TLA [21]) to model a protocol as a state machine described by non-deterministic transition relations. This state machine in turn contains one or more sets of hosts. For example, the Paxos system has three sets of Proposer, Acceptor and Learner hosts respectively.

Hosts are themselves modeled as event-driven state machines that communicate via messages. A host can 1) take a spontaneous action that may or may not send a message, 2) take an action given some received message as input, or 3) crash for an indefinite amount of time.

Formally, a host is defined by a $\textsc{HostInit}(h\text{: Host})$ predicate and a $\textsc{HostNext}(h\text{: Host}, h'\text{: Host})$ relation. $\textsc{HostInit}$ circumscribes the initial states of the host, while $\textsc{HostNext}$ describes the host's state transition relation.

In the Kondo methodology, the developer works with two versions of a distributed protocol, $\mathcal{P}_{sync}$ and $\mathcal{P}_{hist}$, that differ by their network model. $\mathcal{P}_{sync}$ is initially written by the developer, whereas $\mathcal{P}_{hist}$ is derived automatically.

Synchronous Protocol $\mathcal{P}_{sync}$. The global state of $\mathcal{P}_{sync}$ is $S := (\sigma_1, \dots, \sigma_n)$, an n-tuple of host states. Its initial states are defined by the predicate

$$\textsc{SyncInit}(S) := (\textsc{HostInit}(\sigma_1), \dots, \textsc{HostInit}(\sigma_n))$$

asserting that hosts satisfy their respective initial conditions.

The system transitions are defined through the relation

$$\textsc{SyncNext}(S, S') := \textsc{Action}_1(S, S') \lor \cdots \lor \textsc{Action}_\textsc{k}(S, S')$$

where each action disjunct represents an atomic transition that the system may take. Each action also falls in one of two categories. First, one non-deterministically chosen host may take a local action, i.e., one that doesn't send or receive any data. Second, a non-deterministically chosen pair of sender and recipient hosts may take a corresponding send and receive action simultaneously; i.e., the sender transmits a message that is received instantaneously by the recipient.

Note that a consequence of tightly coupling sender and recipient pairs is that one host cannot both receive and send messages within a single action, as that would allow an arbitrary chain of hosts taking steps at once. This limitation does not sacrifice generality, as an action that receives and sends may always be modeled as two consecutive actions, with the first receiving the message and the second sending its response. It is, however, an additional restriction over the host model in prior work [14,15], and may increase proof complexity. Nevertheless, our evaluation shows that even with such a restriction, Kondo allows users to write simpler proofs than previous state of the art (see Paxos discussion in Section 6.3).

History-Preserving Asynchronous Protocol $\mathcal{P}_{hist}$. Given the synchronous protocol $\mathcal{P}_{sync}$, Kondo automatically generates a *history-preserving* asynchronous protocol $\mathcal{P}_{hist}$. This model adds to the synchronous model an asynchronous network that may arbitrarily delay, drop, duplicate, or re-order messages. Like prior work [14,15,45], we model this network as a monotonically increasing set of sent messages. When a host sends a message, the message is added to this set. When a host calls receive, it retrieves from this set some message addressed to it.

Unique to Kondo is the history-preserving aspect of $\mathcal{P}_{hist}$. It maintains a sequence *history* of host snapshots, enabling us to express monotonicity properties. Formally, let $history := [S_0, \dots, S_m]$ be a sequence of host state n-tuples. Each entry in *history* is a snapshot of all hosts in the system. Then the global state of $\mathcal{P}_{hist}$ is $S_{hist} := (history, N)$. The latest entry in *history* represents the current state of the hosts, while N is the set of messages representing the network's latest state.

The initial states of the system are defined by

$$\begin{aligned} \textsc{Init}(S_{hist}) := \; & len(S_{hist}.history) = 1 \\ & \land\ \textsc{SyncInit}(S_{hist}.history[0]) \ \land\ S_{hist}.N = \emptyset \end{aligned}$$

The system transitions are given by the relation

$$\begin{aligned} & \textsc{Next}(S_{hist}, S'_{hist}) := \\ & \quad \land\ len(S_{hist}.history) \geq 1 \\ & \quad \land\ S_{hist}.history = trunc(S'_{hist}.history) \\ & \quad \land\ \textsc{SyncNext}(curr(S_{hist}), curr(S'_{hist})) \end{aligned}$$

Here, $trunc(s)$ yields s with the last item removed. Meanwhile, $curr(S_{hist})$ gives the current state of the system, namely the tuple $(last(S_{hist}.history), S_{hist}.N)$, where $last(s)$ returns the last item in a sequence s.

4.3 Case Study: Echo Server

To illustrate the Kondo methodology, we apply it to a simple Echo Server protocol. It comprises an arbitrary number of clients and a single server. Each client maintains a constant set of *requests* that are defined by unique client and request identifiers.

Clients send their requests to the server. Upon receiving a request, the server responds by echoing the request back to the sender. When a client receives a response, it stores it in a local *responses* set. The safety specification is that clients do not receive rogue responses; i.e. for each client c, every element in c.responses matches a request in c.requests:

$$\forall\, client:\ client.\text{responses} \subseteq client.\text{requests} \qquad \text{(ES-Safety)}$$

We now show how the developer applies the Kondo methodology to proving this protocol.

Step ❶. The user starts by writing a synchronous version of the Echo Server protocol, $\mathcal{P}_{sync}$. They define the states of hosts (Figure 7), and the transitions that they can make (Figure 8).

They then define $\mathcal{P}_{sync}$ as the collection of a group of clients and a server. Here, $\textsc{SyncInit}$ asserts that every host satisfies their respective initialization predicates:

$$\begin{aligned} & \textsc{SyncInit}(S) := \\ & \quad \land \textsc{ServerInit}(S.\text{server}) \\ & \quad \land \forall\, 0 \leq id < |S.clients| : \textsc{ClientInit}(S.\text{clients}[id], id) \end{aligned}$$

```
datatype Request = Req(clientId: nat, reqId: nat)

datatype Message =
      SubmitReq(req: Request)
      | Response(req: Request)

datatype Client = Variables(
      clientId: nat,                          // unique identifier
      requests: MonotonicSet<Request>,
      responses: set<Request>
)

datatype Server =
      Variables(currentRequest: Option<Request>)

predicate ClientInit(v: Client, id: nat)
      ∧   v.clientId = id
      ∧   v.responses = ∅
      ∧   (∀ req ∈ v.requests : req.clientId = id)

predicate ServerInit(v: Server)
    currentRequest = None

```

Figure 7: Client and server states of the Echo Server protocol, written in Dafny. The MonotonicSet type is wrapper around Dafny's built-in set type and implemented in Kondo's monotonic type library. It indicates to Kondo that the sets are non-decreasing. Meanwhile, ClientInit does not constrain the size of a client's *requests* set, but ensures that every item in *requests* is marked with the client's unique *clientId*.

Meanwhile, SyncNext is a disjunction of two system-level atomic actions:

$$\text{SyncNext}(S, S') := \text{Action}_1(S, S') \vee \text{Action}_2(S, S')$$

In Action$_1$, a client-server pair performs ClientRequestStep and ServerReceiveStep respectively, where the client sends a request to the server, and the model ensures that the server instantaneously receives the request. In Action$_2$, a server-client pair performs ServerResponseStep and ClientReceiveStep, with the server sending its response and the client receiving it.

Step ❷. Next, the developer writes an inductive proof that $\mathcal{P}_{sync}$ satisfies its safety specification. Here, the inductive invariant is simple. It is the conjunction of ES-Safety with a single predicate asserting that the server's *currentRequest* belongs in the *requests* set of its sender:

$$\forall\, req : server.\text{currentRequest} = \text{Some}(req) \implies req \in clients[req.\text{clientId}].\text{requests} \quad (1)$$

Step ❸. Given $\mathcal{P}_{sync}$ written in step ❶, Kondo produces a history-preserving asynchronous version of the Echo Server protocol, $\mathcal{P}_{hist}$.

```
step ClientRequestStep(
  v: Client, v′: Client, send: Message)
   ∧ v′ = v                          // client state unchanged
   ∧ send.SubmitReq?
   ∧ send.req ∈ v.requests      // send SubmitReq(req)

step ClientReceiveStep(
  v: Client, v′: Client, recv: Message)
   // client receives Response

step ServerReceiveStep(
  v: Server, v′: Client, recv: Message)
   // server receives Request

step ServerResponseStep(
  v: Server, v′: Server, send: Message)
   ∧ v.currentRequest.Some?        // enabling condition
   ∧ v′.currentRequest = None
   ∧  send = Response(v.currentRequest)

```

Figure 8: Client and server transition relations from state v to v', with the bodies of ClientReceiveStep and ServerReceiveStep omitted for brevity. The argument *send* is a new message sent into the network, and *recv* is a message received from the network. Note that the '?' syntax is used to assert if a value is of a particular type or variant.

Step ❹. Together with $\mathcal{P}_{hist}$, Kondo also derives a set of Regular Invariants, along with their proof of correctness in $\mathcal{P}_{hist}$. In this example, the only hint required from the user is to label the client's *requests* set as a MonotonicSet type, shown in Figure 7. Note that the client's *responses* set does not need to be labeled as a MonotonicSet, because even though it is monotonic, such a property is not relevant to proving safety. The generated Regular Invariants are:

- A Message Invariant stating that every Response(req) is such that req was once processed by the server:

$$\forall\, \text{Response}(req) \in network : \exists\, i : \; history[i].\text{server.currentRequest} = \text{Some}(req) \quad (2)$$

- A Message Invariant stating that every SubmitReq(req) is such that req is in the *requests* set of the sender:

$$\forall\, \text{SubmitReq}(req) \in network : \exists\, i : \; req \in history[i].\text{clients}[req.\text{clientId}].\text{requests} \quad (3)$$

- A Monotonicity Invariant stating that the *requests* set at each client is non-decreasing:

$$\forall\, i \le j, clientId : history[i].\text{clients}[clientId].\text{requests} \subseteq history[j].\text{clients}[clientId].\text{requests} \quad (4)$$

Step ❺. The final step is to prove that $\mathcal{P}_{hist}$ satisfies the safety property. To this end, Kondo generates a draft proof of $\mathcal{P}_{hist}$ by combining the synchronous proof written in step ❶ with the generated Regular Invariants from step ❹. It derives from Equation (1) the history-preserving analogue

$$\forall\, i, req:\ history[i].\text{server.currentRequest} = \text{Some}(req) \implies req \in history[i].\text{clients}[req.\text{clientId}].\text{requests} \tag{5}$$

It then uses the conjunction of Equations (2) to (5) as the protocol's inductive invariant I.

Step ❻. In this example, the draft proof suffices as the final proof for the asynchronous Echo Server protocol, and no additional effort is required from the user.

4.4 Why History Preservation is Important

The Echo Server example also underscores the importance of our history-preservation technique. First, the history-preserving property of $\mathcal{P}_{hist}$ makes deriving and proving Regular Invariants amenable to automation. For instance, observe that for any $\textsc{Response}(req)$, its presence in the network implies that the sender of the message performed a $\textsc{ServerResponseStep}$ at some point in its execution history, during which req was its *currentRequest* value (Figure 8 line 19). This can be expressed as

$$\begin{aligned}\forall\, msg:\ & msg.\textsc{Response}?\ \wedge\ msg \in network \\ \implies & \exists\, i: \textsc{ServerResponseStep}(\\ & \quad history[i].\text{clients}[msg.\text{src}], \\ & \quad history[i+1].\text{clients}[msg.\text{src}], \\ & \quad msg)\end{aligned} \tag{6}$$

Equation (6) is easy to derive mechanically because it does not contain explicit references to internal host state, yet it implies all the properties that such a step entails, such as Equation (2).

Beyond making Message Invariants easy to derive, history preservation is what allows the invariant taxonomy to apply cleanly to a wide variety of protocols. Consider how the inductive invariant derived in step ❺ of Echo Server proves ES-Safety. First, Equation (2) allows us to relate $\textsc{Response}$ messages directly to the state of their sender (i.e., the server). Equation (5) then connects the server's state to a prior state of the respective client. Finally, Equation (4) relates that prior state to the current state to imply ES-Safety.

Without preserving history, Monotonicity Invariants such as Equation (4) would be impossible to express. Moreover, any previous values of $server.\text{currentRequest}$ are overwritten and erased from the system, hence preventing us from expressing simple Message Invariants such as Equation (2). Instead, the developer would have to resort to the alternative statement

$$\forall\, \textsc{Response}(req) \in network:\ \textsc{SubmitReq}(req) \in network$$

which mixes the protocol logic of how the server processes requests together with network reasoning, and is neither a Protocol Invariant nor a Regular Invariant. As explained in Section 2.1, this would result in proofs that are less tractable.

5 Automation in Kondo

Given a file describing a synchronous protocol $\mathcal{P}_{sync}$, Kondo generates the asynchronous protocol $\mathcal{P}_{hist}$, and human-readable files stating the derived Regular Invariants together with the proof that they are indeed invariants in $\mathcal{P}_{hist}$. Kondo also produces a draft proof of $\mathcal{P}_{hist}$ by combining the user-written synchronous proof with the derived Regular Invariants. In this section, we describe how Kondo derives and proves Regular Invariants with minimal user guidance, and how Kondo generates the draft proof of $\mathcal{P}_{hist}$.

We use the Dafny language and verifier [24] to specify and verify our protocols. We also implement Kondo as a new feature [1] inside the Dafny compiler.

5.1 Automating Regular Invariants

Message Invariants. In Kondo, we use the special sum type `Message` to define the messages of the system (e.g., Figure 7 line 2). We also require that messages be tagged with the unique identifier of their source host, accessed via $msg.\text{src}$. Without loss of generality, we assume that for each message variant α, there is exactly one host step T_α that sends that message. If there is more than one, α can simply be split into multiple variants, one for each host step that sends α.

Recall that Message Invariants relate the state of hosts to the state of the network via *Send Invariants* and *Receive Invariants* (Section 3.1). Kondo derives Send Invariants asserting that for each message in the network, its sender must have performed the action that sent that message. To do so, Kondo enumerates over `Message` variants. For each variant α, Kondo produces the statement that for each α message, m_α, in the network, there is some index i in the execution *history* when the source host of m_α performed the step T_α that sent m_α (exemplified by Equation (6)). Such statements yield two critical pieces of information—one, the *enabling condition* of step T_α (i.e., the preconditions required for step T_α to be taken) was satisfied at time i; and two, the state at time $i+1$ is in accordance with the transition. When combined with Monotonicity Invariants, they provide information on the current state of the system.

On the other hand, Receive Invariants derived by Kondo assert that if some witness condition q_α is met at a host state σ, then there must be a message of variant α in the network that made $q_\alpha(\sigma)$ true. More formally, if a host satisfies q_α at index j in its execution history, then there must be an earlier index $i < j$ and message m_α such that q_α is satisfied at index $i+1$ but not i, and this step involved the receipt of m_α. An example of a witness condition and the derived Receive Invariant for

```
// User-provided witness for PROMISE messages in Paxos
predicate PROMISEQ($v$: ProposerHost, $acc$: AcceptorId)
    $acc \in v.\mathit{promisesSet}$

// Generated Receive Invariant
predicate RECVPROMISEVALIDITY($s$: GlobalState)
    $\forall\, \ell,\ j,\ acc$ :
        PROMISEQ($s$. history[$j$]. proposers[$\ell$], acc)
        $\Longrightarrow$
        $(\exists\, i,\ msg :\ i < j$
          $\land\ \neg$ PROMISEQ($s$. history[$i$]. proposers[$\ell$], acc)
          $\land$ PROMISEQ($s$. history[$i{+}1$]. proposers[$\ell$], acc)
          $\land$ RECVPROMISESTEP(
                $s$. history[$i$]. proposers[$\ell$],
                $s$. history[$i{+}1$]. proposers[$\ell$],
                msg ) $)$

```

Figure 9: PROMISEQ is an example of a witness condition for the Paxos protocol. From this definition Kondo generates a corresponding Receive Invariant.

the Paxos protocol is listed in Figure 9. Receive Invariants inform the state of the network given the state of recipient hosts. When combined with Send Invariants, they bridge the relationship between senders and recipients.

Presently, Kondo requires the user to manually write the witness conditions. Kondo then generates one Receive Invariant for each condition. In practice, these are simple conditions that do not require much creativity. For instance, a representative condition is PROMISEQ in the Paxos protocol (Figure 9), which hints that any acceptor's ID in the *promises* set of a proposer host must have arrived via a message. The fact that specific fields in the host state are designed to track information received from messages must already be known by the developer at the time the protocol is conceived.

Monotonicity Invariants. These assert the monotonic policies of common data fields in local host state, such as round numbers and write-once variables used to store consensus decisions. In Kondo, we implement a library of common data types, each of which has a partial order relation, *less-than-or-equal-to* (*lteq*). The library includes write-once option types, grow-only numeric types, and append-only sets and sequences. Developers can easily expand this library with custom data types that implement the *lteq* interface.

Whenever the developer uses a monotonic type, Kondo produces an invariant stating that at any point in history, a value of that type must be *lteq* any future value. Equation (4) is one example, where *lteq* is the $\subseteq$ relation for sets. Importantly, the verifier enforces that these types are used correctly.

```
// User-provided label
predicate HOSTOWNSRESOURCE($v$: Host)
    $v$. hasLock                                  // boolean flag

// User-provided label
predicate INFLIGHTFORHOST($v$: Host, $msg$: Message)
    $msg$. dst $= v$. hostId $\land$ $v$. epoch $< msg$. epoch

// Generated Ownership Invariant
predicate ATMOSTONEOWNERPERRESOURCE(
  $s$: GlobalState)
   $\forall\, h_1, h_2 :\ ($
      $\land$ HOSTOWNSRESOURCE($s.\mathit{hosts}[h_1]$)
      $\land$ HOSTOWNSRESOURCE($s.\mathit{hosts}[h_2]$)
      $\Longrightarrow h_1 = h_2)$

// Generated Ownership Invariant
// RESOURCEINFLIGHTBYMSG is auto-generated wrapper
// around INFLIGHTFORHOST
predicate ATMOSTONEINFLIGHT($s$: GlobalState)
   $\forall\, m_1, m_2 :\ ($
      $\land$ RESOURCEINFLIGHTBYMSG($s, m_1$)
      $\land$ RESOURCEINFLIGHTBYMSG($s, m_2$)
      $\Longrightarrow m_1 = m_2)$

// Generated Ownership Invariant
// RESOURCEINFLIGHT is auto-generated wrapper
// around INFLIGHTFORHOST
predicate HOSTOWNSRESOURCEIMPLIESNOTINFLIGHT(
  $s$: GlobalState)
   RESOURCEINFLIGHT($s$)
        $\Longrightarrow$ NOHOSTOWNSRESOURCE($s$)

```

Figure 10: Example of user-provided ownership labels and the Ownership Invariants that Kondo generates for the Distributed Lock protocol.

Ownership Invariants. Many distributed protocols, such as lock services and sharded stores, revolve around ownership of exclusive resources. Though resources vary greatly in function and behavior, the semantics of what it means for the resource to be uniquely-owned is common. Figure 10 shows an example for how Ownership Invariants work in the Distributed Lock protocol [14], where hosts pass around a unique lock in a ring configuration.

For Kondo to generate Ownership Invariants, the user labels a data type as a uniquely-owned resource and describes its ownership semantics. This is done by defining two predicates under special names. First, HOSTOWNSRESOURCE states what it means for the host to own the lock. Second, INFLIGHTFORHOST describes the enabling condition for a host to receive a lock that is *in-flight*, meaning that the lock is in transit as a network message and can be received by the destination host. In Distributed Lock, HOSTOWNSRESOURCE says that a host owns the lock when its *hasLock* field is true, and INFLIGHTFORHOST evaluates to true when the message's *epoch* value is larger than that of the host.

We emphasize that these labeled conditions are not new concepts that a user must invent for Kondo. Instead, these are formulas that they must inevitably write for any ownership-based protocol. Kondo just requires them to be named in a standardized format.

Using the two predicates, Kondo generates invariants to cover the semantics of a uniquely owned resource. They assert that at most one host can own the resource, at most one copy of the resource can be in-flight, and that if the resource is in-flight then no one can own the resource in the meantime (respectively, ATMOSTONEOWNERPERRESOURCE, ATMOSTONEINFLIGHT, and HOSTOWNSRESOURCEIMPLIESNOTINFLIGHT).

Inductive Proofs of Regular Invariants. All of the Regular Invariants generated by Kondo come with verified Dafny lemmas proving that they are indeed invariants. The systematic structure of Regular Invariants ensures that these lemmas can be derived through simple syntax-driven rules. These invariants are such that every individual Message Invariant and Monotonicity Invariant is self-inductive, while the conjunction of Ownership Invariants is inductive.

5.2 Automating the Draft Proof

The final goal is to prove that the history-preserving asynchronous protocol $\mathcal{P}_{hist}$ satisfies its safety property. To aid the user in doing so, Kondo generates a draft proof based on the proof of the synchronous version $\mathcal{P}_{sync}$.

First, Kondo lifts the inductive invariants of $\mathcal{P}_{sync}$ to the history-preserving asynchronous world using the following mechanical transformation. Given a $\mathcal{P}_{sync}$ invariant $I(S)$, its history-preserving analogue is $I'(S_{hist}) := \forall i : I(S_{hist}.history[i])$, which simply states that I is true at all points in the history of S_{hist}. An example of this is the transformation of Equation (1) into Equation (5).

Second, Kondo also lifts lemmas for $\mathcal{P}_{sync}$ into lemmas for $\mathcal{P}_{hist}$. It converts inductive proofs of synchronous invariants to those of their history-preserving analogues by adding quantifiers over histories and choosing the appropriate elements in the histories as arguments to functions such as I.

One important detail is how Kondo handles *triggers* [29]. Triggers are syntactic patterns involving quantified variables that tell the Dafny verifier when to consider concrete instantiations of the quantifiers. For each quantified formula, the user may either manually supply its triggers or rely on Dafny to infer them automatically. In both these cases, Kondo lifts the triggers used in the synchronous invariants into their asynchronous counterparts. This ensures that the Dafny verifier triggers on the same terms in the draft proof as in the synchronous proof, such that lemmas that pass the verifier for $\mathcal{P}_{sync}$ are also likely to pass for $\mathcal{P}_{hist}$.

Overall, Kondo's generated draft proof is a best-effort syntax-guided translation. As such, it may contain lemmas that do not pass the Dafny verifier. Failing lemmas fall into one of two categories. First, the lemma's body contains $\mathcal{P}_{sync}$-specific constructs, namely the concrete instantiation of synchronous actions that cannot be easily translated into the $\mathcal{P}_{hist}$ context. In these cases, Kondo removes these lines from the $\mathcal{P}_{hist}$ proof, and requires the user to complete the translation. Second, Dafny simply needs more proof annotations to guide the verifier in exploring $\mathcal{P}_{hist}$'s more complex state space. In both these cases, the user embellishes the lemma body with more proof code, and may additionally call upon the generated Regular Invariants. With the candidate inductive invariant already in place, however, the effort demanded in this step is mechanical, and the bulk of user creativity is confined to the initial $\mathcal{P}_{sync}$ proof. We quantify this effort in Section 6.4.

6 Evaluation

We evaluate the Kondo methodology and tool by applying it to a wide range of distributed protocols. Informed by our experience in building and verifying distributed systems, this selection seeks to cover the space of common protocols as much as possible. The result is the list of protocols in Table 1, which concern a variety of application domains, ranging from consensus to mutual exclusion and concurrency control. We used Two-Phase Commit, Ring Leader Election, and Lock Server to develop and refine the Kondo approach. We then applied the Kondo approach to the remaining protocols.

Our evaluation determines whether Kondo is effective in helping developers prove the correctness of their distributed protocols. In doing so, we answer the following questions.

1. How applicable is the Kondo methodology in finding the inductive invariants of various distributed protocols? (Section 6.2)
2. How effective is Kondo in reducing the number of invariants a user must derive manually? (Section 6.3)
3. How burdensome is writing proof annotations when using Kondo? (Section 6.4)
4. Are there cases in which the Kondo methodology fails? (Section 6.5)

6.1 Evaluation Methodology

Each protocol in Table 1 is described as a state machine in Dafny following the IronFleet style [14], together with an associated safety property. For each protocol, the desired output is a theorem checked by Dafny which shows that the

	$\mathcal{P}_{sync}$ LoC	Invariant Clauses					Lines of Proof Code		
		No Kondo	Sync	Owner	Mono	Msg	No Kondo	Sync	Mods
Echo Server	260	5	1	0	1	3	93	40	0
Ring Leader Election [5]	183	6	1	0	0	2	191	56	0
Simplified Leader Election [39]	255	7	3	0	1	2	136	94	0
Two-Phase Commit	400	8	4	0	1	3	184	133	19
Paxos [23]	631	27	20	0	5	6	856	557	220
Flexible Paxos [16]	633	27	20	0	5	6	856	554	226
Distributed Lock [14]	194	2	0	3	0	0	64	31	0
ShardedKV	213	2	0	3	0	0	172	61	7
ShardedKV-Batched	225	2	0	3	0	0	172	31	0
Lock Server [26]	287	7	1	6	0	0	267	44	15

Table 1: Summary of proof effort using Kondo. Column '$\mathcal{P}_{sync}$ LoC' is the lines of code of the $\mathcal{P}_{sync}$ protocol description. Under 'Invariant Clauses', 'No Kondo' is the number of invariants a user writes to prove the asynchronous protocol when not using Kondo, while 'Sync' is the number of Protocol Invariants the user writes in completing the synchronous proof when using Kondo. The columns 'Owner', 'Mono' and 'Msg' count the Ownership, Monotonicity and Message Invariants Kondo generates. Under 'Lines of Proof Code', 'No Kondo' is the amount of code a user writes to prove the asynchronous protocol when not using Kondo. Meanwhile, 'Sync' is the amount of user-written code to prove $\mathcal{P}_{sync}$ in Kondo, and 'Mods' represent the total size of lemmas that the user had to modify in completing the draft proof generated by Kondo.

protocol's safety property is an invariant. In particular, we note that every protocol and its respective inductive invariant is outside of EPR.

To obtain the proof of each protocol, we apply the Kondo methodology by first finding and proving the inductive invariant for a synchronous version of the protocol $\mathcal{P}_{sync}$. From $\mathcal{P}_{sync}$ and its proof, the Kondo tool generates the asynchronous protocol $\mathcal{P}_{hist}$, a set of Regular Invariants, and a draft proof of $\mathcal{P}_{hist}$. Finally, we manually fill in any gaps in the draft proof to complete the final output.

6.2 Applicability of Kondo and the Invariant Taxonomy

We report that the Kondo methodology succeeds in producing inductive invariants for all 10 protocols. Table 1 tallies how the invariant clauses in each inductive invariant are classified in the invariant taxonomy. We note that the Regular Invariant columns in Table 1 only counts those that are useful in the final inductive invariant; i.e., removing such an invariant causes the proof to fail. In all of the examples we tested, the number of extraneous Regular Invariants generated by Kondo is small (at most 2). Hence, there is little threat of the developer being overwhelmed by a deluge of unneeded invariants.

Overall, this result demonstrates the applicability of Kondo along three fronts. First, it shows that the taxonomy is comprehensive in the properties that it covers. Using only invariants that fall within the taxonomic categories, we are able to express all the properties needed to form the inductive invariants of an extensive set of distributed protocols.

Second, the result shows that the inductive invariant for each of these protocols can be formulated in way that respects the classification between Protocol Invariants and Regular Invariants, where host-level reasoning is cleanly confined to Protocol Invariants. This supports the main hypothesis of the invariant taxonomy—it is the well-delineated core of Protocol Invariants that capture the deeper intuitions of the system design. Beyond this core, a set of easily derivable Regular Invariants completes the rest of the proof.

Third, the result supports the conclusion that Kondo is a viable strategy and tool for proof developers. By using only Protocol Invariants derived from $\mathcal{P}_{sync}$ in conjunction with the Regular Invariants generated using Kondo, we are able to find inductive invariants for a wide selection of protocols.

6.3 Reducing the Invariant-Finding Burden

In this study, we investigate the degree to which Kondo alleviates the developer's burden through reducing the number of invariant clauses they need to find manually for a protocol. In the case of Kondo, manually-derived invariants are the Protocol Invariants listed under 'Sync' in Table 1. We compare this to the number of invariants one must devise using the conventional IronFleet approach, listed under 'No Kondo'—these numbers are obtained from performing fully manual proofs of the asynchronous but non-history-preserving versions of the protocols, which represent the conventional way to write these protocols [14, 15].

In most cases, the number of manual invariants is drastically reduced when using Kondo, e.g., by up to 6x for Ring Leader

Election. Surprisingly, for Distributed Lock, ShardedKV and ShardedKV-Batched, the user need not write any invariants at all when using Kondo. This is because these protocols are about managing unique resource ownership, a problem that is trivial in the synchronous model where resources are passed atomically between hosts and there is no need to guard against duplication that may occur in an asynchronous network. In the asynchronous model, Ownership reasoning is in turn handled automatically by Kondo's Ownership Invariants.

For Paxos and Flexible Paxos, we observe that the reduction is less drastic, from 27 to 20 in both cases. An experimental factor contributes to the smaller difference. In the non-history-preserving version of these protocols (used to obtain the 'No Kondo' numbers), we used a simpler state machine for the proposer hosts. In particular, they include a step that received a message and sent the response in the same step, a simplification that made the proofs more tractable. Kondo, however, does not allow steps that perform both a send and a receive (see "Synchronous Protocol" in Section 4.2). Hence, we applied Kondo to a modified proposer state machine where that step was decomposed into two separate steps. Indeed, the fact that Kondo required fewer manual invariants despite this added complication highlights the usefulness of Kondo.

Furthermore, these numbers do not fully reflect the qualitative relief Kondo gives to the developer. Because Protocol Invariants are derived from the synchronous protocol model $\mathcal{P}_{sync}$, the developer can ignore the complications caused by network asynchrony when conceiving them. This luxury makes deriving Protocol Invariants qualitatively easier than the invariants in the traditional setting that is tarnished by the asynchronous network.

Overall, we find that Kondo allows the developer to be responsible for both fewer and simpler invariants across a variety of protocols.

6.4 Proof Experience

Because our protocols are not expressed in a decidable logic such as EPR, the user is inevitably tasked with writing proof annotations to convince the verifier of the correctness of the inductive invariant. In the Dafny language, these proof annotations come in the form of lemmas that resemble a hand-written inductiveness proof. Using the Kondo methodology, the user is responsible for writing proof annotations in two steps of the process (steps ❷ and ❻ in Figure 6, respectively):

1. Prove that the conjunction of Protocol Invariants is an inductive invariant of the synchronous protocol $\mathcal{P}_{sync}$.
2. Complete the draft proof of the asynchronous protocol, if it is not already complete. This involves adding proof annotations to the *bodies* of lemmas that fail to verify. Notably, the user need not introduce new lemmas, or modify the pre- and post-conditions of existing lemmas.

The columns 'Sync' and 'Mods' in Table 1 under the heading 'Lines of Proof Code' quantify the above efforts respectively, using lines of code as a proxy. They are in contrast to the 'No Kondo' column, which represents the amount of proof a user writes when not using Kondo.

Note that in the 'Mods' column, the numbers represent the total lines of lemmas that required additional proof annotations. In other words, even if just one line had to be added to the lemma, the lines of the entire lemma definition are counted. This is to include conservatively the effort the user may spend reading the lemma in order to complete the proof.

Finally, we emphasize that completing the asynchronous draft proof is a mechanical process once the developer has the synchronous proof in place. In particular, in the asynchronous proof, the developer uses exactly those lemmas already defined in the sync-proof, and the logical reasoning behind why the lemmas are true remains identical. The developer simply adds more assertions in the proof to guide the verifier in exploring a larger state space.

6.5 Limitations

Kondo targets safety proofs of crash fault tolerant distributed protocols. As such, liveness proofs are beyond its scope. Moreover, Kondo is not applicable in a Byzantine fault model, as it is not safe to relate a message to the state of a Byzantine-faulty sender or receiver.

Next, Kondo is not guaranteed to be complete, in that it may not work for every protocol or safety property. First, Protocol Invariants derived based on the synchronous protocol may not be correct invariants in the asynchronous model. For instance, the property "there is at least one node holding the lock" is an invariant in the synchronous version of Distributed Lock, but not the asynchronous one where the lock can be in-flight and not held by any node. In our evaluation, however, we have not encountered any safety properties where such invariants were required.

Second, even when the Protocol Invariants derived in the synchronous protocol are correct invariants in the asynchronous version, it is not theoretically guaranteed that their conjunction with Kondo-generated Regular Invariants must be an inductive invariant of the asynchronous protocol. However, we did not come across any such examples.

Ultimately, unlike EPR-based techniques, Kondo is intended to augment, rather than replace, general verification frameworks. In cases where Kondo fails to apply, it is always possible to fall back to the general verification framework, albeit giving up on the full benefits of using Kondo's structured invariants. It is also possible that new invariant categories and techniques may be needed as we apply Kondo to more diverse protocols. In this sense, Kondo comprises a toolkit of techniques that is general enough to cover a useful set of protocols, and it may grow to accommodate new classes of problems as they arise.

7 Related Work

Verification of distributed systems has received substantial attention, with proposed solutions falling along a spectrum of automation with differing trade-offs.

Manual Proofs. IronFleet's proof of Paxos [14] and Verdi's proof of Raft [42] both use general-purpose theorem provers to tackle their respective correctness proofs. They require entirely handwritten invariants and proofs, cumulating in 4,581 lines of Dafny for IronFleet and 50,000 lines of Coq for Verdi. However, they both accomplish the feat of verifying not just the protocol in the abstract, but an entire executable implementation, whereas Kondo is concerned with the protocol.

Automated Invariant Inference. To reduce the substantial effort needed for these proofs, considerable work has focused on automating the process. Ivy [32] makes use of the effectively propositional logic fragment (EPR [34]), which makes inductiveness-checking decidable and efficient in practice. Building on this, several algorithms aim to automate the construction of invariants wholesale; these include I4 [26], SWISS [13], DistAI [44], IC3PO [11], DuoAI [43], Primal-Dual Houdini [33], and P-FOL-IC3 [19].

However, EPR restricts how developers can express their protocols. In invariant inference, this restriction applies to the protocol description and its inductive invariant. For example, to handle Paxos, Padon et al. [31] develop abstractions that transform the verification conditions into EPR, a creative process aided by knowing the invariants in advance. Meanwhile, most approaches that can automatically infer invariants for Paxos (e.g., SWISS) require the protocol to already be transformed. Kondo, however, is not limited to EPR, so it does not share these restrictions. This is possible because it is not a *fully* automatic approach, instead allowing some human intervention. As a result, our solution to Paxos uses a natural, non-transformed protocol description.

Other works that infer invariants outside of EPR include a paper [12] targeting Paxos and the endive tool [36], which verifies a Raft-based protocol using the expressive language of TLA+. Being outside EPR, they cannot check invariants automatically in the unbounded domain, similar to Kondo. The endive authors report providing human guidance but did not quantify such effort.

Leveraging the Structure of Distributed Systems. Like Kondo, some work has used the observation that synchronous systems are easier to reason about than asynchronous ones. Pretend Synchrony [40], for example, rewrites asynchronous protocols into synchronous ones with much simpler invariants. However, it requires protocols to obey a restriction called "round non-interference" which precludes certain optimizations that save state between rounds, as in Multi-Paxos.

Some work introduces reasoning principles for the round-based *Heard-Of model* [6], including PSync [9], the $\mathbb{CL}$ logic [8], and *ConsL* [27]. Of course, these frameworks are only applicable to protocols that operate in rounds. Other work in this area [7] makes use of the communication-closure property of some protocols, but may not apply to protocols that do not have this property, such as the Echo Server.

Like Kondo, the work on *message chains* [28] identifies a class of useful invariants based on an insight into the structure of distributed systems. It proposes *message-chain invariants* that accumulate history inside network messages, explicitly mixing host and network state. In contrast, Kondo aims to isolate these two concerns.

Leveraging Ownership. Frameworks such as Aneris [20] and Grove [38] use separation logic [35] to reason about distributed systems. Separation logic is particularly good at reasoning about resource ownership, a concept also captured by Kondo's Ownership Invariants. Separation logic is very expressive, but it also requires the developer to come up with invariants (a process that is hard to automate), and it often requires significant technical expertise to use effectively.

8 Conclusion

This paper presents an invariant taxonomy that identifies structure in the inductive invariants of distributed protocols. The taxonomy classifies invariants into Regular Invariants (with regular structure that follows from the protocol description) and Protocol Invariants (which capture protocol-specific reasons why the protocol is correct). Building on this insight, the Kondo methodology gives developers a workflow and tool for coming up with an inductive invariant and proving inductiveness. They identify the Protocol Invariants on a synchronous version of the protocol; then use the Kondo tool to get an asynchronous protocol description and Regular Invariants; and finally, prove the inductiveness of the conjunction of Protocol and Regular Invariants, by completing the draft proof generated by Kondo.

Performance Interfaces for Hardware Accelerators

Jiacheng Ma, Rishabh Iyer, Sahand Kashani, Mahyar Emami, Thomas Bourgeat, George Candea
EPFL, Switzerland

Abstract

Designing and building a system that reaps the performance benefits of hardware accelerators is challenging, because accelerators provide little concrete visibility into their expected performance. Developers must invest many person-months into benchmarking to determine if their system would indeed benefit from using a particular accelerator. This must be done carefully, because accelerators can actually hurt performance for some classes of inputs, even if they help for others [53].

We demonstrate that it is possible for hardware accelerators to ship with *performance interfaces* that provide actionable visibility into their performance, just like semantic interfaces do for functionality. We propose an *intermediate representation* (IR) for accelerator performance that precisely captures all performance-relevant details of the accelerator while abstracting away all other information, including functionality. We develop *a toolchain* (ltc) that, based on the proposed IR, automatically produces human-readable performance interfaces that help developers make informed design decisions. ltc can also automatically produce formal *proofs of performance properties* of the accelerator, and can act as a *fast performance simulator* for concrete workloads.

We evaluate our approach on accelerators used for deep learning, serialization of RPC messages, JPEG image decoding, genome sequence alignment, and on an RMT pipeline used in programmable network switches. We demonstrate that the performance IR provides an accurate and complete representation of performance behavior, and we describe a variety of use cases for ltc and the resulting performance interfaces.

The code for ltc is open-source and freely available at [68].

1 Introduction

From datacenters to hand-held devices, modern systems increasingly rely on hardware accelerators to speed up a variety of tasks, such as machine learning [4, 48, 49, 64], video processing [28, 73], compression, encryption [17, 40], communication [29, 53], and even system infrastructure tasks [5, 32].

However, building a system that uses accelerators correctly—i.e., that fully extracts their performance benefits—remains a challenging task, because software engineers have little to no visibility into an accelerator's expected performance behavior. Every accelerator bakes design choices into silicon, such as specific throughput-vs-latency trade-offs [70] or assumptions about the workload [53], and if the software is a poor fit for these choices, acceleration will offer few benefits or even make performance worse [55, 59, 60].

This lack of visibility into expected performance hampers system developers in all three stages of system development: design, implementation, and deployment.

First, during the design stage, what functionality (if any) to offload, and which accelerators to use, is not obvious. Consider the offloading of (parts of) an RPC stack to an accelerator, where the candidates are RPC serializers/deserializers like ProtoAcc [53] and Optimus Prime [70], or one of several SmartNICs. Software engineers need to know what latency and throughput they can expect from each candidate accelerator, given their code and workload. Then they can decide which one offers the best price–performance ratio, before investing in thousands of new chips and refactoring the RPC stack. To answer these questions today, one needs to purchase every candidate accelerator, port the code, and benchmark them together—performance depends not only on the accelerator but also on the code and workload. For example, Optimus Prime is best suited for small data objects (≤300B), while ProtoAcc is best suited for larger data objects (≥4KB) [53], but this does not transpire at all from vendors' datasheets. Blindly offloading to *any* accelerator is not an option either, because this can end up degrading system performance. For instance, for workloads comprising long strings, ProtoAcc can perform worse than a regular Xeon server, because the accelerator is bottlenecked by memory-intensive operations [53].

Second, in the implementation stage, software engineers want to know how they can best optimize their code for the chosen accelerator. Ideally, tools like compilers should answer such questions quickly and automatically, but compilers too are hampered by the lack of visibility into accelerator performance. For instance, the TVM compiler [15]—a widely used compiler for deep learning models—takes several hours to optimize code for a target accelerator [16, 58]. This is because the compiler cannot figure out quickly and accurately what latency can be expected when running a specific sequence of instructions on the accelerator. So it generates multiple variants of the code and profiles them on the accelerator itself (or on slower cycle-accurate simulators [7] when the accelerator is not available) to pick the optimal one. This makes optimizing code for accelerators challenging [16, 58], given the large space of candidate code sequences, the fact that providing an accelerator for each compilation run is costly, and that engineering teams often optimize for the next generation of accelerators even before the hardware is available.

Third, when deploying a system, engineers often need *guar-*

antees on performance properties. Consider an autonomous-vehicle driving system that integrates accelerators for real-time image decoding, object detection, and object recognition. To guarantee safe navigation in all operating conditions, engineers must be able to precisely know, for example, the upper bound on image decoding latency. There exists no good way to "verify" the performance of third-party accelerators today. The state of the art is blackbox testing, which is rarely sufficient, so system designers typically rely on heuristics and accumulated wisdom [35]. Given that accelerators are expected to become ubiquitous [63, 79], this status quo must change.

We argue that hardware accelerators should come with standardized *performance interfaces* [42, 43, 45] that summarize performance behavior just like semantic interfaces summarize functionality. Software engineers routinely use semantic interfaces such as code documentation or header files to quickly find answers to questions like what a system call does, or which library is best suited for their requirements, or how incorporating a library will affect their system's functionality as a whole. Since an accelerator's raison d'être is performance (after all, its functionality could come just as well from software running on a general-purpose processor), performance interfaces are as integral to the correct use of accelerators as are semantic interfaces. As explained above, using an accelerator without a performance interface can fail to deliver on the acceleration promise, or even make performance worse.

We propose a new abstraction for representing accelerator performance that makes performance interfaces possible for hardware accelerators; we call this abstraction a *Latency Petri Net* (LPN). An LPN distills only the performance-relevant details of a circuit and excludes all other information, such as functionality. This distillation enables LPNs to serve as a high-fidelity intermediate representation (IR) of a circuit that is *performance-equivalent*: it takes the same inputs as the original circuit, and its performance behavior matches that of the original circuit. The semantics of the LPN circuit's outputs, however, are different. We envision accelerator developers manually producing the LPN as part of their regular design process, and shipping it with the accelerator. We show that doing so is both straightforward for accelerator developers (takes a few hours) and enables them to better understand and debug their own designs. We also show that the LPN of an accelerator need not disclose proprietary intellectual property.

We develop *a toolchain* (ltc) that, based on an accelerator's LPN, automatically produces performance interfaces in the form of simple, human-readable Python programs. Software engineers can use these interfaces to make informed decisions at the system design stage without needing to write code or to purchase the accelerator. ltc also provides a performance simulator that helps engineers understand how to optimize their code. Since the LPN distills only performance-relevant details, ltc's performance-only simulator is orders of magnitude faster than its state-of-the-art cycle-accurate counterparts that also simulate functionality. Finally, ltc also provides a formal verification tool that enables software engineers to prove key performance properties before deploying their systems (e.g., latency bounds for a specific but potentially infinite class of workloads). Our toolchain prototype works well for fixed-function ASICs (e.g., TPU [49] or the accelerators on SoC-based SmartNICs [4, 9, 53]) and simple programmable accelerators. General-purpose programmable accelerators (e.g., GPGPUs) are left for future work.

We demonstrate ltc's effectiveness on accelerators used for deep learning, serialization of RPC messages, JPEG image decoding, genome sequence alignment, and on a Reconfigurable Match Tables (RMT) pipeline used in programmable network switches. We show that the LPN intermediate representation can precisely capture the latency and throughput of various accelerators. Even after LPN simplifications that trade accuracy for simulation performance, we show that the IR still has an average performance-prediction error of only 1.7% across all accelerators. We present a variety of use cases for the resulting performance interfaces and LPNs, including: enabling informed decision-making during the system design stage without requiring elaborate benchmarking; cycle-level performance simulation that is up to 7821× faster than state-of-the-art cycle-accurate simulators, enabling ML compilers to generate code optimized for the accelerator in seconds instead of hours; and using formal verification to gain confidence in an accelerator's performance before deploying it in production.

The rest of this paper is organized as follows: We provide an overview of our proposed solution (§2), then define the new LPN abstraction (§3) and describe the ltc toolchain (§4). We then evaluate ltc experimentally (§5), discuss further ideas (§6), present related work (§7), and conclude (§8).

2 Design Overview

To help software engineers reason precisely about accelerator performance, we introduce the Latency Petri Net (LPN) intermediate representation: an abstraction of the accelerator's implementation that is *performance-equivalent*, i.e., its performance behavior (but not functional output) matches that of the original circuit. We then propose a workflow that uses the LPN to answer key questions about accelerator performance at the system design, implementation, and deployment stage via an extensible toolchain that we call ltc.

The LPN is inspired by classic Petri nets [69], a class of graphs used for the description and analysis of concurrent systems and processes. They are used in various domains, including the design and verification of digital asynchronous circuits. We define the LPN in §3, and Fig. 2 shows an example.

Petri nets are a good starting point for the LPN abstraction, because the key challenge in reasoning about hardware performance is not reasoning about the individual components but rather about the end-to-end performance that emerges when these components (e.g., multiple pipeline stages) operate together, in parallel. Petri nets were designed to model concur-

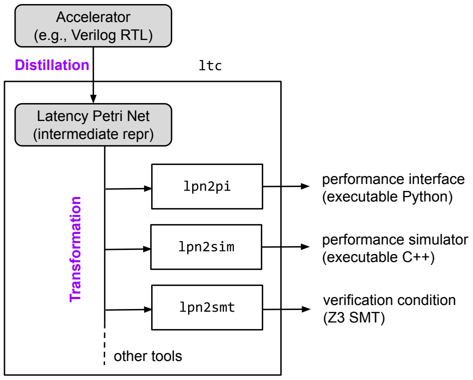

Figure 1: Proposed two-phase workflow: Hardware engineers distill their accelerator design into an LPN IR, and tools transform automatically this IR into the forms desired by accelerator users.

rent systems, and they can precisely capture hardware's inherent parallel and asynchronous execution.

Using a Petri net-like representation also ensures that the LPN is easy for accelerator developers to produce. This is because, when generating an LPN, accelerator developers do not need to reason about the impact of parallel execution on performance, rather they only need to (abstractly) represent the individual components and their local interactions. The ltc toolchain takes the final step to fill in the gaps and turn the LPN into forms that can be consumed by humans.

Fig. 1 illustrates our proposed workflow, consisting of two stages that produce and consume the LPN IR, respectively. The first stage (*distillation*) involves manually translating the accelerator's design into its corresponding LPN (we describe this in §3.3). We propose that distillation be performed by accelerator developers as part of their regular design process, but one could also imagine tools that translate Register-Transfer Level (RTL) designs into LPNs. Since the definitive clock frequency of the circuit is decided in the post-RTL synthesis stage, the LPN abstraction represents execution latency in terms of cycles (i.e., an RTL-level metric), not wall-clock time. The latter is easily calculated once the frequency is known.

The second stage of the workflow (*transformation*) automatically processes an accelerator's LPN into actionable information about accelerator performance. The ltc toolchain consists of several tools: lpn2pi summarizes the performance of the accelerator into human-readable, executable Python programs that enable software engineers to make informed development decisions without purchasing the accelerator or porting their code to it. lpn2sim produces an executable simulator of the LPN that developers and tools can use for fast performance simulation while optimizing their code. lpn2smt translates the LPN together with a user-provided performance property into a verification condition and passes it to the Z3 constraint solver [22] for a proof or refutation of the property.

This two-staged workflow—distilling the accelerator design into a performance IR and then transforming the IR into answers to specific questions about performance—provides flexibility and customizability. Since the LPN is a universal and accurate representation of the accelerator's performance, it can be transformed into answers to arbitrary questions about the accelerator's performance. We envision the set of tools in ltc expanding over time, to address other questions one might ask about an accelerator's performance.

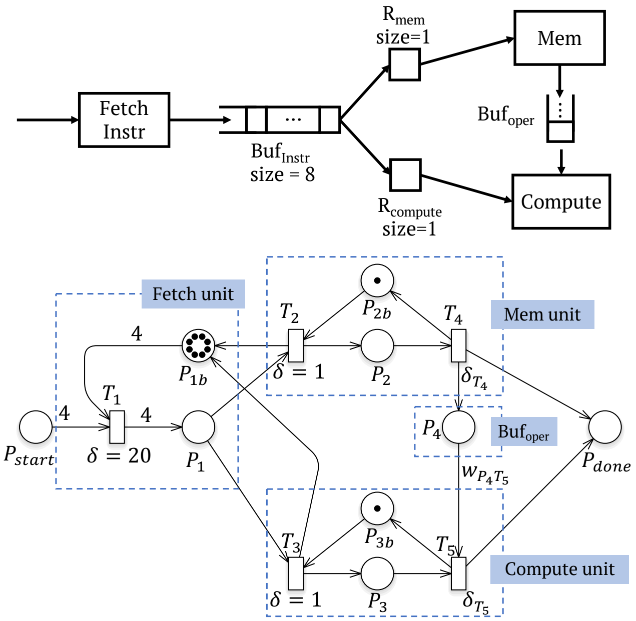

Figure 2: Example hardware pipeline (top) and its LPN (bottom). This is a simplified version of the deep-learning accelerator in §5.

3 The Latency Petri Net Abstraction

We now define the LPN abstraction, first at a high level (§3.1) and then more precisely (§3.2); a complete formal definition is beyond the scope of this paper. We then describe step-by-step how to distill an accelerator design into its corresponding LPN (§3.3). Finally, we discuss the use of LPNs to model components surrounding accelerators, such as memory and interconnects (§3.4).

3.1 LPN Overview

To illustrate the LPN concept, we use the simple hardware pipeline shown in Fig. 2. It consists of a fetch unit that brings instructions into an instruction buffer, followed by an in-order dispatch to a memory and a compute unit. The memory unit fetches the operands for compute instructions from memory into an operands buffer. The memory and compute units operate in parallel, i.e., the memory unit can fetch operands for a future compute instruction while the compute unit is still processing the current instruction. Each unit operates on one instruction at a time, stored in each unit's local register (R_{mem} respectively $R_{compute}$) until the unit finishes processing it.

The memory and compute units have variable latencies d_{mem} and d_{comp}, respectively, that take into account the instruction type and when the operand was last accessed. For simplicity of presentation, we fix the fetch unit's latency to 20 cycles (fetches 4 instructions at a time), set the instruction buffer's maximum size to 8, and let the operands buffer have infinite capacity, unlike in a real accelerator.

Reasoning about the latency of a sequence of instructions is challenging, even for such a simple pipeline, due to the fetch, memory, and compute units operating in parallel. Parallel execution can both hide latencies (e.g., loads that bring in the operands for future compute instructions may complete before the current compute instruction) and introduce stalls (e.g., in the fetch unit due to back pressure when the memory and compute units drain the instruction buffer too slowly).

The bottom half of Fig. 2 illustrates the LPN for this simple pipeline. The LPN is a directed graph with two kinds of vertices: *places* (circles) and *transitions* (rectangles). Adjacent vertices in the LPN must be of different kinds, i.e., edges in the graph can only connect places to transitions and vice-versa. Each place in the LPN contains *tokens* (solid black dots) that collectively represent the state of the circuit, and tokens are stored and consumed in FIFO order.

An LPN models how data flows through a circuit by *enabling* transitions. Each transition has a *guard* (not shown) that determines whether the transition is enabled or not, a *delay* (δ) that specifies the duration of the transition in cycles, and a *producer* function (not shown) that generates new tokens. Once a transition is enabled, after the number of cycles indicated by the delay, it *commits*, i.e., atomically consumes input tokens and produces output tokens. We define each of these operations precisely in the next section.

In Fig. 2, we show the correspondence between the circuit blocks and the subgraphs of the LPN. For some of the LPN details, such as the transition delays, one needs to consult the RTL of the accelerator (not shown). The LPN at the bottom is an abstract representation of a circuit that is performance-equivalent to the one at the top: (1) it operates on the same inputs, using a function (not shown) that converts instructions to tokens in the special place P_{start}; and (2) given any input, the number of cycles it takes the LPN to deposit the last token in P_{done} corresponds to the number of cycles the upper circuit takes to produce its output. However, the LPN's output tokens are meaningless other than indicating completion.

3.2 LPN Definition

In essence, an LPN models a system of queues connected by logic units that consume tokens originating from multiple input queues and generate tokens for designated output queues. The LPN is a directed dataflow graph in which places P_i represent the queues, and transitions T_j represent the logic units. Edges directed from places to a transition are the transition's input edges, while those directed from the transition to places are its output edges. We equip the LPN with a timestamping machinery CLK to denote when each token in the system was produced—this is a key ingredient for modeling performance.

An LPN state $S = ((s_1,\dots,s_n),t)$ is a tuple consisting of a collection $s_1,\dots,s_n$ of sequences s_i representing the in-flight tokens corresponding to places $P_1,\dots,P_n$, and one global non-negative number t, the current value of CLK. A token $k = (p,ts)$ is composed of a map $k.p$ of key-value pairs and a timestamp. Each key in $k.p$ is the name of a property of k. Each token has a type, determined by the set of properties (but not values) that tokens of that type have. All tokens in a particular place have the same type. The timestamp $k.ts$ denotes the CLK value when token k was produced. By construction, the timestamp $k.ts$ of any token in a reachable state S is $k.ts \leq S.ts$. The tokens in a place are always consumed in FIFO order, which is why $s_1,\dots,s_n$ are sequences and not mere sets.

A transition $T = (\gamma,\delta,\pi)$ is a tuple of three functions: a guard γ, a delay δ, and a producer function π. The guard decides when T is ready to execute: $T.\gamma$ reads (without consuming) a subset of the tokens present in T's input places and returns *NotReady* if the transition cannot execute at this time. If it can, then the guard returns $Enabled(w_1,...,w_k)$ with weights w_i. To execute, the transition locks the first w_1 free tokens from its 1st input place, the first w_2 free tokens from its 2nd input place, and so on. The guard must guarantee that $\forall i, w_i$ is less than or equal to the number of free (not locked) tokens already present in the transition's ith input place.

When a guard $T.\gamma$ switches from *NotReady* to *Enabled*, thus enabling T, the transition does not immediately consume the tokens but rather locks them for $T.\delta$ cycles. The lock means that no other transition is allowed to consume those tokens. At the end of the delay $T.\delta$, the transition commits: the locked tokens are atomically removed from T's input places, and the tokens produced by $T.\pi$ are pushed to the output places, with the current CLK (commit time) as their timestamp. Both the delay $T.\delta$ and the producer $T.\pi$ are arbitrary functions of all the input tokens that the transition promises to consume.

To avoid race conditions when two transitions share an input or output place, we require that the two transitions never be simultaneously enabled. The value of a guard $T.\gamma$ is not allowed to change between the moment it switches to *Enabled* and the moment when $T.\delta$ has elapsed (and T commits).

LPN Semantics. Given an initial LPN state $S_0 = ((s_1,\dots,s_n),0)$ with all the tokens in $s_1,\dots,s_n$ having a timestamp equal to 0, we define the semantics of the LPN starting from S_0 as the potentially infinite sequence of states inductively defined by $((s_1,\dots,s_n),t) \rightarrow ((s'_1,\dots,s'_n),t')$.

The next state of an LPN is obtained by applying the effects of all the transitions that are enabled at CLK $= t$ and known to be ready to commit at CLK $= t'$. For a transition T_i to belong to this group, it must be that the guard $T_i.\gamma$ returned *Enabled* at time $\leq t$, its input tokens locked in the corresponding places were produced before T_i started (i.e., the highest timestamp of those tokens is $ts_{\max} = t' - T_i.\delta$), and the earliest time when T_i can commit is t'. All transitions known to be ready to commit at t' commit as a group, and they advance the LPN from $((s_1,\dots,s_n),t)$ to $((s'_1,\dots,s'_n),t')$. When no more transitions can ever commit, the LPN has reached its terminal state.

In an LPN, it is possible that $T_i.\delta = 0$. If a commit at t' enables such a 0-delay transition, T_i will also commit at t', even if this was not previously apparent, i.e., T_i was not previously "known" to be ready to commit at t'. Thus, after the first commit, the LPN transitions $((s_1,\ldots,s_n),t) \rightarrow ((s'_1,\ldots,s'_n),t')$, and subsequently it transitions $((s'_1,\ldots,s'_n),t') \rightarrow ((s''_1,\ldots,s''_n),t')$, i.e., there are multiple states with the same timestamp. The process repeats until no more transitions can commit at t'.

LPNs are reminiscent of several extensions of Petri nets [46, 69, 86], mixing the notion of timestamp and information-carrying tokens with enforced FIFO ordering between tokens. With an LPN, we can accommodate the different modeling needs of hardware accelerators, while keeping the underlying models formal and machine-analyzable. We designed the LPN to provide a favorable trade-off between compactness, analyzability, expressivity, and ease of manipulation for our different uses and tools. We chose the name "latency Petri net" to acknowledge the inspiration we drew from Petri nets, without implying a theoretical equivalence.

3.3 Distillation: From RTL to LPN

We now describe how a hardware engineer can represent the performance of an accelerator using an LPN.

Distilling an accelerator's register-transfer level (RTL) representation into its corresponding LPN is an element-wise, structural conversion of the RTL: FIFO buffers in the RTL become LPN places, and RTL compute elements become LPN transitions. Transitions can operate in parallel (if enabled at the same time), so the engineer can produce the performance-equivalent representation by analyzing in isolation the latency of each stage of the accelerator pipeline. The LPN then glues back together this stage-by-stage performance decomposition.

RTL-to-LPN distillation is a five-step process; we describe each step in reference to the example in Fig. 2.

Step 1 involves listing the places and transitions that map directly to elements in the RTL: places P_1, P_2, P_3, P_4 correspond to the four buffers/registers, transitions T_1 to T_5 correspond to the three units that consume/produce from/to those buffers plus the two copy actions of instructions to the registers $\mathrm{R}_{\mathrm{mem}}$ and $\mathrm{R}_{\mathrm{compute}}$. The latter two are not explicit computations in the block diagram but are units in the RTL source code.

Step 2 involves defining the guard functions and the corresponding weights. For many transitions, becoming *Enabled* simply requires the presence of a specific number of tokens in an input place; their guards do not look at the properties of those tokens (e.g., $T_4.\gamma$ and $T_5.\gamma$). Occasionally, guards may depend on the values of token properties: $T_2.\gamma$ (respectively $T_3.\gamma$) will be *Enabled* if and only if the first free token in P_1 has a value corresponding to a memory (respectively compute) instruction, because instructions are dispatched in order.

Most weights returned by the guards are constants (e.g., $w_{T_1P_1} = 4$ because the fetch unit fetches 4 instructions at a time, and $w_{P_1T_2} = w_{P_1T_3} = 1$ because both registers store 1 instruction at a time). Default weights of 1 are not shown in Fig. 2. Occasionally, weights may depend on the values of token properties: $w_{P_4T_5}$ determines the number of operands transition T_5 reads, and it is a function of the value of the property of the token in P_3 that specifies the type of instruction. In both cases, the weights are intuitive for accelerator developers to define, because they directly correspond to an architectural quantity: the rate of consumption of tokens in the dataflow. This also illustrates why weights need to be computable based on tokens from all of a transition's input places.

Step 3 involves defining the delay and producer functions for each transition. The delay typically comes straight from the RTL. The producer function produces tokens with just those property values that are strictly necessary for the LPN to accurately model performance—performance-irrelevant should be discarded.

Step 4 involves modeling backpressure by adding capacity constraints to each place in the LPN. Take for example the *Mem* unit: we add an extra "capacity place" (P_{2b}) with a fixed initial number of "capacity tokens", corresponding to the capacity C of the buffer in question (1 token for P_2); this is a classic Petri net pattern [46]. The capacity place is connected to the transitions incident on the original place (T_2 and T_4), but in reverse, to form a loop. We adjust T_4's producer function to also produce 1 capacity token into the capacity place P_{2b}, and T_2's guard to require that there be at least 1 capacity token in P_{2b} to enable T_2. This way, when T_2 first commits and consumes the initial token in P_{2b}, it cannot commit again until T_4 has committed and deposited a capacity token in P_{2b}. This models the *Mem* unit backpressure: no new instruction will be copied into $\mathrm{R}_{\mathrm{mem}}$ until the previous memory instruction has finished processing. The same pattern is applied, for instance, to the P_1 place representing the instruction buffer ($\mathrm{Buf}_{\mathrm{instr}}$), except that there are two consumers for $\mathrm{Buf}_{\mathrm{instr}}$ and the capacity is $C = 8$, thus 8 initial tokens in P_{1b}.

Finally, step 5 involves adding *start* and *done* places (P_{start} and P_{done}), and placing the initial tokens. The hardware engineer then provides a "tokens from input" function Ψ to translate the accelerator's input to the LPN tokens placed in P_{start}. A stream of input data (e.g., an image) can be split into task units (e.g., individual blocks), and each task becomes a token that is placed inside P_{start}. Depending on the accelerator's semantics, a task token could also be an instruction, a short DNA sequence, etc. When the processing of a task completes, a "done token" k_{done} should be produced into P_{done}.

Constructing LPNs is a natural fit for accelerator development workflows and a materialization of what hardware engineers already have in mind, i.e., a more detailed architectural diagram annotated with latency expressions. Compared, for instance, to building a simulator, producing an LPN is easier, because the accelerator functionality is abstracted away. ltc provides a Python library with built-in types for places, transitions, edges, etc. that engineers can use to write the LPN.

We asked a hardware engineer to produce an LPN for the Menshen RMT pipeline used in programmable network switches [82]. After taking 3 days to understand the RTL design, he produced the corresponding LPN (which we evaluate in §5) in less than 3 hours. This suggests that the manual distillation step is indeed straightforward for someone who understands the accelerator's design. The same engineer also mentioned that writing the LPN actually helped to better understand the performance behavior of the circuit.

Finally, in most cases, LPNs do not leak much proprietary information about the accelerators. Except for the latency details, an LPN reveals no more information than the high-level architectural diagrams, which are often made public anyway. No implementation details appear in the LPN.

3.4 Memory, Caches, and Interconnects

Accelerators are often part of a larger system, and their performance is influenced by the components surrounding them, such as memory, caches, and interconnects. LPNs can be used to model these components as well. However, they provide fewer benefits over other kinds of performance models than they do for accelerators.

First, LPNs can be constructed even without a reference RTL implementation, by speculatively modeling the internals of a hardware component based, for instance, on documentation and online posts. We built an LPN for a sophisticated PCIe interconnect based on documentation alone, and we describe this example in §5.

Second, modeling complex memory hierarchies is challenging, because semantics are tightly intertwined with performance: the latency of a cache access depends on which entries are present in the cache or not, and knowing this requires tracking the specific contents of the cache, which in turn requires modeling the semantics of the cache in more detail than for most accelerators. This is an example where the ability of an LPN to abstract away functionality is limited, and thus its advantage over, say, a cycle-accurate simulator is reduced. One could model the state of the entire cache with a single token, and each cache line would be an individual property of that token. This LPN, though, would likely be more complex than what the ltc toolchain was designed for.

Nevertheless, an LPN can still abstract away some semantic details of the memory hierarchy and be productively used, for instance, to model and reason about the parallelism within the memory subsystem. If we took the RTL of a cache and distilled it into an LPN by following the steps discussed in §3.3, we could model the cache's internal logic (without taking into account cache state) and simulate it with lpn2sim. This could help reveal that a particular cache design can only handle 1 cache hit every 2 cycles, whereas a better design could handle a cache hit every cycle, through pipelining. The pipeline design does influence cache performance, even if not as much as replacement strategy and associativity configuration do. An LPN can help fine-tune the pipeline design.

4 Transforming the LPN

The LPN is an abstraction that is *performance-equivalent* to the accelerator; nevertheless, it is not easy to read for those unfamiliar with the accelerator's implementation details. As a result, it is not directly useful to software developers who want to use the accelerator in their systems. We now describe how the ltc toolchain bridges this hardware–software gap by transforming the LPN into representations that software developers can use in the different stages of system development.

The ltc toolchain currently consists of three main tools: (1) lpn2pi, which transforms the LPN into human-readable performance interfaces in the form of executable Python programs, which are meant to be read as much as executed; (2) lpn2sim, which merges the LPN with a simulator skeleton to produce an executable simulator that both developers and tools can use for fast performance simulation; and (3) lpn2smt, which translates the LPN together with a user-provided performance property into verification conditions that can be proven or refuted using an SMT solver, to provide performance guarantees before the system is deployed. ltc also provides other, simpler tools that we do not describe here, such as lpnviz, which produces a visualization of the LPN that hardware developers can use to better understand and debug the accelerator. We envision both hardware and software engineers contributing more such tools to ltc over time.

While the lpn2sim simulator (just like the RTL) operates on *concrete* inputs, both lpn2pi and lpn2smt produce outputs—performance interfaces and verification conditions, respectively—that describe performance for an *abstract, symbolic* input. Since the space of all possible inputs to an accelerator is large, often infinite, producing complete performance interfaces or verification conditions is intractable for most LPNs, due to the path explosion problem [11]. We circumvent this challenge by introducing the notion of *input classes* for LPNs, which partition a given input space into input sets for which, individually, it is feasible to produce complete performance interfaces and verification conditions. We now describe how input classes partition an input space (§4.1), and then describe lpn2pi (§4.2), lpn2sim (§4.3), and lpn2smt (§4.4).

4.1 Input Classes for lpn2pi and lpn2smt

To use the lpn2pi and lpn2smt tools, one must first constrain the input space to the one of interest. For example, for the JPEG Decoder, the user might include all images up to a given maximum size (number of pixels × pixel depth in bits) and exclude all others. This input space is then partitioned by an ltc tool into *input classes*, with lpn2pi and lpn2smt then solving the problem for each class independently. This ltc tool employs symbolic execution [13] to partition the input space.

Intuitively, an *input class* is a group of inputs for which simulating the LPN will cause (1) each transition in the LPN to commit exactly the same number of times for all executions corresponding to inputs in that class; and (2) the n^{th} commit of each transition will consume and produce the same number of tokens in all executions, for all values of n. (An "execution" is a complete simulation of the LPN from CLK=0 until it deposits the last k_{done} token into P_{done}.) For example, if executing the LPN with an input from a class causes transition T to commit twice during the execution, consuming 3 tokens for the 1st commit and 4 tokens for the 2nd commit, then executing the LPN with any other input from that class must also cause T to commit twice and to consume 3 tokens for the 1st commit and 4 tokens for the 2nd commit. The tokens consumed and produced in different executions must have the same type (§3.2), but can have different property values. Commits of different transitions can be interleaved arbitrarily in different executions for inputs in a class; the only thing that matters is the commit and token counts. §A.1 in the Appendix contains a formal definition of input classes.

Input classes are defined such that all inputs in any given class impose the same pattern on the trace resulting from the simulation of the LPN. The tools leverage this commonality to do their analysis once per pattern (which could subsume many inputs). Even though input classes are not defined based on human-understandable semantics of the accelerator's input, they often do correspond to input types that are intuitive for users. For example, for the Protoacc LPN (§5), all messages of a given format constitute one input class. For the JPEG decoder LPN (§5), all images of the same size form a separate input class.

As mentioned, ltc includes a preprocessing tool for automatically partitioning the user-specified input space into input classes. It symbolically executes the LPN in a special way and partitions the input space into sets. One input class can possibly span multiple sets, but a set never contains inputs from more than one input class. Then, by operating on each set in isolation, lpn2pi and lpn2smt can avoid path explosion and are trivially parallelizable by input set. Please see A.2 in the Appendix for details of how input classes are generated.

4.2 lpn2pi

The lpn2pi tool transforms the LPN into human-readable performance interfaces represented as executable Python programs, in the spirit of [42, 43]. The performance interface takes the same inputs as the accelerator (e.g., a stream of network packets, multiple RPC messages, a long DNA sequence) and returns the start-to-end latency (i.e., total execution cycles) it would take the accelerator to process that input. The performance interface describes the start-to-end latency not with concrete numbers but with *formulae*, as introduced in [44] but expressed in terms of properties $k.p$ of initial tokens k in the accelerator's LPN. The performance interface returns a single formula per input class. We show examples of lpn2pi-extracted performance interfaces in Figs. 4 - 7.

lpn2pi does not aim for fully precise performance interfaces—while the LPN has suitable constructs to precisely represent the accelerator's asynchrony and parallelism, reflecting these in a precise, closed-form, human-readable formula is typically intractable. Instead, lpn2pi *approximates* the accelerator's start-to-end latency, trading precision for human readability and closed-form expressions. Approximation turns out to be sufficient, because we expect performance interfaces to be used mostly during the system design stage, when software engineers are interested in coarser-grained descriptions of performance. In §5, we show that, while approximate, lpn2pi-extracted interfaces nevertheless enable informed decisions at the design stage, such as choosing the accelerator configuration that fits best a particular workload profile.

The following three assumptions underlie the approximation made by lpn2pi: (1) The size of the input is large enough so that the accelerator's pipeline is almost always full, i.e., the time spent filling and draining the pipeline is a negligible fraction of the overall start-to-end latency; (2) For all inputs in any given input class, the accelerator has the same bottleneck, i.e., the stage in the accelerator's pipeline (or transition in the LPN) that incurs the longest delay is the same for all inputs in that class; and (3) The bottleneck in the accelerator pipeline is stable, i.e., it does not shift from one pipeline stage to another during the processing of an input.

We define the effective delay ε_T of a transition T in an execution of an LPN as the product $N \times \overline{g}_T$ of the number of times N the transition commits in that execution and the average duration between consecutive commits of that transition (called average commit gap $\overline{g}_T$). The transition with the largest effective delay is deemed to be the bottleneck. Based on the three assumptions above, lpn2pi approximates the start-to-end latency to be the effective delay ε_T of the bottleneck transition (i.e., of the bottleneck stage of the pipeline). Recall that the definition of an input class (§4.1) requires the number of times each transition commits in an execution to be the same for all inputs in that class. So, given an input class and a transition T, N is a constant for all inputs in that class. However, $\overline{g}_T$ is a symbolic expression parameterized by properties of the initial tokens, so ε_T is also a symbolic expression.

Determining ε_T for each transition comes down to determining the respective $\overline{g}_T$. Note that $\overline{g}_T$ does not necessarily equal $T.\delta$, because a transition may be stalled for an arbitrary number of cycles (due to its input places not having enough tokens) or it could be non-blocking and become enabled again before it commits (i.e., commit multiple times in parallel).

Accurately estimating the average commit gap $\overline{g}_T$ is challenging in LPNs with loops. In a loop-free LPN, $\overline{g}_T$ for all transitions is just the maximum of all transition delays. But with loops, this simple method is no longer accurate. Consider a simple loop $P_0 \rightarrow T_1 \rightarrow P_1 \rightarrow T_2 \rightarrow P_0$, with initially a single token in P_0 and none in P_1. Every time T_1 commits, it subsequently has to wait for T_2 to commit before it can be enabled again (and T_2 also has to wait for T_1), so the average commit gap for both T_1 and T_2 is the sum of the delays of T_1 and T_2.

To approximate the $\overline{g}_{T_i}$ of all transitions T_i in a loop, we define the loop delay Δ and a parallel factor F_{T_i} for each transition T_i in the loop—we estimate $\overline{g}_{T_i}$ as Δ/F_{T_i}. Here is why: Consider a simple loop that has only one place with M initial tokens. Δ is the time it takes for the M initial tokens to complete a full iteration around the loop, with all transitions committing at least once. Recall that transitions are non-blocking, in the sense that a transition T_i, once enabled, could become enabled again before it commits, if the configuration of free tokens in its input places changes such that $T_i.\gamma$ is satisfied once again. As a result, there can be multiple instances of the same transition enabled at the same time. By F_{T_i} we denote the maximum number of instances of T_i that can be simultaneously enabled. Increasing levels of concurrency proportionally reduce the gap between successive commits, so we estimate the average commit gap for T_i as $\overline{g}_{T_i} = \Delta/F_{T_i}$.

lpn2pi starts out by setting $\overline{g}_T$ $=T.\delta$ for each transition T in the LPN; if $T.\delta$ is a general function on input tokens, $\overline{g}_T$ is the corresponding symbolic expression. Then, for each loop in the LPN, lpn2pi computes Δ and the F_{T_i} factors, and then it recomputes $\overline{g}_{T_i}$ = $\max(\overline{g}_{T_i}, \Delta/F_{T_i})$ for each T_i in that loop. Once lpn2pi has treated each loop once, we say that it has completed one iteration of the process. Dependencies among loops and the order in which the loops are treated can influence the estimated $\overline{g}_{T_i}$ values, so lpn2pi continues iterating in order to improve the estimates. The current version of lpn2pi stops after a fixed number of iterations that is configurable (default 10). In the next version, lpn2pi will automatically stop when the $\overline{g}_{T_i}$ values stabilize, i.e., do not change from one iteration to the next by more than a configurable threshold. Comparing changes at the level of symbolic expressions (which is what some $\overline{g}_T$ values are) is fundamentally hard, so lpn2pi will instead compare concrete values of these expressions, obtained by randomly sampling the input class and computing the corresponding concrete values of the expressions. Once iterative estimation is complete, lpn2pi derives the start-to-end latency formula as the maximum of the ε_T expressions (i.e., $max_{T_i}(N \times \overline{g}_{T_i})$. lpn2pi then uses `sympy` [61] to simplify the formula to obtain an expression that is easier for humans to read.

lpn2pi repeats the process described in the previous paragraph for each input class, after which it emits the corresponding interface program in Python, in the form seen in Figs. 4 - 7.

Please refer to A.3 in the Appendix for more details on the computation of ε_T, Δ, F_{T_i} and on the underlying assumptions.

4.3 lpn2sim

For a given LPN, the lpn2sim tool produces a bespoke cycle-level performance simulator that can be used by both engineers and tools. As we show in §5.3, the LPN's power of abstraction enables lpn2sim-generated simulators to simulate performance orders-of-magnitude faster than state-of-the-art cycle-accurate simulators.

lpn2sim's simulator is event-driven and works as follows: In step ⓪, it sets the value of CLK to zero, and then repeatedly performs the following two steps to make forward progress. In step ①, the simulator finds all transitions that can commit at the current CLK value. If more than one can commit, the one with the smallest ID is committed first. The simulator repeats this step until no transition can commit at the current CLK value. In step ②, the simulator finds the next earliest timestamp at which a transition can commit. If no transition can commit, the simulation terminates. Else, the simulator updates the CLK to that timestamp and goes back to step ①.

lpn2sim automatically translates the LPN (described by hardware engineers using our Python API) to an equivalent C++ program. It first emits equivalent place and transition objects in C++, and then translates individual delay, guard, and output functions. To make such automatic translation of delay, guard, and output functions feasible, our Python API only allows arithmetic operations and conditionals within these functions; this proved sufficient for all the accelerators we evaluated. lpn2sim then combines the translated LPN code with a simulator skeleton we wrote in C++ and compiles to an executable.

4.4 lpn2smt

The lpn2smt tool is used to formally reason about performance properties of an accelerator based on its LPN. It has three inputs: the target LPN, the input space Υ, and a query Φ. The Υ parameter is the subspace of inputs that are of interest to the user. lpn2smt currently supports queries related to latency bounds of two kinds: what is the upper (lower) bound on latency, or can you prove/disprove expression $\phi(x)$ involving latency x. An example of the latter, which we use in our evaluation, is $\phi(x) : |(E-x)/x| < 0.2$, where E is an expression taken from an (approximate) performance interface. This asks for a formal proof that E is within 20% of the true latency for all possible inputs and, if not, asks for a counter-example. lpn2smt can be extended to support other kinds of queries too.

lpn2smt first partitions Υ into input classes (§4.1), then derives based on the LPN a precise SMT expression Λ_i for the start-to-end latency for each input class i. Then it pieces together a global latency expression for the entire input subspace Υ as $\Lambda_\Upsilon = \mathsf{ite}(C_1, \Lambda_1, \mathsf{ite}(C_2, \Lambda_2, \mathsf{ite}(...)))$ using the if-then-else ite operator supported by SMT solvers like Z3 [22] and the inputs constraints C_i that define the corresponding input classes. Note that this is a precise expression, not like lpn2pi's approximations meant to be human-readable.

For the first kind of query, lpn2smt passes Λ_Υ to the SMT solver's optimizer and asks for a formally verified upper (lower) bound on Λ_Υ. For the second kind of query, lpn2smt passes $\phi(\Lambda_\Upsilon)$ to the SMT solver and returns either a formal confirmation that it is true or a counter-example.

The SMT expression Λ_i for input class i is constructed as follows: Let N_i be the number of transition commits in an execution from this class; by the definition in §4.1, there is a unique N_i for each input class i. lpn2smt instantiates N_i symbolic timestamps CLK_1, CLK_2, ... corresponding to when the transitions committed—the start-to-end latency will be $max_{j=1..N_i}\{\text{CLK}_j\}$. To compute this expression, lpn2smt instantiates for each commit j the consumed tokens, and places them in the corresponding input places. For each such token k, lpn2smt sets $k.p$ and $k.ts$ to symbolic values constrained to reflect the relationship to CLK_j. Recall that the number of tokens produced/consumed by a transition is the same for all inputs in a class (§4.1). Then lpn2smt uses the "tokens from input" function Ψ (applied to a suitably constrained symbolic input from this class) to obtain the initial tokens, and places them in P_{start}. It then uses the transitions' producer functions to instantiate the transition-produced tokens into the corresponding places. For each initial and produced token k, lpn2smt constrains $k.p$ and $k.ts$ according to the function that produced it and the respective $T.\delta$ and CLK_j. Then, lpn2smt captures the constraints resulting from the fact that every consumed token must either be an initial token or one resulting from a commit. The constraints that result are propagated to CLK_1, CLK_2, ..., and finally lpn2smt computes $\Lambda_i = max_{j=1..N_i}\{\text{CLK}_j\}$.

In summary, the LPN is a generic IR that is performance-equivalent to the accelerator circuit and can be transformed by tools into higher level representations useful to software engineers. In this section, we presented three of the tools in the ltc toolchain: lpn2pi, lpn2sim, and lpn2smt. We envision both hardware and software engineers contributing more such tools to ltc, increasing its usefulness over time.

5 Evaluation

In this section, we evaluate ltc on several accelerators and show that it answers the questions mentioned in §1. We first describe our experimental setup (§5.1), then present fine-grained results that shed light on detailed aspects of LPNs (§5.2), and conclude with higher-level results (§5.3).

5.1 Experimental setup

We evaluate ltc on 5 accelerators (Table 1), each representative of a particular class of accelerators. We require access to the RTL, so the evaluation is limited to open-source accelerators.

Apache VTA (Versatile Tensor Architecture) [2] is a deep-learning accelerator with a compiler stack based on TVM [15]. The accelerator incorporates tensor cores that perform vector or matrix operations. The design includes parallel units for compute, load and store operations, which decouples memory accesses from the compute, to hide memory latencies [74]. VTA can be used to program arbitrary dataflows when executing the deep-learning model. Certain high-level machine learning operations can be implemented with different VTA instruction sequences. Each instruction sequence exhibits different performance, and so TVM (VTA's compiler) generates multiple instruction sequences and selects the best performing one. This process is called auto-tuning. Our evaluation uses a workload consisting of 1,500 instruction sequences generated from auto-tuning ten 2d convolution tasks from ResNet-18 [34], an 18-layer deep convolutional neural network commonly used to measure auto-tune latency and inference speed.

Accelerator	Domain	Workload	LOC
VTA [2]	Deep learning	Autotune ResNet-18 [34]	6,628 Chisel
Protoacc [53]	RPC message serialization	Hyperprotobench [31] and microbenchmarks	3,197 Chisel
JPEG [80]	Image decoding	30K Flickr [51] and 30K Div2k [50]	7,003 Verilog
Darwin [20]	Bioinformatics	10 DNA test sequences [21]	1,535 Verilog
Menshen [82]	Programmable P4 switch	3 Verilog testbenches (with up to 100 packets)	11,169 Verilog + 4,318 VHDL

Table 1: Open-source accelerators used for evaluating ltc.

Protoacc [53] is a hardware accelerator developed by Google for protocol buffers [71] and integrated into a RISC-V SoC. We only consider Protoacc's serializer, which is the most interesting part of Protoacc: multiple fields within a message are serialized in parallel within the accelerator. Deserialization is sequential and thus less interesting. As in the evaluation of the ProtoAcc paper [53], we use the Hyperprotobench benchmark [31] and their microbenchmarks to measure serialization performance of both large messages (>1MB) and small messages (<1KB). While Protoacc's standard testbench includes a complex memory subsystem (with caches, DRAM, and TLB), we are only interested here in the performance of the accelerator itself, i.e., what a vendor would provide an LPN for. Therefore, in the empirical measurements, we warm up and overprovision the caches and TLB to prevent them from disturbing the performance of the accelerator.

JPEG [80] is an image decoder core for FPGAs written in Verilog. It supports various chroma, fixed and dynamic Huffman tables, DQT tables for JPEG input streams, etc. Our workload consists of the Flickr [51] and Div2k [50] datasets. Each has 30K diverse images, and all images in the Div2k dataset are high-resolution.

Darwin [20] is a GACT (DNA sequence) alignment accelerator. The accelerator has two main stages. The first stage uses a systolic array to fill scores in a 2D score matrix, and the second stage computes alignment actions at each step: insertion, deletion, and match. For the workload, we use ten pairs of test DNA sequences used by the Darwin authors [21].

Menshen [82] is a Reconfigurable Match Tables (RMT) pipeline used in a programmable P4 network switch [12]: incoming packets are processed by flowing through a programmable packet filter, 2 packet header parsers, 5 header processing stages, and 4 header de-parsers. Menshen extends the RMT architecture with isolation mechanisms to ensure that multiple P4 programs running on the same switch do not suffer from performance interference. It spatially partitions its stateful resources (match-action table entries and stateful memories) and uses per-packet configuration overlays for its stateless resources (packet filter, header parsers, header processing stages, and header de-parsers). As workloads, we use Menshen's two original device-level testbenches, plus an additional testbench based on the original but extended to 100 packets. Menshen contains several closed-sourced IP blocks, which restricts some of our experiments.

We ran all experiments on a 2-socket 48-core Intel Xeon Gold 6248R processor with 376 GiB of memory, 1 thread per core, running Ubuntu 20.04.4 LTS with the 5.15 Linux kernel. For the speedup and accuracy baselines, we compare to Verilator [81], the fastest open-source cycle-accurate RTL simulator available today—it generates optimized C++ code from Verilog that is 200–1000× faster than interpreted simulators [81]. We use Verilator v5.010 for all accelerators except for VTA, where we use v4.022, for compatibility reasons. All speedup comparisons are single-threaded. Verilator v4.022 and v5.010 have negligible performance differences on a single thread. We use the Clang-11.1.0 compiler. For the PCIe experiments, we use an AMD Alveo U200 accelerator card connected with a gen3 x16 PCIe interconnect to a host without DDIO.

We build the LPNs for the above accelerators by manually inspecting the RTL source code. The LPNs use tokens to abstractly represent the data of various formats and units that flow through the real hardware. For example, input packets in Menshen are turned into tokens with a property representing the type and length of a packet, each 8×8 image block in JPEG is turned into a token with a property representing the number of non-zero pixels after quantization, each instruction in VTA is turned into a token with properties representing different parts of the decoded instruction, and each field in a message in Protoacc is turned into a token with properties representing the type of the field and field length. LPN transitions represent the different hardware components that operate in parallel, and LPN places represent the buffers.

5.2 Understanding LPNs in detail

We now provide a quantitative deep-dive into the LPN abstraction, and we also describe how hardware engineers can themselves use LPNs to better understand and debug their designs.

5.2.1 Accuracy and completeness of the LPN

As explained in §2, the LPN representation enables accelerator developers to describe performance in terms that are familiar to them, and then rely on the ltc toolchain to translate the LPN to representations palatable to software engineers.

Fig. 3 shows that using the LPN as an IR is justified: across all benchmarks and all accelerators, the average latency prediction error of the simulator generated by lpn2sim based on the LPN is 1.7%. The maximum error never exceeds 10%. For the LPN to be 100% accurate, it would need to retain almost all the RTL-level details, which is unnecessary in practice.

This means that the LPN provides a performance IR that is highly accurate and complete, i.e., it contains all the necessary details to provide predictions that are close to reality. Tools based on the LPN IR can therefore achieve high accuracy.

5.2.2 Representation efficiency

Besides accuracy and completeness, the utility of an LPN also depends on its conciseness, ease of update, understandability by non-technical staff, and so on. As we will show in Fig. 8, by incorporating only performance-related details and nothing else, the LPN brings about orders-of-magnitude improvements in simulation time. This is one measure of representation efficiency. In Table 2 we show the complexity of the LPNs along different dimensions, which serves as another measure of representation efficiency.

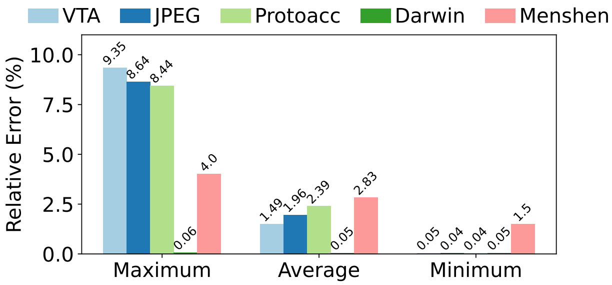

Figure 3: Relative latency prediction errors of the LPN-based simulation vs. Verilator cycle-accurate simulation.

Accelerator	LOC		Number of ...		
	RTL	LPN	transitions	places	edges
VTA	6628 Chisel	506	12	22	41
JPEG	7003 Verilog	109	6	16	33
Protoacc	3197 Chisel	758	97	112	365
Darwin	1535 Verilog	214	2	4	6
Menshen	11169 Verilog	544	29	44	85

Table 2: Comparative complexity of LPN and RTL representations.

5.2.3 Hardware engineer effort to write LPNs

As already mentioned, we asked an accelerator developer with several years of mixed academic and industry experience to read §3 and write an LPN for Menshen, whose design he had not seen before. He wrote the LPN without assistance, and then tested its accuracy with the Menshen testbenches. After understanding the RTL design, it took him less than 3 hours to write an accurate LPN. He estimated that a developer who knew the design and did not need to go back and forth between the RTL and the LPN would take less time.

The Menshen code base is quite substantial. This result therefore strongly suggests that hardware engineers would find it acceptable and practical to write LPNs for their accelerators, especially if they stand to gain (as we argue below).

5.2.4 Utility to SoC and accelerator developers

Besides being easy to write, we believe LPNs, accompanied by the ltc toolchain, can improve the productivity of accelerator designers. For example, finding the right configuration (e.g., sizing the buffers in a programmable switch) is today labor-intensive and error-prone. The wrong choices for buffer sizes can affect the delicate internal balance of an accelerator and lead to performance degradation due to unnecessary stalls.

We discovered the utility of lpn2smt in optimizing buffer sizes while trying to prove an upper bound on the stall-to-cycles ratio (≤ 0.4) for JPEG. In the default configuration, due to an under-sized buffer in the output unit, the previous unit was backpressured early. We had lpn2smt find a buffer size that respects the desired stall-to-cycle ratio: we made the buffer size symbolic and queried lpn2smt to optimize the stall-to-cycles ratio. lpn2smt took 3 minutes to return 0.276 as the optimal ratio and a concrete buffer size that satisfies that ratio. Changing the buffer size (1 line of RTL) led to a 37% performance improvement on the Div2k dataset [50]. Since only some of the images have a stall-to-cycle ratio > 0.4, such a nuanced performance bottleneck would be hard to find.

5.2.5 LPNs beyond accelerators

The performance of the interconnect and external memory accesses affects overall performance when running accelerators, so engineers may want to connect LPNs for accelerators to models for the interconnect and memory, to understand the overall system performance. LPNs are a natural fit for modeling interconnects. We inferred hardware details from PCIe documentations [66], then created an LPN for a reconfigurable PCIe topology, including root complex and switches, and connected it to the LPN for JPEG. With a fixed memory-access latency model, the LPN-based system model achieves on average 1.9% (maximum 5.1%) relative error compared to the end-to-end latency measured with the real hardware system (i.e., a JPEG decoder on an FPGA connected to the host CPU via PCIe). The image set we evaluated on includes 40 images of varying sizes, and the per-image latency ranges from 15 microseconds to 100 milliseconds.

5.3 Key results

In this section, we present high-level results that illustrate the value of LPNs and ltc to accelerator developers and users.

5.3.1 Performance interfaces are human-friendly

This set of results illustrate how LPNs and ltc can answer questions like "What latency/throughput can I expect from this accelerator for my code?" and "Which of accelerators X or Y will best accelerate my workload?". For the latter, we were unable to find two open-source accelerators that provide identical functionality, and so we demonstrate this use case using two configurations of the same accelerator.

Consider the JPEG performance interface in Fig. 4, produced by lpn2pi (as explained in §4.2, the variable names come from the token property names). A quick read conveys that the latency of decoding an image grows with the number of blocks in the image; the compression ratio, which is inversely related to the number of non-zero elements in the block, affects the latency as well. Developers can visually infer the bounds on accelerator latency. To derive a latency in seconds, one multiplies the cycles by the clock period. The `@perf_interface` decorator adapts the input, based on the "tokens from input" function Ψ (§3.3), to make the token properties (e.g., `num_blocks` and `avg_num_nonzero_perblock`) available to the interface at the right level of abstraction.

```python
freq = 75*10**6 # 75MHz
clk_period = 1/freq
@perf_interface
def latency_jpeg_decode(img):
    x = 6*(img.avg_num_nonzero_perblock*3+6)
    cycles = img.num_blocks*max(x,509)/4
    return cycles*clk_period

@perf_interface
def tput_jpeg_decode(img):
    # Images are processed one-by-one
    # We provide throughput for RGB blocks instead
    return img.num_blocks / latency_jpeg_decode(img)
```

Figure 4: Latency and throughput interfaces for the JPEG decoder. Comments are manually added. The throughput interface is manually constructed based on the latency interface.

If developers understand the parameters of their workloads, they can directly look at the performance interface to reason about the latency distribution for those workloads. Otherwise, they can generate test cases and quickly run them with the performance interface, which is executable Python code.

Next, consider the performance interface for Protoacc (Fig. 5), which directly conveys the cost of serializing different message types. The latency for serializing a series of messages is just the sum of the latency of serializing individual messages. As mentioned earlier, lpn2pi extracts the performance interface for each input class—in this case, input classes correspond to Protoacc message types—and assembles them together. The performance interface raises an error if the input message is not part of the input classes for which the performance interface was extracted. Due to space limitations, we do not show throughput interfaces, as they are straightforward to derive from the latency interface.

We use two configurations of Protoacc to demonstrate how performance interfaces can help developers choose between accelerators, or between different configurations of the same accelerator, by comparing their performance interfaces (Fig. 5). The first configuration is the original Protoacc, and the second is a smaller configuration of Protoacc with the number of parallel serialization pipelines reduced from six to one. From the interface, if the message type is *hpbench.m1*, we can infer that, if the total bytes are below 47KB, the original Protoacc is faster. And once the total bytes exceed 47KB, the alternative configuration is faster. This is because, when the message size is below 47KB, the bottleneck is still in processing the message—since the original Protoacc has more pipelines to process the message in parallel, it is faster. Once the message size exceeds 47KB, the bottleneck shifts to the generation of the memory reads/writes, and the alternative configuration is faster, because it has a higher frequency.

Finally, Fig. 6 shows the extracted performance interface for Darwin, and Fig. 7 shows the performance interface for

```python
freq = 1.8*10**9 # 1.8GHz
clk_period = 1/freq
@perf_interface
def latency_protoacc_serialize(msgs):
    cycles = 0
    # Iterate over each message of a list of messages
    for msg in msgs:
        # hpbench.m* are Hyperprotobench msg formats
        if msg.type == hpbench.m1:
            cycles += max(1468, msg.total_bytes/16+310)
        elif msg.type == hpbench.m2:
            cycles += max(2172, msg.total_bytes/16+514)
        elif msg.type == hpbench.m3:
            ...
        else:
            raise NotImplementedError(
                f"message␣type␣not␣supported"
            )
    return cycles*clk_period
```

```python
freq = 2*10**9 # 2GHz
clk_period = 1/freq
@perf_interface
def latency_protoacc_alternative_config_serialize(msgs):
    # Latency interface for another protoacc
     configuration where the number of parallel
     pipelines is reduced from 6 to 1.
    cycles = 0
    for msg in msgs:
        if msg.type == hpbench.m1:
            cycles += max(3609, msg.total_bytes/16+310)
        elif msg.type == hpbench.m2:
            cycles += max(4566, msg.total_bytes/16+514)
        elif msg.type == hpbench.m3:
            ...
        else:
            raise NotImplementedError(
                f"message␣type␣not␣supported"
            )
    return cycles*clk_period
```

Figure 5: Interfaces for default ProtoAcc (top) and an alternative configuration of ProtoAcc (bottom). We speculate that the frequency of the alternative ProtoAcc configuration could be 2GHz (instead of 1.8GHz at the top) because the design is simpler.

```python
freq = 250*10**6 #250MHz
clk_period = 1/freq
num_pe = 4
@perf_interface
def latency_darwin_gact(dna_pairs):
    cycles = (dna_pairs.ref_dna_length + num_pe + 2)*
     dna_pairs.query_dna_length/num_pe
         + num_pe + 2 + 3*dna_pairs.steps
    return cycles*clk_period
```

Figure 6: Latency interface for Darwin GACT for DNA alignment.

```python
freq = 1*10**9 # 1GHz
clk_period = 1/freq
@perf_interface
def latency_menshen(pkts):
    if pkts.type == 0:
        # length of the packets stream is 100
        cycles = max(1320, pkts.sum_nr_words + 176)
    else:
        ...
    return cycles*clk_period
```

Figure 7: Latency interface for Menshen.

Menshen. The interface for Menshen is extracted per packet-stream with a fixed number of packets but of different sizes. We do not show interfaces for VTA because (unlike the other accelerators) it is a programmable domain-specific processor, so it takes "programs" as input. VTA instruction sequences contain thousands of instructions produced by compiling a high-level program with TVM [15]. These performance interfaces are therefore program-dependent and long. We expect developers to use other ltc tools instead of reading these.

5.3.2 Performance interfaces are accurate

We report in Table 3 the accuracy of the ltc-generated performance interfaces for latency. As a baseline, we use the Verilator cycle-accurate simulator to run the workloads on the accelerators' RTL. We compare the prediction provided by the performance interfaces to the values reported by Verilator. The performance interface for Menshen is only evaluated using the 100-packet testbench; the other testbenches contain too few packets to fill the pipeline, so lpn2pi's assumptions don't hold. Of course, this does not affect the LPN's accuracy (§5.2).

Accelerator	Prediction error	
	Average	Max
JPEG	7.04%	23.39%
Protoacc	2.40%	3.83%
Darwin	0.05%	0.06%
Menshen	9.43%	9.43%
VTA	19.49%	58.93%

Table 3: Prediction accuracy of extracted performance interfaces.

The average relative error is low (<20%) for all five accelerators, despite performance interfaces being approximate. They aim to capture the major factors that affect latency, not predict precisely the latency, and (as discussed in §4.2) lpn2pi introduces some inaccuracies.

The extracted performance interfaces for JPEG and VTA have the largest maximum errors. As already explained, lpn2pi does not capture the influence of bottleneck shifts on latency (§4.2). In the JPEG decoder, the input is a stream of image blocks. If one segment of blocks is highly compressed and another is less compressed, the bottleneck for processing segments of blocks will shift back and forth within the accelerator. Similarly, in VTA, each of the parallel components (fetch, load, compute, or store) can be the bottleneck during different periods while processing the instructions.

In future work, we plan to extract a performance interface for each phase of the input stream and add the latencies spent in each phase to derive the final start-to-end latency.

5.3.3 LPN-based performance simulation is up to 3 orders of magnitude faster than existing simulators

Another set of questions is "How do I generate code optimized for accelerator X", "How can I do that quickly, in compile-and-run cycles typical of software development workflows", and "How can I evaluate my envisioned workload on an accelerator that isn't available just yet?" These questions might be relevant directly to developers, or to tools, such as the TVM compiler for deep-learning models mentioned in §1. A common approach to answer such questions, when the real hardware is not available, is to use cycle-accurate simulators.

lpn2sim provides substantial benefits, up to three orders of magnitude. Fig. 8 shows lpn2sim's speedup over Verilator. All cycle-accurate simulators simulate both performance and functionality, which is wasteful when only performance questions are being asked. Speedups are more significant with larger accelerators, because there is more functionality that the underlying LPN abstracts away.

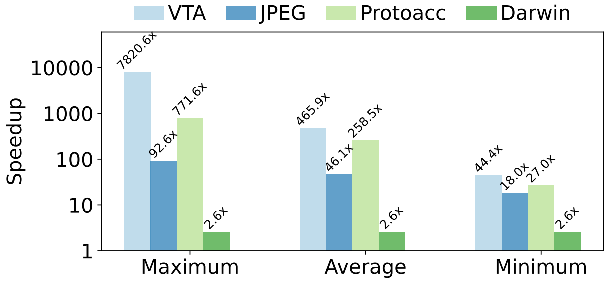

Figure 8: Simulation speedup: LPN-based simulation vs Verilator.

Table 4 shows the absolute simulation times. We believe that orders-of-magnitude changes in performance simulation time, such as going from ∼2 hours to ∼20 seconds, can bring about qualitative changes in how the tools are used.

	Simulation time	
Accelerator	**Cycle-accurate Verilator**	**LPN-based lpn2sim**
VTA	119 min	19 sec
JPEG	2159 min	38 min
Protoacc	25 sec	0.08 sec
Darwin	0.13 sec	0.05 sec

Table 4: Simulation time: LPN-based simulation vs. Verilator.

To get a feel for the impact of faster simulation time on developer productivity, we benchmark the auto-tuning process in the TVM compiler, which optimizes deep-learning models for accelerator targets (§5.1). Auto-tuning can be done either upon initial compilation, or be manually triggered whenever there are changes to the model, to the hardware, or to its configuration. We compare end-to-end compilation time when TVM uses Verilator vs. lpn2sim. Fig. 9 shows the outcome for the 10 auto-tune tasks in our workload (§5.1). As part of this auto-tuning, TVM generates 1,500 sequences of instructions, ranging from 62 to 159,947 instructions.

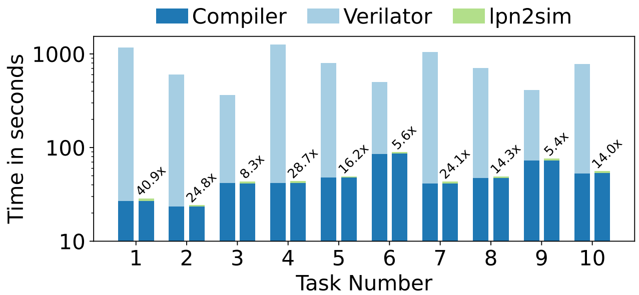

Figure 9: End-to-end compilation time, including auto-tuning. On top of the compiler+lpn2sim bars we overlay the compiler+lpn2sim vs. compiler+Verilator speedup. Despite the log-scale y-axis, one needs to zoom in to see the small amount of time taken by lpn2sim.

lpn2sim reduces auto-tuning time to a negligible amount, turning a highly *non*-interactive process into an interactive compile-and-run cycle. This enables software engineers to think differently about optimization, and to do it more often and without the accelerator hardware. Even if engineers had access to the actual hardware accelerator, using lpn2sim to auto-tune allows many more developers to do so in parallel. Compared to cycle-accurate simulation, it saves not only time but substantial amounts of compute resources and energy.

5.3.4 LPN-based tools enable performance verification

Consider the JPEG decoder in the autonomous driving scenario described in §1. To ensure safe operation in all circumstances, engineers need hard guarantees on the accelerator's performance, particularly for unseen and untested workloads. lpn2smt makes it possible to prove non-trivial bounds that are difficult to infer from source code or semantic interfaces.

The first example is determining, for some image compression ratio x%, the worst-case and best-case latency, and the corresponding worst-case and best-case inputs. Take some specific examples that may be relevant to the engineers: For a typical 90% compression ratio, lpn2smt proves that the worst-case decoding latency is 2,290 cycles for 12 RGB (18 YCrCb) 8×8 macro blocks. If the input images consist of 4 least-compressed and 14 maximally-compressed macro blocks, the best-case decoding latency is 1,717 cycles, and the difference between worst-case and best-case latency is 33%. At a 75% compression ratio, the worst-case and best-case decoding latencies are 3,063 and 2,540 cycles, respectively. lpn2smt took less than 2 minutes to find and prove these bounds.

Similarly, a Protoacc user may wonder about such bounds for serializing a message with a fixed number of bytes. We used lpn2smt to prove that, for message types with 16 fields (total 10KiB), the latency is between 726 and 1,074 cycles. SoC designers could leverage this kind of proofs when incorporating third-party accelerator blocks into their design and reason about performance implications.

lpn2smt can also be used to prove bounds on the accuracy of the performance interfaces produced by lpn2pi. Using lpn2smt, we verified formally that the latency predicted by JPEG's performance interface will always be within at most 43% of the LPN's prediction for 12 RGB (18 YCrCb) 8×8 macro blocks. This result is significant, because the input space is 64^{18} possible images, and thus infeasible to explore directly. This bound is not tight, but guaranteed to be correct.

Of course, the strength of the guarantees depends on the accuracy of the LPN. Validation tools (see §6 below) could provide confidence levels to accompany vendor-provided LPNs.

6 Discussion

In this section, we present further thoughts on how LPNs can help accelerator vendors, whether LPNs leak intellectual property, and how LPNs can be validated against the RTL.

Using LPNs in the accelerator design stage. An LPN can be written even before the accelerator's RTL is finalized. This LPN can be released to software engineers in the same organization, who can then start optimizing software for the accelerator using lpn2sim, as well as identify mismatches in performance expectations early (using lpn2pi and lpn2smt), before the design is finalized. Since accelerator vendors often release SDKs along with their accelerators, the LPN can help speed up development by providing visibility into the expected performance behavior of the accelerator before it is built.

How much proprietary information does an LPN reveal? To ensure that LPNs can be shared beyond the same organization and with software developers at large, they must not leak proprietary information. We argue that this is the case, since (1) most of the information revealed through the structure of the LPN is typically already revealed in architectural block diagrams that are made public by vendors, and (2) while LPNs provide additional information about the latency of the different compute stages, they do not describe how the accelerator achieves this latency, nor give circuit-level details and micro-architectural implementation details that are central to achieving competitive frequency and power consumption. That said, concerned vendors could still provide lower time-resolution LPNs, i.e., LPNs with coarser-grained delay functions; this reduces accuracy to safeguard proprietary details.

Validating LPNs. Since LPNs are distilled manually, they can contain mistakes; hence, after being constructed, LPNs should be validated. Developers could validate the LPN against the RTL using their RTL testbenches. Validating an LPN against the RTL is similar to how engineers validate the RTL itself using functional simulators, code reviews, and testbenches. Nevertheless, we plan to pursue building automated tools that can *formally* validate LPNs against the RTL.

7 Related Work

Petri nets have long been used to model and evaluate the performance of systems [24]. Furthermore, languages modeling a system of queues and actors are not a new idea. Kahn networks [52], dataflow networks [3, 23], and synchronous languages [8] share similarities with LPNs: more or less explicitly describing the flow of tokens in the system.

Analytical modeling of accelerators: Amid the rise of domain-specific accelerators and the need for efficient code generation, research explored semi-analytical modeling for performance models of Domain Specific Accelerators (DSA). For example, to search for good tiling and mapping of loop nests on dense tensor accelerators, [65] proposed performance models that can quickly evaluate the performance of running various loopnests on a family of accelerators. [62] tackles a similar problem for sparse tensor accelerators, and [33] for a SmartNIC. Those approaches use domain-specific knowledge in their modeling, so they typically don't offer abstractions or methodologies that can be reused in other domains. LPNs are domain-agnostic and provide a general substrate for building performance models of accelerators. There are also analytical models for accelerators that focus on data movement costs or asynchronous operations with the CPU [1, 19, 75], rather than the performance of the accelerator itself. Those models have a coarser modeling granularity than LPNs.

Performance models in the hardware community: The monograph [26] covers performance modeling techniques in detail. Analytical models based, for example, on Amdahl's law have studied various computing scenarios to establish performance trends [27, 36]. Similarly, the roofline model [84] allows simple modeling to compute performance upper bounds. Other analytical models [56, 57] build good predictors of processor performance from a few numbers: number of cache misses, branch mispredictions, etc. Finally, interval simulation [14, 30, 37] measures the distribution of performance-structuring events (cache misses and mispredictions) and profile the performance of the machine around those events to produce performance models. The way we construct performance interfaces from LPNs leverages similar principles.

Machine learning has been used to produce so-called predictive performance models of systems [25, 41, 47, 72]. These models are incomplete representations of performance, as they can only answer the questions they were trained on.

The use of simulators [10, 39, 76] to model performance is a battle-tested strategy. To make simulation faster, sampled simulation has been proposed [83, 85]. Challenges include computing warm states (caches, predictors, etc.) and identifying representative parts of benchmarks [6, 38, 67]. Finally, FPGAs [18, 54, 77, 78] can be used to speed up simulation, but FPGA simulation is possible only when the RTL is available, and compilation for FPGA is slow.

In contrast to these approaches, LPNs not only produce accurate *executable* models of hardware but can also be transformed into other useful representations (such as performance interfaces) to address broader performance questions.

LPNs for accelerators are complementary to host simulators like gem5 [10]. One can replace the gem5+RTL simulation mode with gem5+LPN for accelerators. gem5+RTL is normally bottlenecked by the RTL simulation, and gem5+LPN would shift the bottleneck to gem5.

8 Conclusion

Performance interfaces promise to offer a standardized view of accelerator performance. Despite the complexity of accelerators and system software, the LPN IR we propose can accurately represent the dynamics of various accelerators, and ltc can answer non-trivial and valuable performance questions.

A Artifact Appendix

Our work is part of the umbrella project on performance interfaces [68], which aims to increase performance clarity for systems code and hardware, as well as formally prove performance properties. All artifact materials are available on the project website.

The artifact has three parts: LPN, ltc, and the benchmarks. Both LPN and ltc are available through an `lpnlang` Python package. For the first part, LPN includes several constructs for developers to build their own LPNs. The LPNs we built also serve as examples of how to use those constructs. For the second part, we provide simple scripts to run ltc, which includes using lpn2pi to extract executable performance interfaces, using lpn2smt to verify performance properties, and using lpn2sim for fast performance simulation. Note, a new LPN may contain structures that cannot be analyzed by the tools in ltc; in such cases, ltc will raise an error. Automatically transforming a general LPN as defined in §3 to an LPN amenable to analysis by ltc's tools is left as a future work.

In the third part, we provide benchmarks that are used in the paper and scripts to easily run them. Note that, to simulate the Protoacc RTL, the whole SoC needs to be simulated, and the simulation is slow. The simulation speed we provided in §5 for the Protoacc RTL does not include the SoC simulation. The artifact contains also a Docker image with a ready environment to run the tools and the benchmarks. As LPN simulation normally runs for a very short amount of time, reproducing the results requires that the hardware be kept stable: disable hyperthreading, disable CPU frequency variation, etc.

We will be updating LPNs to improve readability, usability, simulation speed, and accuracy. ltc is also subject to updates that improve accuracy of lpn2pi and/or the time it takes lpn2smt to prove/disprove performance properties. The ltc toolchain will evolve to include more tools and improvements.

A.1 Formal definition of an *input class*

To fully understand how input classes are implemented and used in ltc, we present here a more detailed definition to complement that of §4.1.

A trace e of an LPN is a sequence of transition-commit records, represented as tuples $\langle T_{id}, K_I, K_O, s\rangle$. A trace characterizes the outcome of executing an LPN (as per the definition of "execution" in §4.1). The first component of a record is the transition T_{id} whose commit was recorded. The second and third component is the input set K_I, respectively output set K_O, of token IDs corresponding to the tokens consumed (respectively produced) by the commit of T_{id}. Once a token is consumed, it vanishes forever, so a token identifier can appear at most twice in a trace: as part of the commit that produced it and (possibly) as part of the commit that consumed it. The fourth component of a trace record is a sequence number s that represents the transition's commit timestamp augmented with sequencing information s.t. $\langle T, *, K_O, s\rangle \wedge \langle T', K_I', *, s'\rangle \wedge s < s' \Rightarrow$ transition T committed before transition T' (and thus K_O was available at the same time as K_I'), even if T and T' committed at the same timestamp.

In a valid LPN trace, an input token can never be consumed before it is produced, i.e., for all records $\langle T_{id}, K_I, K_O, s\rangle$ and $\langle T_{id}', K_I', K_O', s'\rangle$, $s < s' \Rightarrow K_I \cap K_O' = \emptyset$

For the rest of this section, timestamps are no longer relevant, so we drop them from our notation. We define the operator $[|.|]$ that, for a given LPN, takes a set of initial input tokens and produces a trace e of the execution of that LPN. We define the relation $\sim_1$ between pairs of traces that determines if the two traces are equivalent modulo "harmless" permutations of records as follows ($l_1 +\!\!+\, l_2$ concatenates sequences l_1 and l_2):

$$\begin{aligned} &\mathrm{pre} +\!\!+ [\langle T_{id_1}, K_{I_1}, K_{O_1}\rangle; \langle T_{id_2}, K_{I_2}, K_{O_2}\rangle] +\!\!+ \mathrm{pos} \\ &\sim_1 \\ &\mathrm{pre} +\!\!+ [\langle T_{id_2}, K_{I_2}, K_{O_2}\rangle; \langle T_{id_1}, K_{I_1}, K_{O_1}\rangle] +\!\!+ \mathrm{pos} \end{aligned}$$

A permutation as shown above is harmless if (1) $id_1 \neq id_2$; (2) T_{id_2} did not consume a token produced by T_{id_1} in the corresponding commit, i.e., $K_{O_1} \cap K_{I_2} = \emptyset$ (trace validity already implies that $K_{O_2} \cap K_{I_1} = \emptyset$); and (3) T_{id_1} and T_{id_2} do not conflict, i.e., they do not share an output or an input place.

We define relation $e1 \sim e2$ as the reflexive, transitive closure of $\sim_1$ over the set of traces of a given LPN. We can now define the set of all traces that are harmless permutations of an initial trace e as $\bar{e} = \{e' | e \sim e'\}$.

Given a trace e, we abstract it by dropping all the token IDs and keeping only the cardinality of the input and output sets in each record. Formally, we obtain the abstract trace $\alpha(e) = \mathrm{map}(\gamma, e)$ by applying the operator $\gamma(\langle T_{id}, K_I, K_O\rangle) = \langle T_{id}, |K_I|, |K_O|\rangle$ to each record in e.

We say that the inputs (i.e., sets of initial tokens) i and i' are in the same *input class* if and only if $\{\alpha(e) | e \in \overline{[|i|]}\} = \{\alpha(e) | e \in \overline{[|i'|]}\}$.

A.2 Input class separation algorithm

Both lpn2pi and lpn2smt rely on a pre-processing step that partitions a user-defined input space into input classes. This pre-processing tool employs symbolic execution [13].

Before diving into the details of the tool, we first define the concept of a *conflict-free* transition. A transition T is conflict-free if and only if its input places are not input places for any other transition, and its output places are not output places for any other transition.

The tool symbolically executes the LPN with symbolic inputs, i.e., input space defined by the user. The tool has three main steps: (1) it first groups LPN transitions into sorted strongly-connected components (SCCs). Transitions are grouped into SCCs according to the edge directions regardless of the edge functions. (2) It then iteratively commits conflict-free transitions. The timestamp of a commit is computed locally based on the tokens (locked in the input places) and on the transition's delay. After a transition becomes enabled, the tool commits it immediately without waiting for a delay and without synchronizing with other transitions' commits. This implies that a commit with a timestamp *ts1* can be materialized before a commit from another transition with *ts2*, where *ts1* > *ts2*, The produced tokens will carry the timestamp of the commit that produced them. (3) Once there are no more conflict-free transitions to commit, it commits one conflicting transition at a time, synchronously (with priority given to transitions in SCCs preceding other SCCs); this implies that the earliest commit is materialized first.

After symbolically executing the LPN exhaustively, the tool will find multiple paths. The input constraints associated with each path defines an input class.

A.3 Estimating $\overline{g}_T$ and ε_T in lpn2pi

To complement the description in §4.2, we provide further details on how $\overline{g}_T$ and ε_T are estimated, as well as assumptions made by lpn2pi.

We first define loops and properties of loops that lpn2pi handles. A loop in LPN is an alternating sequence of places and transitions $P_n \to T_1 \to P_1 \to \ldots \to T_n \to P_n$. Assume, for simplicity, that weights of edges are constants. lpn2pi only handles loops with the following properties:

1. The loop does not fully contain another loop, i.e., no strict subset of places and transitions in this loop forms another loop.

2. The loop has one and only one place with initial tokens.

3. The loop guarantees token conservation. Without loss of generality, assume the place with initial tokens is P_n, and it has M initial tokens. Token conservation means that initial tokens in P_n flow through the transitions, potentially changing in quantity, but eventually all M tokens flow back to P_n. This completes an iteration through the loop. More formally, a loop is token conserving if $\frac{w_{T_nP_n}}{w_{P_nT_1}} \times \frac{w_{T_1P_1}}{w_{P_1T_2}} \times ... \times \frac{w_{T_{n-1}P_{n-1}}}{w_{P_{n-1}T_n}} = 1$, where $w_{T_iP_j}$ is the weight of the edge from T_i to P_j.

Given these assumptions, the loop delay Δ and parallel factors F_{T_i} for each transition T_i are calculated as shown below. Recall that, initially, $\overline{g}_T$ of each transition is set to $T.\delta$, and that $\varepsilon_T = N \times \overline{g}_T$, where N is the number of commits for transition T.

$$\Delta = \sum_{i=1}^{n} \left(T_i.\delta + \overline{g}_{T_i} \times \left(\frac{F_{T_i}}{C} - 1 \right) \right)$$

$$\text{with} \quad F_{T_1} = \frac{M}{w_{P_nT_1}}, \quad F_{T_2} = F_{T_1} \cdot \frac{w_{T_1P_1}}{w_{P_1T_2}}, \quad F_{T_3} = \ldots$$

$$C = \min(F_{T_1}, F_{T_2}, \ldots, F_{T_n})$$

$$\text{and} \quad \overline{g}_{T_k} = \max\left(\overline{g}_{T_k}, \frac{\Delta}{F_{T_k}} \right)$$

IronSpec: Increasing the Reliability of Formal Specifications

Eli Goldweber Weixin Yu Seyed Armin Vakil Ghahani Manos Kapritsos

{edgoldwe, weixinyu, arminvak, manosk}@umich.edu

Abstract

The guarantees of formally verified systems are only as strong as their trusted specifications (specs). As observed by previous studies [22, 52], bugs in formal specs invalidate the assurances that proofs provide. Unfortunately, specs—by their very nature—cannot be *proven* correct. Currently, the only way to identify spec bugs is by careful, manual inspection.

In this paper we introduce IronSpec, a framework of automatic and manual techniques to increase the reliability of formal specifications. IronSpec draws inspiration from classical software testing practices, which we adapt to the realm of formal specs. IronSpec facilitates spec testing with automated sanity checking, a methodology for writing *Spec-Testing Proofs (STPs)*, and automated spec mutation testing.

We evaluate IronSpec on 14 specs, including six specs of real-world verified codebases. Our results show that IronSpec is effective at flagging discrepancies between the spec and the developer's intent, and has led to the discovery of *ten* specification bugs across all six real-world verified systems.

1 Introduction

Formal verification has emerged as a promising technique for increasing the robustness of complex systems by helping developers prove that their implementation meets a formal specification. As promising as this approach is, it has a fundamental Achilles' heel: its guarantees of eliminating *all* bugs in the implementation rely on the *specification being correct*.

The crucial observation that the guarantees of a mechanized proof are only as strong as their specifications is not new and was first identified in 1985 [33]. Specifications (a.k.a. specs) are inherently trusted, rather than proven correct. Relying on trust alone is not enough to ensure that specs remain bug free. If a spec contains a bug, proving that the system meets this spec may be meaningless; the *proven* system could also contain a bug that is hidden by the buggy spec.

The correctness of specifications is the rock upon which the entire edifice of formal verification is built.

Despite the importance of writing correct specs, current best practices rely solely on manual inspection. Developers argue [25, 26] that because specs are typically small compared to the size of the corresponding proof and implementation, it is feasible to manually inspect specs thoroughly enough to ensure that they **capture the intended behavior** of the system. While expert developers are more likely to write correct specs, they are not infallible. As formal verification becomes widely adopted, more and more non-experts will write specs, only exacerbating the risk of introducing bugs. Thus, it is imperative that the process of writing specs be as robust as possible.

In fact, several studies [22, 32, 52], through extensive manual effort, have shown that formally verified systems—many of which were developed by experts in formal verification—contain critical bugs, which originate with problems and inconsistencies in their specs. For example, in January 2022, Notional Finance found a double-spending vulnerability in a deployed verified smart contract missed by manual inspection [34]. In this case, part of the spec was vacuous, causing it to be too weak, and thus the proof would still pass with a *buggy* implementation.

Since a spec is a formal expression of a developer's intent, *proving* the spec correct is ultimately impossible. Ensuring a spec matches a developer's intent will always be best-effort. Whilst no approach can guarantee a bug-free spec, that does not mean attempts to do so must exclusively rely on extensive manual effort and system expertise to resolve. Indeed, there are no structured or automated approaches for a developer to debug this complicated state space. To fill this gap, we propose a means to better handle this challenge.

Inspired by classic testing techniques [17, 24, 48], we introduce IronSpec, a spec testing framework. To enable testing specs, IronSpec adapts the automation of mutation testing [19, 31] and sanity checking along with a customized manual testing approach inspired by unit testing. Together, this framework introduces a systematic way to boost assurance that a spec captures the intended behavior of the system.

If there is a bug in a spec, it originates in the same manner as any other type of bug; there is a disconnect between the intent of the developer and what is written. A spec is *incorrect* if it is too weak, allowing for the existence of even a single implementation that exhibits undesired behavior, or if the spec is too strong, precluding some desired behavior. To identify spec bugs, we leverage the insight that spec bugs manifest themselves as a consequence of *a disconnect of intent* to search for and highlight such disconnects through structure and automation.

IronSpec aids in pinpointing where the developer's intent diverged from the current spec by providing various tools that encapsulate this notion. Common cases where the intent of the developer deviated from the spec can be flagged with IronSpec's Automatic Sanity Checker. If a system has a passing proof, IronSpec leverages this to provide additional automation with spec mutation testing. Mutation testing can automatically identify cases where the behavior of the implementation differs from the spec, by using the proof to identify relevant mutations. The hints of potential intent disconnect provided by automation are bolstered by a manual methodology for writing *Spec-Testing Proofs (STPs)*. STPs are inspired by traditional unit testing and allow developers to test if their understanding of what behavior the spec should allow matches the current spec. STPs can be used to investigate the hints provided by automation to either confirm the existence of a bug or to absolve the disconnect as intended behavior.

We evaluate IronSpec by testing six specs produced in-house, two specs containing artificial bugs that were studied in Abreu et al. [6], and six specs of open-source verified systems. We demonstrate the effectiveness of the automation and manual testing methodology of IronSpec by describing *ten* spec bugs found across a verified Distributed Validator Protocol [4], a verified SAT solver [7], a verified QBFT system [2], a formal spec of the Eth2.0 spec [1], daisy-nfsd [15], and a verified AWS Encryption SDK library [3].

Overall, this paper makes the following contributions:

- Introduces IronSpec, a spec testing framework that allows developers to pinpoint places where the current spec may have diverged from their original intent.
- Proposes an Automatic Sanity Checker, a testing methodology for writing *Spec-Testing Proofs (STPs)*, which are applicable to test specs even in the absence of a completed proof or implementation, and describes how to adapt mutation testing to specs to automatically identify divergences between the spec and the implementation.
- Demonstrates the effectiveness of IronSpec, by illustrating how we applied IronSpec to *six* real-world, verified systems leading to the discovery of *ten* spec bugs.

2 Manually Scrutinizing Specifications

Relying on manual inspection alone to ensure an intended specification is not practical. Fonseca et al. [22] performed a study aimed to challenge the assumption that just because a system is verified, it is bug-free. In this study, the authors thoroughly examined three formally verified distributed systems, IronFleet [26], Verdi [53], and Chapar [41] and identified sixteen bugs across their specifications, verification tools, and their unverified shim layers. Two of these bugs were found to be in specifications. This study was chiefly manual and required close examination of the respective specifications to identify. The authors do introduce some basic automation, yet their techniques still rely predominantly on manual effort and expertise in the system. This work demonstrated the need for and acknowledges the lack of a more rigorous and automated approach to testing formal specifications. Similarly, Yang et al. [54] conducted a bug study of compilers and discovered two bugs within the verified compiler CompCert due to underspecification, and similarly observed that specifications are complex and lack scrutiny.

The concerning discovery of these previous works identifies the gap that this work aims to fill; to provide a means for developers to help automatically and methodically identify specification bugs across the spectrum of specifications.

Complicating this problem, specifications can take on different forms, making uniform debugging approaches difficult. In their simplest form, specifications can be in-line predicate assertions [29]; boolean functions that check the state of the system against some property. A more specific class of predicate assertions based on the Floyd-Hoare style logic [21, 28] are preconditions and postconditions, which establish invariants about the state of the program before and after the execution of a piece of code. For more complex systems, rather than directly proving properties about the system, it can be easier [26, 53] to prove state machine refinement [37]. For refinement, the specification is an abstract state machine that encapsulates the desired behavior of the system.

To highlight the subtlety of trying to manually ensure a specification is correct, consider an *incorrect* specification for a simple `Sort` method found on line 3 of Specification 1. This `Sort` method takes a sequence of integers as input and promises to return a sorted sequence of integers in ascending order. The specification for this method is a single postcondition which ensures that the value at every index in the output sequence is less than or equal to the value at subsequent indices. At first glance, this may seem to be a correct specification for `Sort`—a mistake that many newcomers to verification make.

However, this specification is incorrect, as it neglects to mention any relationship between the input and output sequences. This is considered a buggy specification because a proof could still pass even with an *incorrect* implementation that exhibits undesired behavior, erroneously giving the illusion of correctness. For example, if the input sequence were $[1,6,7,2]$, an incorrect implementation could arbitrarily return $[1,42,100]$ or even the empty sequence $[\,]$. The *incorrect* implementation for `Sort` in Specification 1 is triv-

Specification 1 Incorrect Sort Spec

```
method Sort(input:seq<int>)
  returns (out:seq<int>)
  ensures forall i | 0 <= i < |output| - 1 ::
           out[i] <= out[i+1]
{ return []; }
```

Specification 2 Correct Sort Spec

```
1 method Sort(input:seq<int>)
2   returns (out:seq<int>)
3   ensures forall i | 0 <= i < |output| - 1 ::
4            out[i] <= out[i+1]
5   ensures multiset(input) == multiset(output)
6 { /* body omitted */ }
```

ial and always returns an empty sequence. Yet, the proof for this method would still pass, as this trivial implementation satisfies the incorrect, too-weak specification.

Manually identifying a spec bug, like that in Specification 1, can be challenging. In fact, a correct specification for `Sort` should also capture the relationship between the input and output by adding an additional post-condition to ensure that the multiset of the input is equal to the multiset of the output, see line 5 in Specification 2.

The opposite case, where a specification is too strong, can be equally as important and challenging to manually identify. For example, if we replace line 5 in Specification 2 with `ensures input == output`, the specification becomes unnecessarily strong. Multisets do not take order into account, whereas sequences do, so the updated postcondition is overly strong. The only input and output pair that could satisfy this specification is if the sequences are identical and already in ascending order. Even if one has a correct implementation of `Sort`, proving that the implementation upholds this specification is impossible. To debug the inevitably failing proof, the developer must examine their implementation for bugs, check their proof for missing invariants *and* manually inspect their spec to make sure it captures the intended behavior. Having high confidence in the spec would make this scenario much more unlikely and would give the developer more time to focus on the proof itself, knowing they are proving the right property.

3 How To Test A Specification

It is challenging to diagnose spec bugs because specs are trusted, and a buggy spec can often be at odds with a developer's original understanding of the system. Complicating the problem, specs are often intended to be abstract, allowing different, correct implementations to meet the spec. Hence, we introduce IronSpec, a framework for testing specs to help gain confidence that a spec is bug-free. This work represents the first systematic effort to bridge the gap between the mature and extensive work in software testing and the lack of rigor in ensuring spec correctness.

IronSpec is inspired by the insight that the existence of a spec bug is inherently due to a disconnect between what the developer intended and what properties were actually captured in the spec. IronSpec provides tools to allow a tester to identify and test possible occurrences where the original intent of the developer may have diverged from the current spec. Some aspects of IronSpec only rely on the spec and have no dependence on the existence of an implementation or a passing proof. However, if there is an implementation and a corresponding passing proof, IronSpec can leverage this to use the implementation as an additional reference point to help focus the testing process.

This section introduces and provides a high-level overview behind the ideas of why each testing component of IronSpec is useful in exposing disconnects between the intent of the developer and their spec. Section 4 discusses each in more detail.

3.1 Testing Specifications In The Absence Of A Passing Proof

Akin to test-driven development [10], it is desirable to test a spec without requiring a proof or corresponding implementation. If there is a bug in the spec when it comes time to write a proof, a developer may struggle and expend unnecessary manual effort in debugging in the wrong place. The Automatic Sanity Checker and *Spec-Testing Proofs (STPs)* provide two frames of reference for a tester to check their specs against, even in the absence of an implementation and proof.

Regardless of the context of the system, it is clearly never intended for a verified method to be permitted to return arbitrary values. If the spec is too weak, an incorrect implementation might be free to return *any* value, unconstrained by the spec. The Automatic Sanity Checker raises high-confidence flags when the spec of a verified method fails to properly constrain its output based on the given input. The sanity checker also alerts the developer to partially constrained input and output, which provide weaker hints to the existence of spec bugs but are also worthwhile to investigate further.

Because the Automatic Sanity checker only looks for underconstrained input and output, this technique can be used even in the absence of an implementation or proof. Section 4.1 describes the Automatic Sanity Checker in more detail.

The Automatic Sanity Checker excels at automatically finding common spec bugs by leveraging generic code patterns, but cannot leverage any user-provided hints and insights. We address this gap by introducing a methodology for manually writing *Spec-Testing Proofs (STPs)*. STPs are inspired by traditional unit tests and are proofs about the spec for context-specific input and output. STPs help developers expose differences between the expected behaviors they intend to include in the spec and what is currently permitted. This testing methodology is useful in the presence of a passing or failing proof, but can also be applied in the absence of a proof. Section 4.2 explains how to write STPs and interpret their results.

An STP is, by definition, a proof; this is the key difference between STPs and standard unit tests. Since STPs are proofs, STPs help to answer different questions than what unit tests allow for. Instead of attempting to prove a general property, an STP demonstrates the validity of the spec for a specific, concretized value or a range of values. This testing methodology exploits the insight that crafting proofs for specific cases is often less challenging than producing a comprehensive proof and can frequently be proved by the verifier with minimal manual intervention. Each STP is a small proof about *distinct* properties of the spec. The steps of writing STPs are generic, and so can be useful tools in investigating the correctness of many variations of specs.

Differing from a failed unit test, if an STP fails to verify, it could be for various reasons. The STP may fail due to a divergence between the expectation of the spec and the STP, indicating a bug. If the tester suspects that a disconnect caused the failed proof, the appropriate next step is to write a concrete *Counterexample* STP. The counterexample proves that unintended behavior is permitted by the spec. Alternatively, an STP may fail because the STP body lacks sufficient proof annotations for the verifier to prove the final postcondition. Distinguishing between a spec bug and the need to add proof to the body of the STP is impossible to immediately diagnose for every case because in this work we are targeting undecidable programs.

3.2 Testing Specifications With The Assistance Of A Passing Proof

Even when a system is verified with a passing proof, it is still possible for the system to contain bugs if the spec itself is buggy; thus testing a spec at this point is still very valuable. A too-weak spec could allow for a proof to pass with an incorrect implementation, falsely giving the illusion of correctness. Alternatively, even if the current implementation contains no bugs, a too-weak spec could allow for a buggy update to the current implementation, such that a proof would still pass with the same too-weak spec. Relying on a developer to write a bug-free implementation given a buggy spec, goes against the very reason to verify systems in the first place; so it is just as vital to identify spec bugs when the proof passes.

Using the Automatic Sanity Checker and writing STPs are applicable when testing a spec with a passing proof, but the proof and implementation together contain untapped information that can further assist testing. Like the spec, the implementation also captures the intent of the developer. Identifying the difference of intent between the behavior allowed by the spec and what is actually in the implementation, calls the developer's attention to potential disconnects. IronSpec can take advantage of the proof and implementation to automatically test a spec with *mutation testing*. Mutation testing identifies cases when the spec is weaker than the current implementation. IronSpec uses the passing proof as a reference point to automatically distinguish cases where the existing implementation is weaker than the behavior allowed by the spec. Further details concerning how IronSpec adapts mutation testing to specs are described in Section 4.3.

Departing from traditional mutation testing, IronSpec starts with a spec, implementation, and passing proof and then only mutates the spec. IronSpec relies on an existing passing proof to indicate whether a mutation should be killed, whereas traditional mutation testing relies on a test suite. A mutation is kept and considered *alive* if the original proof still passes with the mutated spec, indicating that the implementation also meets this different spec. The behavior allowed by the original spec but not the mutated spec serves as an example of a subset of behavior that may not be intended.

The existence of even a single alive spec mutation serves as a flag to the developer. An alive mutation is clear evidence that a different spec still allows the proof to pass with the unmodified implementation, and represents specific behavior unaccounted for by the original spec. The difference between the original spec and the passing mutated spec is a strong hint for the tester to determine if that specific behavior is intended. Identifying alive mutations is accomplished automatically, but understanding the implication of any such alive mutation cannot be automated and ultimately still relies on the developer's intuition to understand.

An alive mutation is simply a hint highlighting a divergence between the spec and the implementation. However, not all alive mutations immediately lead to the discovery of a spec bug. If a spec is correct but also weaker than the current implementation, there is a chance for an alive mutation to be considered a false positive and marked as intended behavior. In a contrasting, albeit rare case, if both the spec and implementation are buggy, but the implementation is not weaker than the buggy spec, then no alive mutations may be found.

To reduce the chance of false positives only a subset of the generated mutations are eventually considered. Logically equivalent or weaker mutations than the original spec and mutations that trivially make the proof pass can be safely ignored. The details for how specs are mutated and what constitutes valid mutations are expounded upon in Section 4.3.

Note that we deliberately mutate only specs and not implementations for two reasons. Firstly, specs are smaller than implementations, therefore reducing the number of mutations necessary to consider. Secondly, mutating only the spec rather than the implementation is advantageous for automation. Specs, being boolean functions, enable automatic filtering of irrelevant mutations. Assuming the proof passes given the original spec, any logically weaker spec mutation will still allow the proof to pass and does not provide any new relevant information. By automatically checking the relative logical strength of a mutated spec in relation to the original, weaker mutations can be identified and ignored. This automation is impossible when mutating the implementation, as determining relative logical strength is not possible in all cases. Logical relationships can be determined automatically for boolean functions, like specs, whereas not all imperative code shares this attribute. Implementation-based mutations would increase the manual burden on the tester, as many more false positives would be an unavoidable outcome that would require manual effort to sift through. The process of automatically filtering spec mutations is further explained in Section 4.3.2.

In certain cases, mutation testing is also useful in identifying too-strong specs. A spec in the Hoare-Logic style can also be considered incorrect by virtue of having a too strong precondition. IronSpec's mutation testing is still applicable in this case. If the spec mutation target is a precondition, rather than attempting to identify where the spec is disconnected from the implementation due to weakness, IronSpec reverses the criteria used to determine relevant mutations by considering mutations that are *weaker* than the original spec.

Mutation testing does not provide complete coverage of spec testing but rather focuses the attention of the tester on a disconnect between the spec and the implementation. STPs can be used to help fill this gap. Focusing on writing STPs about the discrepancy hinted at by an alive mutation leads to a more efficient way of identifying bugs. STPs guided by the hint of alive mutations can allow a tester either to arrive at a counterexample, showing a bug in the spec, or to absolve the alive mutation as intended behavior.

4 The IronSpec framework

IronSpec consists of three spec testing tools; an Automatic Sanity Checker, a methodology for writing *Spec-Testing Proofs (STPs)*, and an automatic mutation testing framework. Each assists in identifying and flagging divergences between the developer's intent and the existing spec.

The IronSpec prototype is built in C# as an extension to Dafny [40], a verification-aware programming language that enables verification with the Z3 SMT solver, and also supports practical imperative implementations by compiling to C#, Java, JavaScript, and Go. IronSpec was applied to test specs written in Dafny, but the concepts of how to test specifications are not Dafny-specific and could be re-implemented in other environments.

4.1 Automatic Sanity Checker

The Automatic Sanity Checker (ASC) examines the input, output, and spec of verified methods to identify cases where the spec may be weaker than intended. The ASC implementation consists of approximately 300 lines of C# code and achieves this check by traversing the AST of the method under test while maintaining some local state. Table 1 outlines the properties that are checked and their assigned severities. All of these properties can be determined by examining the AST, and as such, they can be checked efficiently without invoking a verifier. Either of the HIGH severity flags signifies a high likelihood of spec bugs, whereas the other severity levels indicate a cause for additional manual inspection. Both HIGH severity flags reveal a weakness in the flagged spec. If the postconditions do not depend on the input, then the weakness is in regard to the lack of necessity for that input. Whereas, if the postconditions do not constrain the output, an implementation with a passing proof could return arbitrary output values. Regardless of the particular functionality of the system, either case represents a clear disconnect between the intent of a correct spec and the current spec.

Table 1: Automatic Sanity Checking Flags

Flag Severity	**Condition**
LOW	Post conditions only depend on a portion of the input
MED	Only part of the output is constrained by the postconditions
HIGH	None of the postconditions depend on any of the input
HIGH	None of the output is constrained by any of the postconditons

The power of the Automatic Sanity Checker arises from exploiting the relationship between a spec and the input/output of its corresponding method. Both HIGH severity flags signal the condition when the spec constraints on the input/output of the method are non-existent. If no postcondition depends on any of the input values, then an obvious aspect of the spec is missing. The buggy sort spec in Specification 1 exemplifies this scenario. The spec is not constrained at all by the input, making the spec weak enough to allow for a proof of an incorrect implementation to pass. Similarly, if a method has an output not constrained by its postconditions, an incorrect implementation can return *any* output. The lower severity flags hint to partial violations of the general properties and do not immediately indicate bugs; rather, they signal a missing part of the spec that could be the source of a bug.

4.2 STP Methodology

The testing methodology outlines four classes of STPs. The first three help guide developers in understanding the **Usefulness**, **Correctness**, and **Provability** of their specs. Lastly, if there is a bug in the spec, developers can prove its existence with a **Counterexample** STP. The methodology focuses on specs written following the Hoare-Logic style [51] but can be applied to any type of predicate-based spec. All types of STPs enable the developer to prove a specific property about their spec. A developer proves that context-specific input and

Lemma 3 General Precondition STP

```
lemma PreconditionSTP(in:InType)
  requires TestInputProperty(in)
  ensures Precondition(in)
          // or !Precondition(in)
```

Lemma 4 General Postcondition STP

```
1 lemma PostconditionSTP(in:InType,out:OutType)
2   requires TestInputProperty(in,out)
3   ensures Precondition(in)
4   ensures Postcondition(in,out)
5           // or !Postcondition(in,out)
```

output values are valid or invalid, and gauge if those results match their *intent* based on their understanding of what the spec should or should not permit. Lemma 5 is an example of an STP which tests if a sort spec is strong enough to reject specific *invalid* values. A passing STP shows that the intent of the developer matches the spec and is a proof for that particular property of the spec.

4.2.1 Writing STPs

The construction of different types of STPs share many similarities, but the results are interpreted differently. STPs also enable decoupling of pre- and postconditions so that they can be tested individually. The general form for these STPs are found in Lemmas 3 and 4.

Usefulness STPs help to answer the question of whether the preconditions are weak enough to remain useful; the preconditions should accept all intended valid inputs. Usefulness STPs follow the general form of Lemma 3. The specific input values are defined as part of the precondition for this lemma as the `TestInputProperty`, and should be a value that the test writer *expects* to be a valid input allowed by the spec. The postcondition for a Usefulness STP should be the preconditions from the spec, i.e. `ensures Precondition(in)`.

Correctness STPs examine whether the postconditions are strong enough to reject all intended invalid outputs. Writing Correctness STPs is based on the general form of Lemma 4. To test if the postcondition is strong enough to reject buggy behavior, the test writer supplies an output value that is *expected* to be invalid and should not be allowed by the spec i.e. `ensures !Postcondition(in)`. To isolate testing the postcondition from the precondition, the test writer should also prove that the undesired output does not satisfy the spec as a result of an invalid input value (Line 3 in Lemma 4), ideally with a separate Usefulness STP validating the input.

Conversely to Usefulness and Correctness STPs, Provability STPs test whether the preconditions are strong enough and whether the postconditions are weak enough for the existence of a provable implementation. Provability STPs are most useful before having a passing proof, as a passing proof is evidence that the spec has this property. That said, they can still provide value in the presence of a passing proof, as they can test the strength of transitions in a state machine (see Section 5.2.2).

Lemma 5 Correctness STP Example - Incorrect Sort Spec

```
lemma CorrectnessSTPSort(
    input:seq<int>, sorted:seq<int>)
  requires input == [42, 1, 500]
  requires sorted == [42, 500]
  ensures !SortSpec(input, sorted)
{ }
```

STPs for Provability are concerned with both preconditions and postconditions, thus follow the structure from both Lemmas 3, and 4. Precondition STPs prompt the test writer to prove that *expected* invalid input should not pass the precondition, i.e. `ensures !Precondition(in)`. Whereas postcondition STPs check that input and output *expected* to be permitted by the spec is allowed by the postconditions, i.e. `ensures Postcondition(in,out)`.

If suspecting a spec bug, a test writer can also directly write a Counterexample STP. A passing Counterexample STP is concrete evidence of a bug in the spec. Counterexample STPs can take on two different forms but are still derivative of Lemma 4 if concerned with postconditions and Lemma 3 for preconditions. A Counterexample STP can either show that an expected **valid input-output pair is rejected** by the spec or that an expected **invalid input-output pair is accepted**.

4.2.2 Adding Proof Help To STPs

When an STP fails to verify, it could be due to a divergence between the expectations of the test writer and the current spec, indicating a spec bug, which can be confirmed with a Counterexample STP, or it could be the result of the fundamental undecidability of this type of problem. If it is the latter case, it is possible to circumvent this roadblock in some instances by adding additional proof to the STP body.

The process of proving an STP is no different than writing a proof for any lemma, but the specificity of the STP narrows the scope necessary to reason about. However, before spending the manual effort to add proof annotations to the body of an STP, the first step is to negate the conclusion, i.e. the ensures of the STP. Negating the conclusion transforms an STP into a Counterexample STP. Thus, if the proof now passes there is a clear indication of a bug.

As an example of the process of writing an STP, consider the **Correctness** STP in Lemma 5 for the incorrect sort spec from Specification 1. This STP tests that the sort spec should reject the case when the output sequence is sorted, but only contains a subset of the original input. The Sort method does not have a precondition, so any input sequence would satisfy a Usefulness STP, so this step can be skipped. Running a verifier on this STP would initially result in failing to prove the postcondition automatically. Before spending manual effort to

Table 2: Mutation Operators

Operator	Description
AOR	Arithmetic Operator Replacement
LOR	Logical Operator Replacement
ROR	Relational Operator Replacement
COI	Constant Operator Insertion
UOR	Unary Operator Replacement
ENO	Expression Negation Operator
VNOR	Variable Name Operator Replacement
SOR	Set Operator Replacement
HOR	Heap Operator Replacement

prove this STP, the first step is always to negate the postcondition (i.e. changing Line 5 to `ensures SortSpec(input, sorted)`), transforming the Correctness STP into a Counterexample STP. The attempt to prove this counterexample would now pass and serves as a concrete example of where the spec has diverged from the test writer's understanding.

4.3 Mutation Testing

If the system has a passing proof, IronSpec can leverage the proof and implementation as a reference point for further automation. IronSpec systematically generates a set of specification *mutations*, slight syntactical modifications of the original spec, but only considers those that are not weaker than the original spec. If the original proof still passes with one of these stronger specs, this alerts the developer to the original spec being weaker than the implementation; a disconnect that may hint at an unintentional spec weakness.

All mutations are subjected to three verification-assisted checks, outlined in the following subsections. Each of these checks filter the set of mutations by discarding irrelevant mutations; any discarded mutation is deemed *killed*. If a mutation is still *alive* after all three checks, it serves as a hint of a potential spec bug.

4.3.1 Mutation Generation

We generate mutations inspired by the method-level mutation operators from MuJava [44,45] and from a study that used the Z3 SMT solver to optimize a set of mutation operators based on subsumption relationships [23]. We further introduce an additional predicate-based mutation operator, Set Operator Replacement (SOR). SOR introduces mutations about set inclusion, for example, an expression, $e \in s$, would be mutated to become, $e \notin s$ or vice versa.

The IronSpec prototype is implemented in Dafny, so all mutations are applied to expressions in the Dafny AST. For Dafny expressions that reason about the heap, we introduce the Heap Operator Replacement (HOR) mutation operator, which mutates expressions containing the Dafny keyword `old`. The full list of the mutation operators used in IronSpec is shown in Table 2.

Lemma 6 *IsAtLeastAsWeak* Lemma

```
lemma IsAtLeastAsWeak(p:Params)
    requires OriginalPredicate(p:Params)
    ensures MutatedPredicate(p:Params)
```

Predicate 7 *Mutation* Target Example

```
predicate SafetyProperty(p:Params)
{ SubPredA(p) ==> SubPredB(p) }
```

Each generated mutated spec is the result of IronSpec applying a single mutation operator at a time. The set of all mutated specs consists of all possible single-operator mutations for a given spec applied to each subexpression in the mutation target.

An example of one of the many possible spec mutants starting with the single postcondition from Specification 1 would be: `forall i | 0 <= i < |output| - 1 :: out[i]` **<** `out[i+1]`. This mutation is generated using the Relational Operator Replacement (ROR) mutation operator which generates mutations by replacing relational-based operators from the set of `{==, <, <=, >, >=, !=}`. One application of this mutation operator results in replacing the <= to a < in the RHS of the forall expression.

4.3.2 First Pass: Logical Redundancy

Not all mutations produced from the original spec are relevant. A spec defines a set of behaviors, and a passing proof shows that the behavior of a specific implementation is a subset of the behavior allowed by the spec. A spec that is weaker than the original would allow a larger set of implementations to satisfy this subset property. Any mutated spec that is logically equivalent or *weaker* than the original spec would not provide any new information to the tester about the current implementation and can be safely disregarded.

A mutation can cause a spec to become weaker if it weakens a postcondition or if it strengthens a precondition. Either case allows for a larger set of implementations to satisfy the spec. Therefore, for each mutation to a postcondition, IronSpec tests if the mutation *is at least as weak* as the original spec.

Definition 4.1. Given predicates S and S' with parameters p, S *is at least as weak* as predicate S' iff $\forall p.S'(p) \implies S(p)$

IronSpec captures this definition by automatically formulating Lemma 6 for the original and mutated specs. If this lemma passes, then the mutated spec must be equivalent to or weaker than the original spec, indicating that it can be killed.

Conversely, if the mutation modified a precondition, IronSpec checks the opposite, to see if the mutation *is at least as strong* as the original spec. The lemma to check if a spec is at least as strong as the original is similar to Lemma 6, but with the requires and ensures reversed.

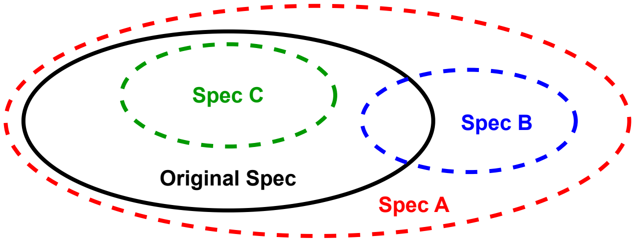

Figure 1: A mutated spec can either be strictly weaker (Spec A), strictly stronger (Spec C), logically equivalent, or partially stronger and weaker (Spec B) than the original spec.

As an example of Definition 4.1, consider Figure 1, where each circle represents the set of behaviors allowed by each respective spec. Any behavior in the circle encapsulated by the Original Spec is still inside the set of allowable behaviors of Spec A, making Spec A strictly weaker than the Original Spec and thus would be automatically discarded based on the result of Lemma 6. Both Specs B and C are not at least as weak as the Original Spec and would survive the *Logical Redundancy* pass.

The *IsAtLeastAsWeak* lemma is generated automatically to test the spec's overall safety property, rather than directly testing the mutated expression. This is important to avoid false positives. For example, consider if `SubPredB(p)` in Predicate 7 contains the mutated expression. Testing the *IsAtLeastAsWeak* Lemma with just `SubPredB(p)` may fail, indicating that this mutation is stronger than the unmodified version of `SubPredB(p)`, but this mutation may cause its caller, Predicate 7, to become weaker.

4.3.3 Second Pass: Vacuity

IronSpec's second pass aims to identify the mutations that cause vacuity [36]. For example, if a mutation to `SubPredA(p)` from Predicate 7 resulted in it always evaluating to *false*, then Predicate 7 would always be true. A vacuous spec would allow for the system's proof to pass trivially because any behavior of the system would be allowed by the vacuous spec. Checking vacuity is more complicated than purely checking if the mutated predicate is itself vacuous, as the conditions of a predicate that calls the mutated predicate, in conjunction with the mutated predicate could result in the caller becoming vacuous. This is especially important with specs that are state machines where a mutation could cause a state transition to become *false*, removing that behavior from the spec. IronSpec automatically generates a lemma to check for vacuity by considering the full call path.

4.3.4 Third Pass: Full Proof

The final check is to see if the full proof will pass with the mutated spec. In this final pass, the system is re-verified with the addition of the mutated spec to ensure that no intermediary lemmas now fail. If the full proof passes, the mutation is considered *alive* and serves as a flag to the developer to reexamine the spec.

4.3.5 Hierarchical Classification of Alive Mutations

Rather than providing the tester with a list of all alive mutations, IronSpec performs an additional pass to characterize the alive mutations, minimizing the output to the most relevant. To maximize the hint provided by an alive mutation, IronSpec evaluates the set of alive mutations to calculate a Direct Acyclic Graph (DAG) indicating which mutations are weaker or stronger in relation to one another. The DAG is structured so that each node is stronger than all of its children. The tester need only further concern themselves with the root of each connected component of this *mutation DAG*, as all children are weaker than the root in each component. This hierarchical classification is inspired by previous research to classify and remove equivalent mutations [8,23,46,50].

4.4 Using Alive Mutations As Hints For STPs

When testing specs, human intuition is always the final oracle, thus, STPs are still needed to finish the investigation started by mutation testing. On their own, alive mutations only indicate a relative divergence between the spec and the implementation, but these hints can be used to write focused STPs. The relative strength of an alive mutation can be used to shrink the state space necessary to test, focusing on the divergence between the original spec and the mutation.

Armed with an alive mutation, a test writer can effectively exploit its hint by deviating from the standard guidelines of writing STPs and work **backwards** from the *spec difference*. The spec difference is the set of behaviors allowed by the original spec S and not by the alive mutation S'; essentially $S - S'$. The spec difference embodies the fundamental insight IronSpec is based on; it captures a specific disconnect between the original spec and the implementation. The behavior allowed by this reduced expression is permitted by the original spec, but not by the more restrictive mutation. The spec difference uniquely presents the tester with this subset of behavior to determine if that particular disparity is intended.

Working backwards allows the test writer to find concrete values that satisfy only the spec difference, achieving more concentrated STPs. Typically, when writing STPs, a tester starts by manually specifying values they intend for the spec to allow or disallow. This process increases in difficulty with the additional constraint that these intended values also need to satisfy the spec difference. The shift of working backwards helps to alleviate this burden.

Driven by the insight that the actual semantic change between the mutation and the original spec is small—only a single mutation—the expression of the spec difference is min-

Table 3: Spec bugs identified using the Automatic Sanity Checker. All bugs were confirmed with Counterexample STPs based on the initial hint of either MED or HIGH flags.

Bug	Specification	Method Name	Flag
TS1	TrueSat [7]	Formula Ctor	HIGH
TS2	TrueSat [7]	Start	MED
ETH1	Eth2.0 [1]	on_block	MED
AES1	AWS ESDK [3]	Encrypt	MED
AES2	AWS ESDK [3]	Decrypt	MED

imal. Working backwards allows the test writer to generate *any* input and output, and then use the verifier to check that the input and output are accepted by the expression constituting the spec difference. After generating such values, the final decision relies on the tester to decide whether the input-output pair is intended. At this stage, the existence of an *unintended* value is a counterexample to the original spec.

5 Evaluation

We evaluate the effectiveness of the IronSpec prototype by applying the Automated Sanity Checker, the STP Methodology and the automated mutation testing framework to test 14 different specifications written in Dafny [40]. Six of these specifications are produced in-house and include artificially introduced bugs, with an additional two specs containing artificial bugs described by Abreu et al. [6]. Six of the specifications are of real-world, open-source verified systems, which include: QBFT [2], DVT [4], TrueSat [7], Eth2.0 [1], daisy-nfsd [15] and an AWS Encryption SDK library [3].

When testing a spec, the ultimate oracle is the test writer, thus the final step is always to write an STP. When testing a spec, a tester could start with any aspect of IronSpec. We discuss the various facets of IronSpec by highlighting their use in supplying the initial hints used to discover *ten* spec bugs, all confirmed by their corresponding authors.

We consider all spec bugs identified and discussed in this section useful and significant; all could have allowed or did allow an incorrect implementation that would violate safety **while still allowing the proof to pass**.

The IronSpec artifact is publicly available on GitHub [5].

5.1 Automatic Sanity Checking Evaluation

Applying the Automatic Sanity Checker to the six open-source verified systems led to the discovery of five spec bugs across three specs, listed in Table 3.

Of the bugs identified, only TS1 was identified immediately with a HIGH severity flag, whereas the other four bugs were each discovered in less than an hour by writing STPs based on the hint of MED severity flags. The corresponding implementation for all five spec bugs appeared correct, but the specs were buggy, being too weak. To confirm these spec bugs, we wrote buggy implementations as Counterexample STPs for each spec and demonstrated that the proof still passed.

Spec bugs TS2, ETH1, AES1, and AES2 were identified by investigating each respective MED severity flag. We found that in these cases, the bug was a result of the output consisting of a complex datatype with many sub-fields and having postconditions concerning only a subset of these fields. This combination allows for a different implementation to update the remaining unspecified fields arbitrarily.

A MED severity flag is not as strong of a hint of a spec bug as a HIGH severity flag because *the unspecified fields may or may not be critical for safety*. The HIGH severity flag raised for TS1 was; "None of the postconditions depend on any of the input." This spec bug allows a buggy implementation to completely ignore the input values when constructing the output. The authors have remedied bugs TS1 and TS2 with a pull request we submitted.

The two bugs, AES1 and AES2, from the AWS Dafny Encryption SDK library (ESDK) [3] are both cases of spec weakness. The Dafny ESDK is a verified SDK used as a reference to build ESDKs for other languages. These bugs exist for the high-level methods of `Encrypt` and `Decrypt`. They are caused by a combination of the postconditions under-constraining the output and because the postconditions of sub-methods are not exported. This underspecification allows for the proof of trivially incorrect implementations for `Encrypt` and `Decrypt` to pass, such as returning a ciphertext or plaintext consisting of a zero byte regardless of the input.

Specs with output containing complex datatypes with many sub-fields are a critical source of spec bugs. Judging from the results of applying the Automatic Sanity Checker, under-constraining complex output can easily be overlooked. To avoid these types of spec bugs, it is vital to specify the expected values for all sub-fields of the output.

5.2 STP Methodology Evaluation

In this section we describe our experience in writing Usefulness, Correctness, and Provability STPs for specs following the Hoare-Logic style; and in the cases of identifying a spec bug, Counterexample STPs. We discuss the effectiveness of these STPs to expose differences in what behaviors the spec allows in contrast to a test writer's expectations in the presence of artificially introduced bugs.

We also discuss a case study, where following the STP methodology we discovered three spec bugs in a verified QBFT protocol. We wrote STPs for all open source specs, and when an STP failed to verify and the result conflicted with our understanding of the spec, we wrote Counterexample STPs to prove the existence of a spec bug. For brevity, the case study in this subsection focuses on the QBFT spec, where STPs acted as the initial flag that hinted at the existence of a spec bug.

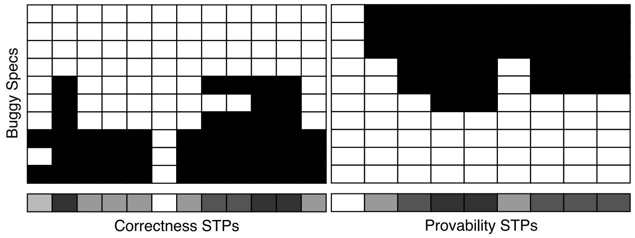

Figure 2: STP coverage for various buggy sort specs

5.2.1 STPs For Contrived Spec Bugs

We wrote STPs for five specs written in-house that follow the Hoare-Logic style. These specs include methods for finding the max of two integers (*Max*), sorting a sequence of integers (*Sort*), searching for an integer in a sequence (*Binary Search*), a cryptocurrency token creation contract (*Token-with-revert-external-wre*), and an auction contract (*SimpleAuction-with-revert-external-wre*). The *Token* and *SimpleAuction* specs were modified from Cassez et al. [14].

We wrote a total of 70 STPs for all variations of the contrived specs. The bugs introduced into the specs vary, but the resulting specs comprised an approximately equal split between too-strong and too-weak specs. Only 30% of these STPs (21) needed additional proof help and of those, each STP needed, on average, an additional 1.7 lines of proof help. The STP suite was successful in all cases in identifying introduced spec bugs—confirming the notion that a failing STP is a reliable flag suggesting a discrepancy between the intent encoded in the STPs and the spec.

Not all classes of STPs are useful in identifying all spec bugs because of the different natures of each type of STP. To demonstrate why writing a diverse suite of STPs is useful, consider Figure 2 that shows the coverage of 21 STPs across 10 different bugs for a `Sort` spec. In this experiment, the suite of STPs consisted of Correctness and Provability STPs because the different `Sort` specs were all postconditions, and Usefulness STPs are only concerned with preconditions. Each row corresponds to a different introduced bug and each column matches to a different STP. A darkened cell indicates that a specific STP successfully identified the bug after transforming the failing STP into a passing Counterexample STP. The bug was identified if a row contained a **single darkened cell**, whereas each column gives insight into the **coverage** of a single STP in identifying different bugs. The bottom row is a heat map corresponding to the ratio of bugs identified by each STP. The two STPs that uncovered zero spec bugs tested trivial enough cases such that they passed with all of the buggy specs. Depending on the spec bug, there were cases where the Correctness STPs were insufficient to identify the bug on their own, and there were cases where the same was true of the Provability STPs. So, when writing STPs it is important to have good coverage of different types of STPs to increase testing effectiveness.

Lemma 8 Simplified QBFT Provability Adversary STP

```
lemma AdversaryForwardMessageSTP(
    a:Adversary,
    a':Adversary,
    inMsgs: set<Message>,
    outMsgs: set<Message>)
  requires validAdversaryConfig(a,a',inMsgs)
  requires inMsgs == {ProposalMsg(CS1,block)}
  requires outMsgs == {NewBlockMsg(CS1,block)}
  ensures AdversaryNext(a, a', inMsgs, outMsgs)
```

5.2.2 STPs: QBFT Case Study

Writing STPs for the QBFT spec [2], a Byzantine fault-tolerant consensus protocol used in the Ethereum ecosystem [47], led to the discovery of three spec bugs confirmed by the authors. The spec in this system consists of a single safety property, *Blockchain Consistency*, and the environment, which includes the high-level distributed system, the network, and the adversary which are all modeled as a state machine. Upon manual inspection of these STPs, we found that the adversary spec was *incomplete*, based on our understanding of what the adversary spec should be. The overall proof still passed even in the presence of these three bugs because they essentially cancel each other out; two making the spec weaker than it should be, and the other making the spec stronger.

The first bug identified in the adversary spec was an example of the spec being too strong; limiting the actions of what an adversarial node *should* be able to do. The initial hint indicating the possibility of this case was provided by failing Provability STPs. The initial reason for writing Provability STPs was to answer if the adversary spec was too strong; which is answered by the general form of Provability STPs. An overly restricted adversary model would weaken and perhaps invalidate the guarantees of the overall proof. Following the guidelines for writing STPs in Section 4.2.2, negating the conclusion of the failing Provability STPs led to the discovery of a passing Counterexample STP. Lemma 8 is a simplified example of such a failing Provability STP.

The failing simplified STP in Lemma 8 hints at the fact that the ability of the adversary to extract signed data structures is unnecessarily restricted. In the system model for QBFT, and other Byzantine fault-tolerant consensus protocols, a Byzantine node should be allowed to behave arbitrarily while not violating cryptographic assumptions. In this QBFT spec, adversaries are only able to extract and forward `CommitSeals(CS)` from a subset of received message types. The STP in Lemma 8 specifies the behavior of an adversary node receiving a `Proposal` message signed with a quorum of `CS1`, and constructing and sending a *NewBlock* message containing the `block` and `CS1` data structures copied from the `Proposal` message. The postcondition for this STP stipulates that this scenario constitutes a valid state transition from state `a` to state `a'`. After observing that this STP failed to immediately

Lemma 9 Simplified QBFT Adversary Correctness STP

```
lemma AdversaryForgeMessageSTP(
    a:Adversary,
    a':Adversary,
    inMsgs: set<Message>,
    outMsgs: set<Message>)
  requires validAdversaryConfig(a,a',inMsgs)
  requires outMsgs == {ProposalMsg(CS2)}
                        // forged msg
  ensures !AdversaryNext(a,a',inMsgs,outMsgs)
```

verify, negating the conclusion to, `!AdversaryNext(a, a', inMessages, outMessages)`, resulted in the proof passing for this transformed counterexample STP.

While investigating the implications of the behavior in the failing STP, we modified the adversary spec, weakening it to allow an adversary to forward `CS1` regardless of what message first contained it. After making this change, the full system's safety proof failed. To differentiate the proof failure from a now incomplete lemma, we constructed and proved a concrete counterexample resulting in a violation of the system's safety property, confirmed by the authors.

The second bug in the adversary spec is an example of the spec being too weak. This weakness is the reason why we can show a concrete counterexample to safety after addressing the first spec bug. The spec allows an adversarial node to send a `Proposal` message containing a `block` data structure with arbitrary values, including using the `CommitSeals` of honest nodes even if the adversary had not previously received such `CommitSeals` in previously received messages. `CommitSeals` are only used to make a final decision of committing a block, but this weakness in the spec allows an adversary to propose new blocks containing `CommitSeals` as if from honest nodes. This behavior allows an adversary to send a message that appears to be signed by an honest node, violating the security assumptions made by the QBFT system model. The STP in Lemma 9 is a simplified version of the Correctness STP used to discover this spec bug.

The third bug identified is related to the previous bug and is concerned with the underspecified spec of the function *getNewBlock()*. This function is empty-bodied and only contains the spec. Due to the underspecification of this function, a caller of this function, including an honest node can immediately send a message, such as a `Proposal` message, containing a full quorum of commit seals. If a buggy implementation is provided for this function, it too, could lead to a violation of the safety property.

5.2.3 STP Discussion

STPs enable fine-grain testing of specs and have been effective at helping to identify all ten spec bugs in the six open-source verified systems. By leveraging the insight that writing proofs for specific values is easier than a general proof, the manual effort required to write STPs remains minimal.

In the QBFT spec the presence of three spec bugs, two manifesting as a weakness in the spec and the other counteracting the first by overly restricting the adversary, makes manually or automatically identifying these bugs extremely difficult. Following the STP testing methodology, we efficiently, and without being experts in the system, identified these disconnects between what was written in the spec and our understanding of the intent of the spec.

5.3 Mutation Testing Evaluation

We applied IronSpec's automatic mutation testing to a set of six in-house specs, the two spec examples from Abreu et al. [6], and the spec of six open-source verified codebases. The evaluation attempts to answer how prevalent *alive* mutations are in specs, and how useful the provided hints are in assisting to identify spec bugs.

All mutation testing experiments were performed on a cluster of 21 servers where each node was equipped with two Intel E5-2660 v2 10-core CPUs at 2.20 GHz and with 256GB ECC Memory. In each experiment, one root node would create all mutations and send all subsequent verification requests in each stage of the mutation testing process to be processed in parallel at the other 20 nodes in the cluster using Dafny version 3.8.1. The results from running IronSpec can be found in Table 4 and are further explained in the following subsections.

5.3.1 In-House Specifications

In addition to the five in-house specs introduced in Section 5.2.1, we applied mutation testing on a simple key-value store state machine spec.

The top half of Table 4 contains the experimental results of running mutation testing on the in-house specs. Each buggy spec was tested with a correct implementation (C) and an incorrect implementation (I). Mutation testing all in-house specs with a correct spec and a correct implementation resulted in no alive mutations.

Mutation testing identified relevant alive mutations, regardless of whether the implementation is correct. For all six incorrect specs, mutation testing resulted in helpful alive mutations. The only exception is Sort (C), whose implementation contained additional loop invariants that caused the proof to fail when using weaker preconditions. In all other cases alive mutations were useful hints in manually identifying a weakness in the spec.

5.3.2 Alive Mutations in Open Source Systems

The Div and NthHarmonic specs are simple buggy specs introduced by Abreu et al. [6], where the authors proposed initial techniques to repair simple spec errors in Dafny. The alive mutations IronSpec found for these specs coincide with

Table 4: Results from running IronSpec's automatic mutation testing. In-House, buggy, specs marked with "(C)" correspond to experiments with a buggy spec but a correct implementation, whereas "(I)" indicates a buggy spec with an incorrect implementation. The Predicate Name is the specific mutation target within a spec. Spec LOC is the size of the mutation target, and Proof/Impl LOC is the size of the full end-to-end implementation and proof. Mutations are the total number of mutations generated, Alive Mutations indicate the number of alive mutations after all three passes and hierarchy classifications.

	Specification	**Predicate Name**	**Spec LOC**	**Proof/Impl LOC**	**# Mutations**	**# Alive Mutations**	**Time**
In-House Specs	**Max (C)**	maxSpec	2	5	80	1	11.3s
	Max (I)			7		4	7.5s
	Sort (C)	sortSpec	1	55	50	0	4.5s
	Sort (I)			4		1	7.3s
	Binary Search (C)	searchSpec	4	31	170	1	10.4s
	Binary Search (I)			18		2	24.3s
	KV SM (C)	Query Op	4	187	37	7	21s
	KV SM (I)					7	28.8s
	Token-wre (C)	GInv	1	87	13	1	7.8s
	Token-wre (I)			91		1	7.8s
	SimpleAuction-wre (C)	GInv	9	181	187	3	15.25s
	SimpleAuction-wre (I)					3	15.5s
Open-Source Specs	**Div**	Div	3	14	50	3	3.5s
	NthHarmonic	NthHarmonic	1	4	11	2	3s
	QBFT	NetworkInit	3	15071	44	3	80 min
	QBFT	AdversaryNext	48		197	7	162 min
	QBFT	AdversaryInit	3		35	4	80 min
	Distributed Validator	AdversaryNext	23	24747	110	7	191 min
	daisy-nfsd	GETATTR	4	18	35	1	4.3 min
	daisy-nfsd	WRITE	7	54	119	3	4.6 min

the conclusions made by Abreu et al. in demonstrating that these specs are buggy by being too weak.

QBFT Of the 44 generated mutants for the initial state of the network state machine spec, `NetworkInit`, three mutations remained *alive* as the roots of their respective components in the *mutation DAG*. Upon manual inspection of the surviving mutants, the spec differences all referenced an aspect of the Network's state that was never mentioned elsewhere. Thus, any value for part of the state would be considered "safe". These mutations do not imply the existence of a bug, but neither are they strictly false positives; rather they are examples of spec bloat. These alive mutations should still serve as flags to the developer, forcing them to answer the question of whether this state is needed, and if so why are these parts of the state not referenced?

The alive mutations for the `AdversaryNext` and `AdversaryInit` predicates, both parts of the adversary state machine spec can be considered false positives. The alive mutations were all *stronger* mutations, but it is always safe to restrict the actions allowed by an adversarial node. Some alive mutations implied that the proof would still pass with no adversaries in the system, or only taking trivial actions. This observation led us to question and then to test with STPs if the adversary spec was initially more restricted than it should be, leading to the bugs discussed in Section 5.2.2.

DVT The Distributed Validator Technology Protocol (DVT) spec and proof [4] captures the behavior of an Ethereum Validator, where a group of nodes coordinates to perform the Ethereum validator duties. The DVT spec consists of the desired *non-slashable attestation* property and the environment, with the latter defined as the high-level distributed system, an adversary, and the network. All aspects of the environment are modeled as state machine specs. The *non-slashable attestation* property ensures that the system avoids committing a slash-able offense and produces valid attestations.

Applying mutation testing to the `AdversaryNext` predicate in the adversary spec resulted in seven *alive* mutations. One of the mutations was a false positive. Three of the mutations hinted towards a limitation of the messages allowed to be sent by an adversary, leading to a similar discovery as in the first QBFT bug. The remaining three alive mutations were concerned with the creation of attestations. This weakness lies in the spec's lack of specificity regarding the attestations an adversary can create. Armed with this observation, we show with a counterexample that this weakness could lead to a safety violation.

daisy-nfsd Applying the mutation framework to daisy-nfsd's [15] top-level NFS API spec resulted in alive mutations in two different methods' specs, `GETATTR` and `WRITE`. These mutations hint at the same spec weakness that both methods contain; one that would allow for a different trivial implementation to always return an error. This bug was confirmed by the authors as a known issue in their spec.

5.3.3 Combining STPs With Mutation Testing Hints

An alive mutation is a compelling hint that the spec may be weaker than intended, but it is just a hint; writing STPs (Section 4.4) is always the final step in testing. Consider the DVT spec bug from Section 5.3.2. The original mutation target predicate is non-trivial and consists of 22 lines including multiple quantified conjuncts. Working backwards from the alive mutations and focusing only on the expression derived by the difference between the original spec and an alive mutation, resulted in shrinking the 22-line predicate into only a single conjunct. Writing STPs concerning this single conjunct is much more tractable than writing STPs for the entire predicate. The tradeoff of the slightly increased manual effort to calculate the simplified expression and writing STPs concerning it outweighs the effort needed to consider the entire spec.

5.3.4 Mutation Testing Discussion

Mutation testing supplied the hints that led to the discovery of spec bugs in two verified codebases. These results exemplify the usefulness of adding automation to search for disconnects between the implementation and the spec. The insight of identifying tangible differences as potential areas of disconnected intent is a beneficial hint that can be leveraged to identify spec bugs. The results in Table 4 demonstrate that even with a small set of mutations, we were successful in identifying spec weaknesses.

The large increase in execution time of running mutation testing taken between different specs can be attested to the varying sizes of the full system proof and the time that it takes to verify the entire proof with the mutations that survive the first two passes. For instance, even running the full end-to-end proof once of the unmodified QBFT system can take approximately an hour to complete. The cost of running IronSpec on a large verified system is worth the execution time to debug a potential spec bug.

The results of testing specs with mutation testing demonstrate the effectiveness of this approach, but we did find that not all alive mutations led to the discovery of spec bugs. While the possibility of discovering false positive alive mutations exists, all cases were quickly diagnosed. Of the 61 alive mutations identified across all tested specs, we consider 13 to be false positives, because the spec weaknesses they hint at were deemed intended. All mutations for QBFT's `AdversaryNext` and `AdversaryInit` were considered false positives. A single alive mutation in the set of alive mutations for both DVT `AdversaryNext` and daisy-nfsd `WRITE` were also characterized as false positives. The one false positive mutation found in DVT `AdversaryNext` was classified as such because it would have only allowed the adversary to make attestations already created, which would not have led to any unintended, incorrect behavior.

Verified methods that modify ghost state are at a higher risk of mutation testing producing false positives. Ghost state is only maintained for the sake of the proof, and often, underconstrained postconditions related to ghost state would not result in a buggy implementation. The false positive mutation in daisy-nfsd's `WRITE` method hinted towards underconstrained ghost state that was modified in the method's implementation. Nevertheless, the daisy-nfsd authors confirmed that a different implementation, which modified this ghost state differently, would not lead to a safety violation or break the proof. However, they did acknowledge that this weakness was not immediately apparent.

Rather than finding false positives, it is also possible, especially with larger systems, for no alive mutations to be identified. For QBFT, DVT, and daisy-nfsd there were other spec mutation targets we applied IronSpec to, which resulted in no alive mutations. For example, in both QBFT and DVT, the alive mutations identified were part of the trusted specified environment, whereas no alive mutations were found for their respective safety properties, *Blockchain Consistency* and *non-slashable attestation*.

The IronSpec prototype takes the first steps to bring automation and structure to testing specs. The prototype targets Dafny specs, but the conceptual techniques are not tied to Dafny.

5.4 Amount Of Manual Effort Required

In the same way testing traditional software systems requires developer effort, testing specifications does too. IronSpec provides a framework and automation aid to help developers in this endeavor. If one is willing to spend the effort to verify their system, it is worth spending a few additional hours to gain confidence in proving the intended property. While manual effort is unavoidable, this effort can be greatly reduced as the automation of IronSpec helps to focus the developer's attention on a few potentially problematic aspects of the spec.

The majority of manual effort we expended in applying IronSpec was spent on understanding each system well enough to interpret the hints from the automation of IronSpec and to write appropriate STPs. Even so, the amount of manual effort expended remained relatively low despite not having specific expertise in each system. For example, the specification bug identified in daisy-nfsd took approximately 1-2 hours to determine from first examining the code base and running IronSpec to confidently identifying the spec bug. When testing daisy-nfsd, it took minutes to run the mutation framework, and the rest of the time was spent comprehending the hint of the alive mutation, writing STPs, and understanding the underlying system well enough to determine if the flagged behavior was intended. In conversations with the daisy-nfsd authors, they admitted that this spec bug was subtle. Familiarity and expertise in a system and its spec will only help to further reduce the necessary manual effort.

Writing STPs for complex systems takes more effort than for simple examples. Yet, the limited scope of writing STPs with concrete values drastically limits the size of any potential additional proof annotations needed for those STPs in comparison to what would be necessary for proof of the unconstrained behavior. The effort of writing STPs varied per the complexity of the system. Writing a comprehensive suite of STPs ranged from a few hours to multiple days worth of effort for the larger QBFT and DVT specs. Writing-focused STPs based on alive mutations ranged from tens of minutes to hours per alive mutation.

6 Related Work

Kemmerer [33] first identified the potential benefits of testing specifications. Kemmerer proposed a technique based on symbolic execution to check if a spec satisfied the English-based functional requirements. Since then, several studies have proposed techniques to test informal user requirements [13, 18, 35, 42, 43].

The closest related previous work is the study by Fonseca et al. [22], which manually and painstakingly identified weaknesses in verified codebases, including two spec bugs. Other works have also begun to apply more structured approaches to increase reliability in formal methods. Kupfeman [36] discussed the possible advantages of vacuity and coverage checks for temporal-logic model-checking tools. Inspired by vacuity testing, and the concept of *unit proofs* from Chong et al. [16], Priya et al. [52] performed a case study of some AWS verified libraries, uncovering some hidden bugs. Bernardi et al. [11] also identified formal specifications as a weak point in the verification process, and proposed to reuse specifications once correct, for smart contracts. Le Traon et al. [38] even discussed the notion of applying a mutation analysis to Eiffel contracts.

With verification becoming more commonplace and the discovery of spec bugs in verified systems, a few, mostly manual efforts have attempted to identify spec bugs. The 2022 Notional Finance bug found in verified code inspired Certora to investigate ways to introduce testing into the verification process [49]. Recently, Abreu et al. [6] proposed initial efforts in using the dynamic invariant inference tool *Daikon* [20] to aid in automatically repairing specifications. When faced with a failing proof, their prototype assumes that the implementation is correct, and uses the implementation to generate test cases for the spec. Any failing tests present an opportunity to attempt to fix the spec by suggesting strengthening or weakening modifications. Of course, this approach only works if the implementation is correct, which partially defeats the purpose of performing verification in the first place.

Testing and formal methods share a close relationship and a common goal. Often, rather than questioning specs, developers have relied on specs or other formal methods to assist in testing traditional software [11, 16, 27, 39]. Works concerned with the Oracle problem [9, 12] have often utilized specs thus. There has even been work to test verification tools [30].

7 Conclusion

The correctness of specifications is the rock upon which the entire edifice of formal verification is built. As formal verification becomes increasingly popular, it is imperative that the foundation be as solid as possible.

This work proposes IronSpec, a systematic framework of manual and automated approaches to aid developers in finding bugs in their specs. We show how IronSpec was used to identify a number of subtle bugs in the specs of open-source codebases, without requiring copious amounts of expertise on the proven system. We believe IronSpec is a necessary step forward towards writing correct software.

Abstract

The rapid advancement of computer system components has necessitated a comprehensive profiling approach for both on-CPU and off-CPU events simultaneously. However, the conventional approach lacks profiling both on- and off-CPU events, so they fall short of accurately assessing the overhead of each bottleneck in modern applications.

In this paper, we propose a sampling-based profiling technique called *blocked samples* that is designed to capture all types of off-CPU events, such as I/O waiting, blocking synchronization, and waiting in CPU runqueue. Using the blocked samples technique, this paper proposes two profilers, *bperf* and *BCOZ*. Leveraging blocked samples, bperf profiles applications by providing symbol-level profile information when a thread is either on the CPU or off the CPU, awaiting scheduling or I/O requests. Using the information, BCOZ performs causality analysis of collected on- and off-CPU events to precisely identify performance bottlenecks and the potential impact of optimizations. The profiling capability of BCOZ is verified using real applications. From our profiling results followed by actual optimization, BCOZ identifies bottlenecks with off-CPU events precisely, and their optimization results are aligned with the predicted performance improvement by BCOZ's causality analysis.

1 Introduction

Application profiling encompasses the analysis of two types of events: on-CPU events and off-CPU events. Profiling on-CPU events aims to analyze instructions executed on a CPU [1, 4, 7, 15, 17, 19–21, 33, 45, 53, 54]. In contrast, profiling off-CPU events aims to analyze waiting events within an application such as waiting for blocking I/O completion, locks, scheduling, etc [27, 35, 38, 39, 55, 58].

In the past, applications were clearly characterized as either CPU-boud or I/O-bound due to the use of slow I/O devices such as HDD or SATA SSD. Therefore, existing profiling tools have applied bottleneck analysis techniques separately for on-CPU events or off-CPU events. However, with the recent advancements in fast storage and many-core CPUs, modern applications often exhibit complex behaviors. Especially, their performance bottleneck is combined by on-CPU events and off-CPU events, necessitating the need for comprehensive profiling of both on-CPU and off-CPU events *simultaneously* and capturing their interactions. For example, with the emergence of NVMe SSDs and ultra-low latency SSDs, the critical path of I/O-intensive applications often shifts from I/O to CPU events [23, 30–32]. Consequently, studies have focused on optimizing on-CPU events rather than I/O events to enhance the performance of I/O-intensive applications [23, 30–32].

However, existing profilers focus on analyzing only on-CPU [17, 20, 33] or off-CPU events [3, 38], so they cannot analyze the complicated behaviors of modern applications. COZ [15], a state-of-the-art causal profiler, estimates performance gain through its virtual speedup approach. COZ intentionally delays competing threads to estimate the performance impact by optimizing certain code lines without actually optimizing them. However, COZ applies virtual speedup profiling exclusively to on-CPU events as it lacks the capability to incorporate execution information from off-CPU events. wPerf [58], a state-of-the-art off-CPU analysis profiler, traces waiting events between threads during the execution and reports the result in the form of a graph (called a wait-for graph). While wPerf can analyze interactions between on-CPU and off-CPU events, it falls short in assessing the actual impact of bottlenecks on application performance. Furthermore, although wPerf identifies off-CPU bottlenecks, it lacks detailed information about the application contexts related to these bottlenecks. These limitations require programmers to attempt optimizations for various bottlenecks to achieve actual performance improvements and demand additional effort to pinpoint the application code to be optimized (Section 2.2).

This paper introduces a new profiling technique called *blocked samples*, which is designed to capture off-CPU events. Drawing inspiration from the event-based sampling (e.g., Linux perf subsystem [17]), our approach employs sampling-based profiling of off-CPU events. Similar to Linux perf, the blocked samples technique periodically captures snapshots of events with designated information, such as the instruction pointer (IP) and the call stack of each thread. However, unlike Linux perf, which disables profiling while the target thread is blocked, the blocked samples technique overcomes this limitation by allowing sampling of off-CPU events while the target thread is blocked. Leveraging the information provided by blocked samples, we aim to devise profiling techniques that consider both on-CPU and off-CPU events simultaneously, identify bottlenecks and estimate their performance impact if optimized.

To demonstrate our idea, we devise two profilers, *bperf* and *BCOZ*. bperf is an easy-to-use sampling-based profiler, following the interfaces of the familiar Linux perf tool. bperf incorporates the blocked samples technique. By considering the sampling results that include blocked samples, bperf accurately calculates the overhead of each event. This enables bperf to provide precise overhead information for both on-CPU and off-CPU events. Additionally, bperf reports detailed information about the sampled off-CPU events such as call stacks, kernel stacks, and blocking types (e.g., I/O, synchronization, scheduling, etc.), assisting users in gaining a deeper understanding of overheads.

BCOZ is a causal profiler that leverages the concept of virtual speedup [15] for off-CPU events obtained by blocked samples. BCOZ provides estimated performance improvement not only of a single off-CPU event but also of a function involving multiple on-/off-CPU events. Additionally, BCOZ supports a per-subclass virtual speedup technique, which estimates the potential speedup if off-CPU events of a particular type are optimized, such as using faster I/O devices or eliminating CPU scheduling delays. This feature allows users to consider various optimization alternatives, such as upgrading I/O devices or assigning additional CPU cores.

Our evaluation results demonstrate that BCOZ successfully identifies bottlenecks of real applications including both on- and off-CPU events. Specifically, BCOZ identifies various bottlenecks of the RocksDB key-value store [50] with read-intensive and write-intensive workloads. We observe that with various memory configurations and workload patterns, diverse parts of the program exhibit distinct performance bottlenecks. BCOZ precisely identifies such bottlenecks and provides an estimated speedup of the optimization of each bottleneck. We verify that the reported virtual speedup results are also aligned with the actual speedup when various optimization techniques are applied. These results prove the effectiveness of BCOZ by profiling on- and off-CPU events simultaneously.

Our contributions are summarized as follows:

- We demonstrate the need for integrated profiling of both on-CPU and off-CPU events to overcome the limitations of conventional profilers (Section 2).
- We propose a new sampling technique called blocked samples, designed for capturing off-CPU events. By incorporating blocked samples with on-CPU samples, we enable the identification of application bottlenecks related to both on- and off-CPU events (Section 3.1).
- We introduce two profilers, bperf and BCOZ, that utilize the blocked samples technique. These profilers provide insights into the overhead of off-CPU events and uncover potential performance improvement opportunities that were previously unrecognized (Section 3.2 and 3.3).
- We present practical use cases of our profilers, bperf and BCOZ. Through profiling, we identify off-CPU bottlenecks in applications. Then, we validate the identified bottlenecks through simple optimizations or comparison with previous optimization studies (Section 4).

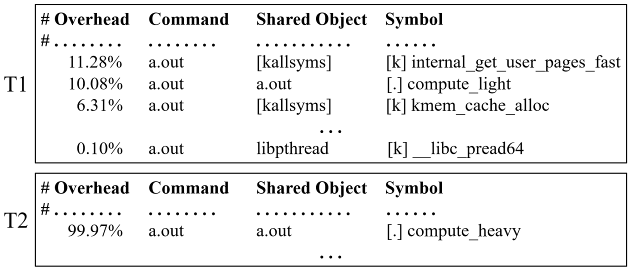
2 Background

2.1 Sampling-based Profiling

Sampling-based profiling (e.g., task-clock in Linux perf [17]) is a widely used and efficient method for profiling the application execution with low overhead [17, 20, 33]. It periodically captures (or samples) the execution information of programs on the CPU such as the instruction pointer (IP) and the callchain of each thread (or CPU). With the sampling results, profilers can report statistical overhead [17, 33], perform causal analysis [15], and visualize callchains of captured events [21]. However, identifying the exact bottleneck in sampling-based profiling remains challenging due to the absence of off-CPU events, such as I/O waiting, synchronization, and CPU scheduling.

We illustrate the limitations of profiling without off-CPU events using a simple example program. Figure 1 presents an example of an application involving both on-/off-CPU events. In this example, two threads are executed concurrently and are synchronized through a `barrier` that is implemented using a mutex and condition variable. *Thread 1* executes `compute_light`, which is a small on-CPU computation (iterative integer increment), one 4-KB disk write (`pwrite`), and eight 512-byte disk reads (`pread`). The two types of off-CPU events, hence disk write and reads, are the majority of the execution of Thread 1. *Thread 2* executes `compute_heavy` only, which performs a large on-CPU computation. We adjust the computation load of Thread 2 to make two distinct cases: *Case 1* where Thread 2 is on the critical path and *Case 2* where Thread 1 is on the critical path, as shown in the right



```
     # Overhead  Command   Shared Object  Symbol
     #........   ........  ...........    ......
        11.28%   a.out     [kallsyms]     [k] internal_get_user_pages_fast
T1      10.08%   a.out     a.out          [.] compute_light
         6.31%   a.out     [kallsyms]     [k] kmem_cache_alloc
                                ...
         0.10%   a.out     libpthread     [k] __libc_pread64

     # Overhead  Command   Shared Object  Symbol
T2   #........   ........  ...........    ......
        99.97%   a.out     a.out          [.] compute_heavy
                                ...
```

Figure 2: Sampling-based profiling result of Case 2.

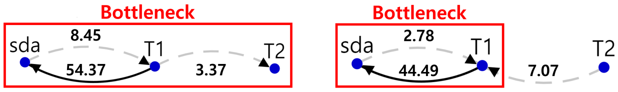
part of the figure. In Case 1, the bottleneck is `compute_heavy`. In Case 2, the bottlenecks are `compute_light` and the I/O events, and their optimization leads to performance improvement. However, in both cases, the optimization of one thread does not improve the performance indefinitely due to the barrier synchronization between the two threads; the critical path changes from one to the other. Hence each optimization has limited global impact on the performance [15, 58].

Limitation of On-CPU Analysis with Sampling. Consider Case 2 where the actual bottleneck is the off-CPU events (i.e., `pread`/`pwrite`), the on-CPU analysis only cannot identify the correct bottleneck. Figure 2 shows the profiling results of Case 2 with the Linux perf tool [17], a popular on-CPU sampling-based profiler. In the figure, each line represents the overhead portion, command name, shared object name, and event symbol; `[.]` and `[k]` indicate user-level and kernel-level symbols, respectively. Due to the tool's inability to capture off-CPU events caused by the blocking I/O events, it only reports the overhead of on-CPU events such as `compute_heavy`, `compute_light` and Linux kernel internal events. The C library function related to `pread` (i.e., `__libc_pread64`) is captured, but it includes only the on-CPU parts, indicating only 0.10% of the overhead. Consequently, the user may examine the results shown in the figure, identify the `compute_heavy` event as the significant overhead among on-CPU events, and focus on optimizing it even though the computation of Thread 2 is not on the critical path. This limitation necessitates off-CPU analysis and causality analysis to precisely identify the performance bottleneck.

2.2 Off-CPU Analysis

Basic Utilities. Basic utilities, such as `top` or `iostat`, can provide information of the overall I/O usage. However, these utilities are primitive and ineffective for detailed analysis of I/O events and correlating those to application contexts, such as IP and callchain.

Off-CPU Tools. Various off-CPU profiling tools [27, 35, 38, 39, 55, 58] exist to support profiling of off-CPU events. However, these profilers are limited in terms of (1) focusing on a specific type of off-CPU events (e.g., syncperf [35]) or (2) providing unsorted information (e.g., off-CPU time distribution [14], call-chains of off-CPU events [40]), which requires a programmer's additional efforts to identify important bottlenecks and their impact on the program performance. For example, off-CPU flamegraph [39] provides and visualizes the overhead of off-CPU events and their callchains. However, the tool does not provide the performance impact of each off-CPU event; an off-CPU event with the largest overhead does not necessarily mean its optimization results in performance improvement to the same extent [15, 58].



(a) Case 1 in Figure 1.　　(b) Case 2 in Figure 1.

Figure 3: *wait-for* graph results of Figure 1. For Case 1, the knot includes both I/O and synchronization (`barrier`), while the knot in Case 2 includes only I/O.

wPerf. wPerf [58] is a state-of-the-art profiler that traces all types of waiting events including off-CPU events and reports their relationship in the form of a wait-for graph. Moreover, wPerf identifies bottlenecks by analyzing the global impact of waiting events on other threads. Hence, wPerf reports the performance bottleneck by identifying waiting events for which all the worker threads are waiting to progress; these waiting events are called a knot. Each knot contains a bottleneck.

However, we observe two important limitations when identifying bottlenecks using wPerf. Let us explain the limitations using the example program in Figure 1.

Profiling Result. Figure 3 shows the profiling result of Case 1 and Case 2 in Figure 1 using wPerf. In this figure, the vertices labeled *T1* and *T2* correspond to Thread 1 and Thread 2, respectively, and *sda* represents the disk, hence an I/O device. `sda` ← T1 indicates that Thread 1 is waiting for completion of disk I/O requests (i.e., `pread` and `pwrite`), and `sda` --→ T1 represents the I/O device is waiting for I/O requests from Thread 1 (i.e., `compute_light`) [58]. Moreover, T1 --→ T2 (Case 1), and T1 ←-- T2 (Case 2) indicate the waiting period caused by the synchronization (`barrier`). The numbers on the edges are the global impact of each edge reported by the wPerf which can be interpreted as waiting time.

Firstly, wPerf does not precisely identify bottlenecks and their actual impact on the program performance. In Figure 3a, the red box denotes the knot of Case 1. Hence, Thread 1/2 and `sda` are the bottlenecks. In addition, `sda`, hence the disk, has the largest global impact; the edge has the weight of 54.37 which is an order of magnitude larger than the weight of the other edges. Hence, the profiling result mislead to optimizing I/O events associated with `sda`. However, as shown in Case 1 in Figure 1, optimizing `pread` or `pwrite` does not improve the performance since the real bottleneck is Thread 2 (i.e., `compute_heavy`). Consequently, wPerf's bottleneck identification can be imprecise and can yield a waste of ineffective optimization efforts.

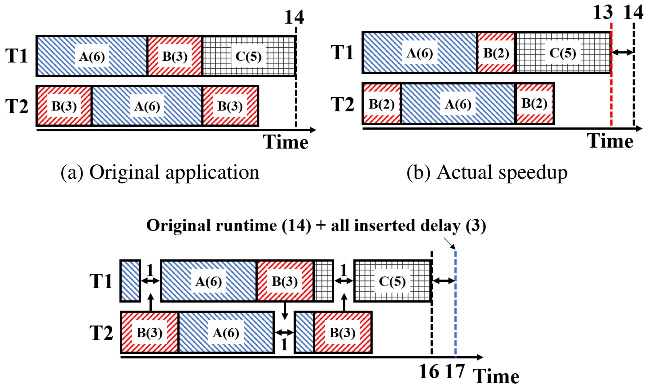
Secondly, wPerf can identify bottlenecks approximately but detailed information or context can be missing, which necessitates programmers' additional efforts to figure out bottleneck points in program codes. In Figure 3b, the knot includes T1 and `sda`. Both are in Thread 1, which are the correct bottlenecks of Case 2 in Figure 1. However, Thread 1 runs three different events, `compute_light`, `pread` and `pwrite`, each of which is on the critical path. As shown in Figure 1, the eight disk reads have the most significant impact on the program performance in Case 2. However, the profiling result of wPerf demonstrates only `sda` has the biggest impact and blurs the precise bottleneck identification among the two off-CPU events. For instance, the programmer may try to optimize `pwrite` but may fail to improve the write performance while the code `compute_light` has a latent performance improvement since the code is implemented inefficiently. Consequently, wPerf's analysis result is less informative and requires additional efforts before targeting events to optimize.

2.3 Causal Profiling

Optimization of bottlenecks identified through conventional profiling does not always guarantee performance improvement [15, 58]. This is especially true for multi-threaded applications since events with significant overhead may not be on the critical path (e.g., `compute_heavy` in Case 2 of Figure 1). Causal profiling [15] is a profiling methodology that estimates the actual impact of optimization on the program performance.

Virtual Speedup. Virtual speedup is a core technique for performing the causality analysis. It offers an estimation of potential performance improvement by virtually speeding up a particular event (e.g., a program code line) [1, 15, 26, 45, 46]. The virtual speedup technique does not require the actual optimization of a particular code line but can assess the causality of the performance optimization. This can be achieved by delaying concurrently running events (or threads). Hence, if a particular event is sped up by a certain amount, it can be simulated by delaying other concurrent events by that amount but not the target event itself.

Figure 4 illustrates an example of the virtual speedup technique by showing the timeline of a two-threaded application. Figure 4a shows the original timeline and Figure 4b shows the actual speedup case when the execution time of function B is optimized from 3 to 2, and as a result the total execution time is reduced by 1. Figure 4c shows the virtual speedup case. The virtual speedup technique speeds up a particular function (B in this case) virtually by delaying co-running threads on every invocation of the target function. This has an effect of which the target function is sped up since other than the function is delayed by the same amount. Hence, in this example, whenever B is called, the other thread is injected a delay of the amount to speed up. The virtual speedup technique measures the speedup by identifying the difference between the actual runtime, 16 in this case, and the expected execution time if function B is not sped up. The expected execution time without speedup is 17, which is obtained by that whenever B is invoked, all the threads are delayed by 1. Hence, the application's virtual speedup is 1 (17 minus 16).



(a) Original application

(b) Actual speedup

(c) Virtual speedup

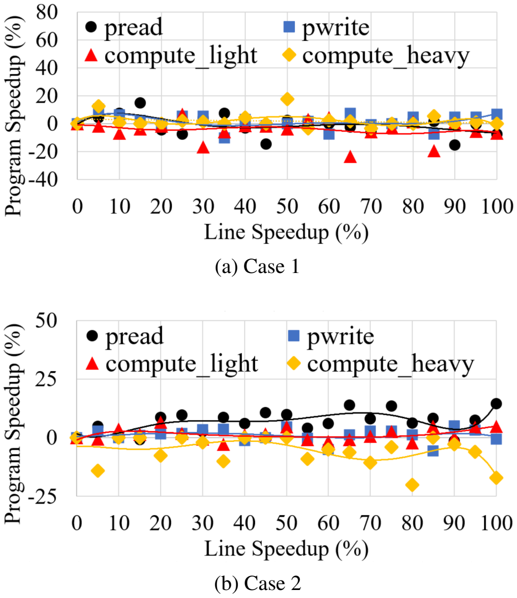
Figure 4: Illustration of virtual speedup when speeding up B. X(n) means function X runs for n time units.

COZ. COZ [15] is an implementation of the causal profiler employing the virtual speedup method. It reports to a user with information about the application's bottlenecks and provides an estimation of performance improvement for each optimization point. To apply the virtual speedup technique, COZ employs sampling-based profiling using the Linux perf subsystem. Periodically, COZ reads sampling results, IPs and callchains of each thread. Then, when the target code line to speed up is being executed, COZ applies the virtual speedup technique by delaying the execution of other threads, hence forcing sleep of co-running threads.

COZ carefully handles dependencies between threads and injects delays between threads with dependency in order to avoid incorrect estimation of virtual speedup. For example, if thread A is woken up by thread B, any injected delays to thread B while thread A is sleeping are considered the injected delays to thread A as well. This is because thread A is woken up after thread B has consumed its injected delays. In other words, if thread A is delayed by the same amount of injected delay after its wakeup, thread A experiences double delays from one source of delay injection. Accordingly, COZ manages dependencies arising from thread synchronization primitives (e.g., mutex, condition variable), and exempts delays during thread wakeups.

COZ employs two optimization methods to enhance its profiling performance. First, COZ processes multiple samples in batches. Second, it tries to skip consuming delays whenever all the threads need to consume the same amount of delay. This helps reduce the profiling time since otherwise, all the injected delays may increase the application's runtime significantly.

Profiling Result. While causal profiling is effective and informative in specifying bottlenecks and providing the estimated



(a) Case 1

(b) Case 2

Figure 5: Virtual speedup result of Figure 1.

outcome of bottleneck optimization, it lacks the capability of considering off-CPU events for profiling, often leading to incorrect profiling results. Figure 5 shows the profiling result of the example program in Figure 1 using COZ. In this figure, the x-axis represents the reduction in the execution time of a particular line, while the y-axis indicates the predicted overall runtime reduction of the program if that specific line speeds up by x%. For instance, a 0% program speedup indicates no performance improvement, whereas a 75% program speedup implies the runtime is reduced by 75%.

In Case 1, the actual bottleneck is `compute_heavy` but COZ fails to identify its potential performance improvement if it is optimized. Actually, COZ identifies marginal virtual speedup of all the four events in Case 1 as shown in Figure 5a. A similar phenomenon happens in Case 2 of the same example program as shown in Figure 5b. These results stem from the fact that COZ does not consider off-CPU events.

The causal profiling is an essential technique considering the ever-increasing complexity of applications on modern computer systems. However, the inability to profile off-CPU events is a critical limitation of existing causal profiling. The CPU performance improvement has stopped due to the end of Moore's law and Dennard scaling, and domain-specific accelerators, such as GPUs, FPGAs, and Smart SSDs, are gaining significant attention [25]. These heterogeneous computing environments make the behavior of applications more complicated with various off-CPU events for offloading computation to such accelerators. In addition, various low-latency I/O devices, such as CXL memory expander [16], RDMA-capable several-hundred gigabit network interface cards [49], flash-based or persistent memory-based solid-state drives [41, 59], are making application behavior increasingly complex. Traditional I/O-boundness or CPU-boundness is no longer a proper application classifier. The mixture of both I/O- and CPU-bound applications require sophisticated performance profiling methodology. Among these, profiling on-CPU and off-CPU events together is especially important for optimizing application performance.

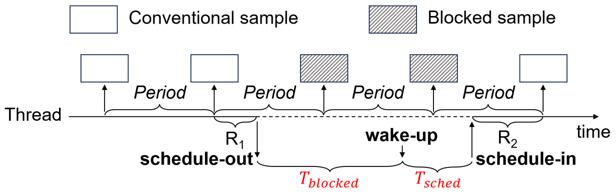


Figure 6: Blocked samples and conventional samples.

3 Design and Implementation

In this section, we present our methodology to profile on-CPU and off-CPU events simultaneously. Our methodology begins with proposing a new method of sampling off-CPU events, called *blocked samples* (Section 3.1). Then, we present two profilers for accommodating blocked samples: *bperf*, an easy-to-use sampling-based profiler (Section 3.2) and *BCOZ*, a causal profiler that profiles both on- and off-CPU events simultaneously and estimates potential speedup of optimizations (Section 3.3).

3.1 Blocked Samples

Blocked samples captures information of blocking events of threads, such as waiting for I/O completion, waiting for synchronization (e.g., mutex, condition variable), waiting for CPU scheduling, etc. The conventional on-CPU event sampling is thread-oriented (e.g., *task-clock* of the Linux perf subsystem [17]). When a thread executes its instructions on the CPU, the event-based sampling periodically collects a sample, hence snapshot, of thread context (e.g., IP and callchain) as shown in Figure 6. When a thread is blocked, the sampling is paused until the thread is woken up and resumes its execution. Different from the conventional on-CPU sampling, blocked samples augments the missing samples while threads are blocked, providing the execution context of blocking periods (shaded boxes in Figure 6).

Each blocked sample contains four attributes for tracking an off-CPU event: *IP*, *callchain*, *weight*, and *type*. The IP is the address of the last instruction before a thread is blocked. This is actually the return address of invoking a CPU scheduler (e.g., `schedule` or `io_schedule` in Linux). The callchain is the call stack of functions from the main function of a thread to the current instruction before being blocked.

The length of a blocking event can be varied (e.g., a few microseconds for CPU time-sharing or hundreds of milliseconds for disk I/O). Hence, one blocking event can contain multiple blocked samples of the same properties (i.e., identical IP, callchain, etc.). We encode the number of repeats to the *weight* field, saving space and time when handling blocked samples.

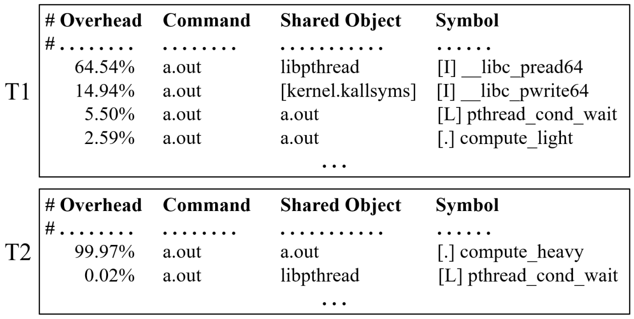
The *type* field is used to categorize blocked samples into the following subclasses:

- **I/O:** The I/O subclass corresponds to an off-CPU event that occurs when a thread requests and waits for an I/O event. Specifically, when a current thread submits a synchronous I/ O request and is blocked by invoking a CPU scheduler (e.g., a `task_struct` with `in_iowait` set in Linux), this blocking event is categorized as the I/O subclass.
- **Synchronization:** The synchronization subclass refers to an off-CPU event where a thread is waiting for a lock or condition variable. To identify synchronization subclasses, we slightly modified a process control block (e.g., `task_struct` in Linux) to include a field (`in_lockwait`) that identifies lock waiting. The field is set/cleared when a thread sleeps/wakes using the kernel-supported synchronization primitives (e.g., `futex` of Linux).
- **Scheduling:** The scheduling subclass refers to the off-CPU event that occurs when a thread is runnable but not scheduled on a CPU.
- **Others:** This subclass refers to off-CPU events that does not correspond to the above subclasses. Typically, off-CPU events related to sleeping (e.g., `usleep`) are in this category.

Implementation. Blocked samples are collected by extending the *task-clock* event in the Linux kernel's perf subsystem. The original sampling using task-clock collects samples by using a periodic timer (e.g., high-resolution timer). While a task is running on the CPU, the timer allows periodic sample collection. Meanwhile, when a task is off-CPU, hence blocked, the timer is paused until the task resumes execution.

Blocked samples augment the original task-clock-based sampling by including the blocking state of a thread. As the blocking state of a thread remains unchanged until the thread resumes its execution, our scheme captures the blocking state at the moment a thread resumes, rather than relying on the periodic timer. This is achieved by incorporating three task scheduling-related operations: *schedule-out*, *wake-up* and *schedule-in* functions.

First, when a thread is *scheduled out*, our scheme records the subclass of the thread's blocking, along with a timestamp marking the start of the off-CPU interval. Then, when the thread is *woken up*, our scheme records a timestamp to mark the end of the off-CPU interval. When the thread is eventually *scheduled in*, we record a timestamp and calculate the blocking interval ($T_{blocked}$) and the waiting interval for CPU scheduling (T_{sched}) as shown in Figure 6. For threads that are runnable but remain in the runqueue due to CPU contention, the off-CPU interval has no wake-up timestamp and hence belongs to the scheduling subclass of blocked samples. Finally, in the schedule-in function, if the blocking interval overlaps with one or more sampling points in time, a new sample is created. This sample contains the IP, callchain, weight and type attributes. For example in Figure 6, the two off-CPU events, $T_{blocked}$ and T_{sched} contain two sampling points. Hence, two blocked samples, one for blocking and the other for scheduling, are collected. If an off-CPU interval does not overlap with any sampling points, no blocked samples are collected. This approach minimizes the overhead of the collection of blocked samples, even with frequent off-CPU events, as the three hook points only perform timestamping.



```
    # Overhead  Command  Shared Object      Symbol
    # ........  ........ ...........        ......
       64.54%   a.out    libpthread         [I] __libc_pread64
T1     14.94%   a.out    [kernel.kallsyms]  [I] __libc_pwrite64
        5.50%   a.out    a.out              [L] pthread_cond_wait
        2.59%   a.out    a.out              [.] compute_light
                             ...

    # Overhead  Command  Shared Object      Symbol
    # ........  ........ ...........        ......
T2     99.97%   a.out    a.out              [.] compute_heavy
        0.02%   a.out    libpthread         [L] pthread_cond_wait
                             ...
```

Figure 7: bperf sampling results of Case 1 in Figure 1.

A single blocking event can encompass multiple sampling points. This means that the blocking event can generate multiple blocked samples. However, since these samples share identical attributes, our scheme avoids replicating them. Instead, it encodes the repetition using the *weight* field of a blocked sample. This approach reduces both the space and time overhead associated with handling blocked samples.

3.2 bperf

bperf is an online profiling tool that profiles applications using sampling-based profiling and provides statistics of sampling results. *bperf* is an extension of the Linux *perf* tool [17] to support blocked samples. Similar to perf, bperf can be an online or offline tool as its sampling-based profiling can be attached and detached at any time while a program is running and its profiling overhead is generally low (1.6%), as demonstrated in Section 4.4.

Basically, treating blocked samples has no significant difference from handling conventional on-CPU samples. Samples are classified using their IP and callchain. Using the information, their statistics are reported such as overhead portion, function symbol, and the object file as shown in Figure 7.

We extend the Linux perf tool to (1) interpret the *weight* field of blocked samples and (2) annotate a subclass to blocked samples. Firstly, when bperf processes blocked samples, the weight field denotes the number of repetitions of the same event. Therefore, this repetition is taken into account when calculating the statistics. Secondly, bperf examines the subclass of blocked samples and annotates their subclass type in the reported result. Currently, bperf uses the following annotations, `I` for the I/O subclass, `L` for synchronization, `S` for scheduling and `B` for the rest. This information enables the user to identify and analyze the performance impact of blocked samples distinguished by each subclass.

Figure 7 shows the profling result of the example program in Figure 1 using bperf. As compared to the results of the original perf sampling (Figure 2), bperf provides on-CPU and off-CPU events together, thereby allowing developers to understand the overhead of various events more precisely. In Thread 1, `pread` incurs the largest overhead, followed by `pwrite`, and `pthread_cond_wait` ranks third. In Thread 2, `compute_heavy` dominates the thread's execution time.

The advantages of using bperf are two-fold. First, bperf can allow in-depth analysis of blocking events and their interactions inside the operating system kernel. For example, `fsync` is a complex operation that accompanies many types of disk writes. Without bperf, only a tiny amount of user-level and kernel-level codes are collected as on-CPU samples. With bperf, various off-CPU samples are collected to allow in-depth understanding of the `fsync` operation, such as write-back of data blocks, waking up and waiting for `jbd2` file system journaling thread, write-back of journal blocks and commit blocks. Consequently, bperf allows profiling of the interaction between kernel services (e.g., `fsync` call) and accompanying off-CPU events (e.g., data-block writes, synchronization with `jbd2`) with the detailed information of their callchains.

Second, the profiling results using bperf can provide the following performance optimization guidelines.

- When profiling results show a substantial overhead attributed to I/O subclasses, this suggests that the application spends a significant portion of time waiting for I/O operations, such as synchronous I/O. To enhance performance under these conditions, upgrading to faster I/O devices could be considered. Alternatively, adopting asynchronous I/O interfaces could help minimize the blocking time associated with I/O operations [43, 58].
- When profiling results attribute a large overhead of scheduling subclasses, the result indicates the application threads are spending a large fraction of time in CPU runqueues waiting for scheduling. An optimization guideline can be (1) adjusting the number of threads [58], (2) allocating more CPU resources to an application [47, 58], (3) pinning threads to cores to avoid the performance noise caused by CPU load balancers [36, 37], etc.
- When the overhead of the synchronization subclass is notable, performance improvement can be attained by optimizing the events executed within the critical section through application analysis [35].

3.3 BCOZ

This section introduces BCOZ, a causal profiler designed to identify performance bottlenecks. BCOZ is an offline tool that is designed to help programmers identify performance bottlenecks and improve the performance of their programs. At its core, BCOZ profiles on- and off-CPU events collected by blocked samples and estimates performance improvement through virtual speedup. BCOZ precisely identifies interactions between on- and off-CPU events with symbol-level information obtained from blocked samples. This section explores the challenges of accurately estimating the virtual speedup of off-CPU events and discusses various features that are useful for analyzing applications with off-CPU events to optimize performance.

Sampling Kernel Codes. Off-CPU events are tightly coupled with the operation of the operating system kernel codes. Such events occur through the use of operating system services, such as blocking system calls, synchronization primitives, and multi-tasking. In particular, applications with a high number of blocked samples tend to include frequent interactions with kernel [8, 9]. Hence, not only the period during which a thread is blocked but also the kernel operations for such kernel services are important for analyzing and estimating the speedup of their optimization. Accordingly, it is necessary to capture samples for kernel operations and support virtual speedup on those. The original COZ captures only user-space samples for its virtual speedup. However, BCOZ captures samples from not only user space but also kernel space to identify the target of virtual speedup. The target of virtual speedup is basically selected as a part of user-space code. Then, every sample includes their callchain. If the sample includes the instruction pointer of the kernel space, the callchain contains both user-space and kernel-space ones because bperf collects both of them. BCOZ considers them as a unified callchain and identifies the target of virtual speedup by traversing the callchain from the kernel space to the user space.

Virtual Speedup of Blocked Samples. Estimating the virtual speedup of blocked samples is the core of the causality analysis of off-CPU events. BCOZ needs special care when processing blocked samples in order to produce correct virtual speedup estimation. Recall that blocked samples are captured when a thread is scheduled in. Such blocked samples are queued to the perf subsystem and are reported to BCOZ. BCOZ handles blocked samples in batches similar to what COZ does. Processing blocked samples indicates that if a blocked sample is the target of virtual speedup, a proper delay is injected to other co-running threads as in COZ [15]. A blocked sample contains a callchain from the kernel space to the user space. Hence, if the user-space callstack contains target code lines to speed up, the blocked sample becomes the target of virtual speedup. For example, if `pread` is the target of virtual speedup, not only on-CPU samples such as library codes or kernel I/O stack but also off-CPU samples for disk I/Os issued by these code lines are the target of the virtual speedup. This is because such on-/off-CPU samples have a callchain whose user-space part contains `pread`.

Additionally, special care is required in handling dependencies during the virtual speedup of blocked samples. As blocked samples are processed after a blocking event, hence an I/O event, is finished, the processing of blocked samples can incorrectly inject delays to threads which have depen-

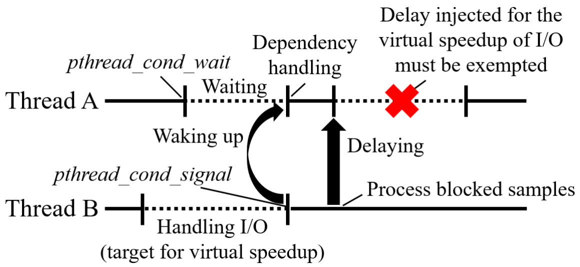


Figure 8: Illustration of virtual speedup when the target includes the off-CPU event while another thread waits for the completion of the target.

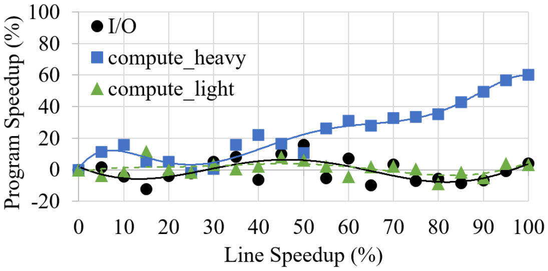
dency on the blocking event. For instance, as illustrated in Figure 8, thread A indirectly wait on I/O issued by thread B, and hence after thread B finishes its synchronous I/O, it wakes up thread A. The problem happens if the synchronous I/O becomes the target of speedup. When the blocked samples associated with the I/O are processed sometime after the wake-up operation, the delay injected to thread A, which is for the virtual speedup of the I/O event, makes thread A experience unnecessary delay. In other words, if thread A is injected with the delay, the situation is like the I/O is not sped up. This is because if the I/O event is sped up, the execution of threads waiting for the I/O event directly or indirectly should be boosted as the I/O waiting time is reduced. With the virtual speedup technique, such threads should not be delayed.

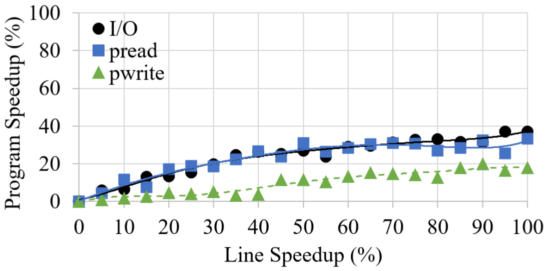
To this end, BCOZ processes blocked samples for virtual speedup before conducting the thread wakeup operations in synchronization primitives (e.g., `mutex_unlock` and `cond_signal`). In the example, the blocked samples of the I/O event are processed before waking up thread A. By doing so, once blocked samples contain the target for virtual speedup, the delays for the virtual speedup are not injected to thread A as thread A is not running. Therefore, the delays are exempted in thread A.

Subclass-Level Virtual Speedup. Optimizing off-CPU events sometimes requires different types of optimization attempts compared to optimizing code. For instance, enhancing the execution environment can often achieve greater performance gains than optimizing the application's code, such as upgrading from HDDs to flash-based SSDs in database applications [51]. Conversely, some applications may exhibit no or marginal performance improvement even when faster hardware devices are employed [23,30,32] due to application-side bottleneck. Similarly, the scheduling subclass off-CPU events have no particular code lines to attempt to optimize. These off-CPU events are challenging to optimize and may require prior knowledge of the optimization effects.

BCOZ provides a subclass virtual speedup technique designed to predict the performance gains from optimizing a specific type of off-CPU events. Hence, the target for virtual speedup is not selected from the application code but from the class of off-CPU events. Applying virtual speedup at subclass granularity is straightforward. During the sample processing, instead of checking whether the sample's callchain includes the target code, it checks whether the *type* field of blocked samples (Section 3.1) matches the target subclass.



(a) BCOZ results of Case 1 in Figure 1



(b) BCOZ results of Case 2 in Figure 1

Figure 9: Profiling results of Figure 1 using BCOZ.

Please note that the synchronization subclass does not support this subclass-level virtual speedup. From an actual optimization perspective, it is not possible to speed up the lock waiting period itself. Instead, the optimization focuses on speeding up the operations in the critical section. Hence speeding up the lock waiting period is invalid but speeding up the critical section is valid. In other words, the virtual speedup of critical sections can be done when the critical section is selected as the target of speedup. Therefore, we exclude the synchronization subclass from the subclass-level virtual speedup technique.

Selecting Virtual Speedup Targets. BCOZ supports both automated virtual speedup target selection and explicit target designation, similar to COZ. The *automated target selection* conducts virtual speedup for multiple targets in a single run by monitoring frequently sampled code lines during execution and dynamically changing the targets [15]. Where BCOZ differs from COZ is that conducting virtual speedup is not limited to on-CPU events executed by the target code line, but also includes virtual speedup for off-CPU events of the target. Additionally, BCOZ can designate an off-CPU subclass rather than a code line as a target for subclass-level virtual speedup. If a particular off-CPU subclass dominates in the sampling result, users can designate such subclass as a virtual speedup target to assess whether optimizing for that off-CPU event can yield performance improvements.

Profiling Results using BCOZ. Figure 9 provides a summary of the virtual speedup results of the example program depicted in Figure 1. This result illustrates that the actual performance improvements can be achieved by optimizing `compute_heavy` in Case 1 and I/O operations (especially `pread`) in Case 2. Furthermore, the virtual speedup results indicate the actual performance gains are bounded by the point at which the critical path moves. Consequently, by filtering out the false bottlenecks, we can prevent unnecessary optimization efforts for users.

4 Evaluation

In this section, we illustrate the experience of application profiling with bperf and BCOZ. The goal of our evaluation is to answer the following questions: (1) Do bperf and BCOZ identify bottlenecks precisely? (2) Does the estimated virtual speedup align with the actual speedup? (3) As compared to other state-of-the-art profilers (i.e., COZ and wPerf), are bperf and BCOZ more useful?

4.1 Experimental Setup

All experiments were conducted on a machine equipped with two Intel Xeon Gold 5218 CPUs (2.30 GHz, 16 physical cores), 375 GB DDR4 DRAM, and a flash-based SSD (PM983), which can deliver performance of up to 540 K I/O operations per second (IOPS). We modified the perf subsystem of the Linux kernel 5.3.7 to support blocked samples, which requires to modification of 295 lines of code. Furthermore, bperf was developed based on the perf tool of the Linux kernel. Finally, BCOZ is implemented based on the existing COZ code [13].

The application codes are complied to include frame pointers to correctly trace callchain. Hence, we disabled frame pointer omitting using `-fno-omit-frame-pointer` option. This is necessary for BCOZ (and COZ [15]).

We present virtual speedup results obtained through either the automated target selection mode or the subclass-level virtual speedup method, as explained in Section 3.3. In the automated target selection mode, the profiler produces virtual speedup graphs for frequently executed lines of code, from which we select the top-N results that demonstrate a positive speedup value. In the subclass-level virtual speedup method, a dominant off-CPU event is manually selected for conducting the virtual speedup profiling.

We measured performance using throughput, defined as the number of processed queries per second, where any performance enhancement reflects as an improvement in throughput. This is based on the assumption that reducing query processing time will naturally lead to increased query throughput, especially in environments where clients continuously submit queries, as in RocksDB. However, as the program speedup in the virtual speedup graphs indicates the percentage of the reduction in execution time, a simple conversion is necessary to translate it to the throughput improvement. A program speedup of y% means that the time it takes to process the same number of queries is now reduced to $(100-y)\%$ of the original, indicating that the throughput has increased by $\frac{100}{100-y}$ times. For instance, 75% program speedup is translated as 4x throughput improvement.

4.2 Case Study: RocksDB

In this section, we provide our experience of profiling RocksDB, a widely used log-structured merge (LSM) tree-based key-value store. By profiling RocksDB in various system configurations, we aim to identify off-CPU event bottlenecks that were previously difficult to pinpoint. We also validate these bottlenecks by attempting actual optimizations or comparing them with findings from previous studies on RocksDB optimization.

Optimization 1: Block Cache Contention. As a first optimization, we identify and address the bottleneck of block cache operations in a read-intensive workload. Figure 10 shows the profiling results for read-only execution of *Prefix Dist* [10], an open-sourced real-world workload by Facebook. In this experiment, the key-value size is 91 bytes (48 bytes key and 43 bytes value), the block cache size is 10 GB, the workload runs eight worker threads, and the dataset is set to 1-billion key-value pairs. The workload performs using a single shard to reproduce the well-known lock contention problem of RocksDB's LRU-based block cache [6].

Figure 10a illustrates the virtual speedup results using by BCOZ (solid line) and COZ (dotted line). In the results, two operations, `GetDataBlockFromCache` and `ReadBlockContents` are identified as bottlenecks. The

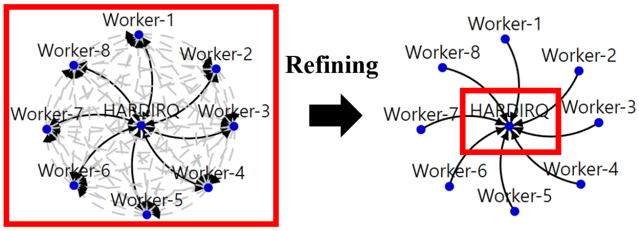

Figure 11: The wait-for graph and identified knots using wPerf

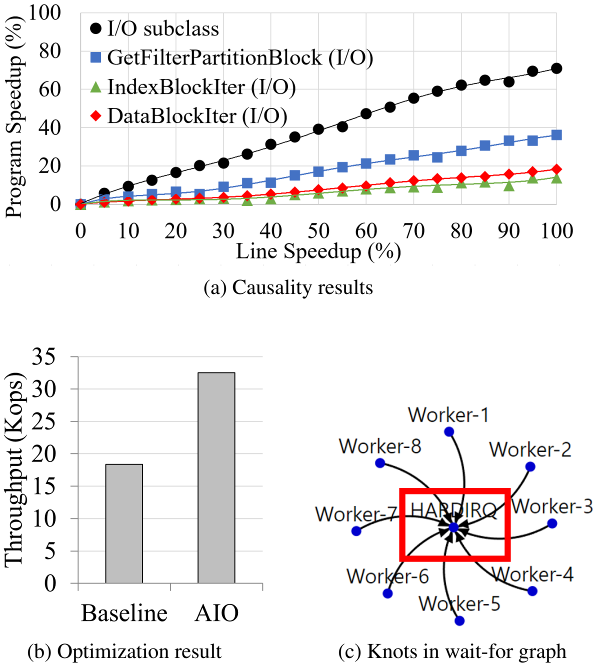
worker threads of RocksDB handles get operations by (1) looking up desired blocks (e.g., filter, index and data block) from the block cache (`GetDataBlockFromCache`) and (2) issuing block I/O requests to underlying disks upon a cache miss from the block cache (`ReadBlockContents`). The cache lookup operation is the real bottleneck since all the workers are contending on the lock of the block cache. As shown in Figure 10a, BCOZ shows up to 60% speedup when the cache lookup operation is optimized and up to 20% speedup when the block read I/O operation is optimized. Although the two operations accompany off-CPU events, COZ does not show any virtual speedup result for the two operations because it cannot take off-CPU events into account for profiling.

In order to verify the virtual speedup results, we conducted optimization of the two operations. First, we replaced the flash-based SSD with a faster one [44] which delivers performance of up to 1,500 K IOPS; this optimization is denoted as *SSD+*. We expect the speedup of `ReadBlockContents`. Figure 10b, however, shows no performance gain with SSD+ since the lock contention is the major bottleneck. Our second optimization is to apply sharding. The block cache is partitioned to multiple shards, which is denoted as `Shard-N` where N is the number of shards. As shown in the figure, Shard-N shows improved performance. The more shards there exist, the less lock contention occurs thereby showing more improved throughput. This tendency is shown in the virtual speedup analysis of BCOZ in Figure 10a.

To compare profiling capability of wPerf, we use wPerf to analyze the application again. Figure 11 shows the profiling results of wPerf, the initial knot (left) and the knot after trimming edges with a small global impact [58] (right). After trimming the low-weight edges (right), the wait-for graph identifies only the I/O (`HARDIRQ`) as the bottleneck. This profiling result requires a programmer's additional efforts to identify which user-level functions incur such bottlenecks. In addition, improving the I/O performance (SSD+) does not lead to actual performance improvement, which may increase the user's burden of profiling. The wait-for graph before trimming (left) is too complex but provides two bottleneck points: (1) worker --> HARDIRQ edge indicates the I/O waiting of worker threads and (2) worker <--> worker edge indicates lock waiting between worker threads. Therefore, the strategy that the user can try is to optimize the I/O event of the worker thread or to solve the lock contention. However, wPerf does not provide the potential speedup when the bottlenecks are optimized. One lucky programmer may attempt to optimize the lock contention and success to improve the performance. Meanwhile, one unlucky programmer may attempt to optimize the block read I/O operations and may not be able to improve the performance. Therefore, the missing causality analysis of wPerf can increase the burdens of users.



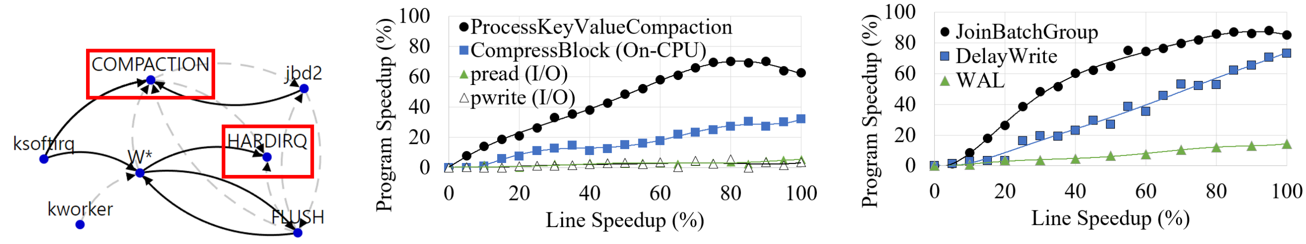
(a) Causality results

(b) Optimization result

(c) Knots in wait-for graph

Figure 12: Results of (a) causality analysis, (b) actual optimization, and (c) wPerf in *all random*.

Optimization 2: Block Read Operation. After resolving the block cache contention by sharding, we profiled RocksDB again with the *all random* workload in order to identify and optimize off-CPU events. The configurations of the workload remain unchanged, except that the block cache size is reduced to 128 MB to incur a large amount of off-CPU events, hence disk read I/Os. Figure 12 shows the profiling result of the workload using BCOZ and wPerf. The profiling results of BCOZ demonstrate the three bottleneck points, `IndexBlockIter`, `GetFilterPartitionBlock`, `DataBlockIter`, which handle index blocks, filter blocks and data blocks, respectively. All the operations are off-CPU-intensive operations. In addition, the I/O subclass-level virtual speedup is applied and depicted as `I/O subclass`. As shown in the figure, each of the three operations shows from 15% to 40% of speedup and their aggregated speedup is more than 70% (I/O subclass). Among the three operations, `GetFilterPartitionBlock` shows the largest expected speedup. An LSM tree has multiple levels and a key-value entry can exist in any of the levels. In each level, a key-existence test is done using a bloom filter. Therefore, `GetFilterPartitionBlock` performs the key existence testing using the filter blocks that need to be fetched from the disk. Since a single get operation traverses multiple



(a) Knots in the wait-for graph of wPerf.

(b) Compaction thread.

(c) Worker thread.

Figure 13: Results of (a) wPerf, (b) compaction thread, and (c) worker thread in *fillrandom*.

levels of the LSM tree, optimizing the filter read I/O operation is expected to show the largest performance gain.

Our optimization strategy is to apply asynchronous I/O to fetch filter blocks of the next levels of the LSM tree. Hence, for a get operation, our optimization performs a read of the filter blocks speculatively through the LSM tree. Hence, while the first level is processing the key existence test, the filter blocks of successive levels are speculatively fetched thereby reducing the read I/O waiting time. Our experimental results show that our optimization results in 77.3% of performance gain as shown in Figure 12b.

We compared the profiling result of BCOZ with wPerf. The wait-for graph of wPerf is shown in Figure 12c. As shown in the figure, the knot is `HARDIRQ`, which denotes the disk. However, wPerf provides no more information on the bottleneck. Hence, the user's additional effort is necessary to specify the bottleneck. In addition, the lack of the causality analysis causes users to hesitate about which of the I/O operations to speed up. However, BCOZ provides the causality analysis to off-CPU events and illustrates that the filter I/O operations have the largest potential speedup. This analysis is followed by successful optimization of the filter I/O operations by parallelizing filter I/O operations by using asynchronous I/O.

Optimization 3: Write-intensive Workload. Our next optimization attempt is the write-intensive workload, *fillrandom* against RocksDB. For this experiment, we utilized a key-value size of 1 KB, with 16 worker threads concurrently writing a total of 10 million records. Figure 13 shows the profiling result using BCOZ and wPerf. First, wPerf identifies two potential bottlenecks: the `COMPACTION` thread and the `HARDIRQ` I/O thread. The initial wait-for graph was too complex and we applied the *merging similar threads* technique [58] to obtain the wait-for graph of the figure. From the wait-for graph, we can identify two bottlenecks: (1) the compaction operation of the LSM tree and (2) the write I/O operations of the worker threads (`W*`, the merged worker threads). Since the worker threads perform write-ahead-logging (WAL), WAL write I/Os can be the bottleneck. For the compaction, wPerf does not specify among the operations of compaction the significant overhead. In addition, wPerf reports that `HARDIRQ` shows a bigger global impact than `COMPACTION`.

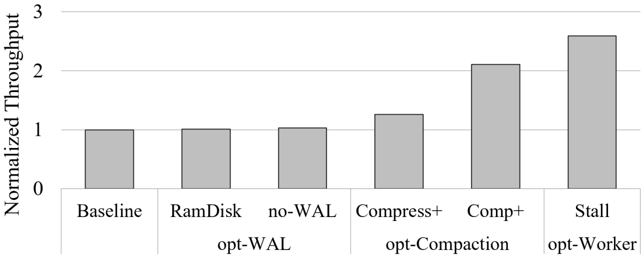


Figure 14: Results of actual optimizations in *fillrandom*.

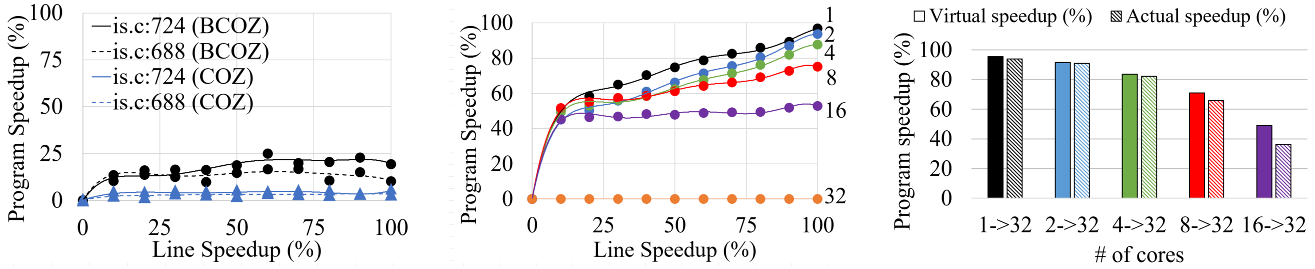
Meanwhile, BCOZ provides more informative analysis results. First, BCOZ identifies the compression operation (`CompressBlock`), which is on-CPU, as the significant bottleneck as shown in Figure 13b. Although BCOZ can estimate the potential speedup of I/O operations (`pread` and `pwrite`), their speedup is expected to be marginal. Second, BCOZ expects marginal speedup for the WAL operations as shown in Figure 13c. Third, BCOZ analyzes that the contention between the worker threads (`JoinBatchGroup`) is the bottleneck and its optimization can potentially improve the performance. Finally, BCOZ identifies the write throttling (`DelayWrite`) of the RocksDB's memtable write policy as the bottleneck.

The actual optimizations of the identified bottlenecks are performed as follows. First, the WAL operation is optimized by (1) using a *RamDisk* as the WAL storage and (2) disabling WAL (*no-WAL*). Second, the compaction operation is optimized by (1) disabling compression (*Compress+*) and (2) allocating many compaction threads (*Comp+*). Figure 14 shows the performance of the RocksDB *fillrandom* workload when the optimizations are applied. Third, the writeback stall is relieved by increasing the number of maximum memtables from 2 to 16 (*Stall*). As shown in the figure, WAL-related optimizations show marginal performance gain. This result indicates that BCOZ estimates the potential speedup correctly. In addition, *Compress+* and *Comp+* show improved performance, which is also predicted by BCOZ. Also, *Stall* shows the largest performance gain, which is estimated by BCOZ in Figure 13c. In the meantime, wPerf only identifies `COMPACTION` and `HARDIRQ` as the potential bottleneck points. `HARDIRQ` has shown marginal performance since worker threads are reported to wait for the I/O thread but accelerating WAL opera-



(a) Line-level virtual speedup

(b) Subclass-level virtual speedup

(c) Virtual speedup vs. actual speedup

Figure 15: Virtual speedup results of NPB-is under the CPU contention.

tions show no performance gain. From these results, BCOZ is effective in specifying performance bottlenecks.

Profiling Accuracy. Although BCOZ is proven to effectively identify performance bottlenecks, predicting the potential speedup accurately is sometimes difficult and intricate. For example, BCOZ predicts that optimizing the block cache lock contention can lead to 50% of program speedup (or doubling the throughput) as shown in Figure 10a. However, after relieving the block cache contention by applying sharding, the performance has been improved by four times, which is more than two times higher than the expected improvement. This is because sharding not only relieves the lock contention of cache lookup (`GetDataBlockFromCache`) but also reduces the contention of other operations (e.g., `PutDataBlockToCache`). Furthermore, certain optimizations may speed up a target code line but increase the amount of other events. For example, BCOZ predicts that optimizing `CompressBlock` will result in a 32% program speedup (or 1.47x throughput improvement) in Figure 13b, but the actual throughput improvement is 1.26x. This is because, by disabling compression, `CompressBlock` is no longer invoked, but this optimization has the side effect of increasing the total amount of disk I/Os.

Therefore, virtual speedup results can under- or overestimate actual speedup. However, the strength of BCOZ (and COZ) lies in their ability to precisely identify specific lines that could potentially lead to actual speedup when optimized. Our evaluation results have shown that optimizing these predicted lines can indeed lead to actual speed improvements.

Takeaway. During the profiling of RocksDB, we have identified bottlenecks that align with those mentioned in existing RocksDB optimization studies. Firstly, we examined the overhead and virtual speedup results of the compaction, which involved a mix of off-CPU events (I/O subclass) and on-CPU events. The potential for performance improvement through compaction optimization, as indicated in numerous studies [2,12,28,42,48], was validated using bperf and BCOZ. The significance of the proposed profiling techniques has become evident as the existing Linux perf tool or COZ could not easily or accurately predict the bottlenecks in the absence of blocked samples. Furthermore, the necessity to optimize operations related write stalls and batched group writing was also identified by BCOZ. These operations have been also identified as bottlenecks in previous studies [11,18,24,29,34,52,56]. Finally, we have examined the bottleneck caused by I/O subclass off-CPU events during the execution of RocksDB and validated the performance improvement.

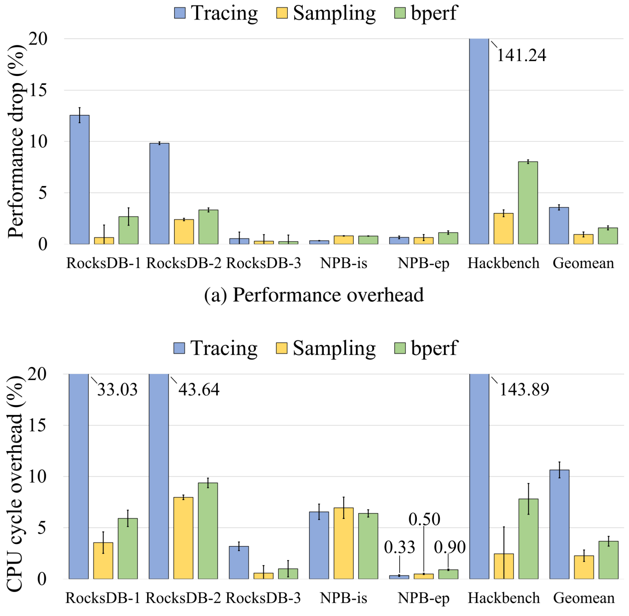
4.3 Case Study: NAS Parallel Benchmark

In this section, we evaluate the effectiveness of the scheduling subclass and subclass-level virtual speedup. For this experiment, we use a compute-intensive workload, *is* (integer sort) from the NAS parallel benchmark [5].

As discussed in Section 3.3, virtual speedup of application code lines can be ineffective if application threads are contending on the CPU cores. To demonstrate this situation, we intentionally controlled the number of CPU cores assigned to the NPB-is workload. The workload is configured to run 32 threads and the number of cores is varied from 1 to 32 cores. Figure 15a illustrates the profiling result of the main computation code lines using COZ and BCOZ when the number of cores is limited to one. As shown in the figure, COZ has estimated marginal performance improvement. On the contrary, BCOZ has predicted potential performance improvement if these code lines are optimized. Under high CPU contention (32 threads vs. 1 core), off-CPU events are frequent as the threads are frequently scheduled out due to the high CPU contention. In this case, BCOZ is able to estimates the optimization opportunity that when such scheduling subclass off-CPU events are removed, the performance can be improved.

Figure 15b presents the profiling results for the scheduling subclass-level virtual speedup as the number of cores increases from 1 to 32. With the highest CPU contention (using only one core), the estimated program speedup is at its peak. As the number of cores increases, thereby reducing CPU contention, the estimated program speedup decreases. Since the number of assigned CPU cores is fewer than the program's 32 threads, these profiling results seems valid.

To validate the virtual speedup profiling results, we measure the program performance with varying the number of cores. This approach reflects the optimization strategy of allocating additional CPU cores to mitigate CPU contention. Fig-



(a) Performance overhead

(b) CPU cycle overhead

Figure 16: Overhead analysis results of bperf.

ure 15c shows both the virtual and actual program speedups as the number of cores changes from X to 32 (X->32), transitioning from high CPU contention to no CPU contention. As shown in the figure, the actual speedup generally corresponds with the speedup predicted by BCOZ. These results confirms that it is important to correctly profile off-CPU events in highly parallel workload, and BCOZ leverages blocked samples to provide valuable profiling results to users.

4.4 Profiling Overhead

bperf. We compare the overhead of bperf with existing profiling techniques, (1) *tracing* which profiles only off-CPU events (`sched_switch` and `sched_wakeup`) using Linux perf's tracing mode [17, 38, 58], and (2) *sampling* which samples only on-CPU events using Linux perf's sampling mode (`task_clock`) [17]. All these tools have the same goal of profiling statistical overheads of target programs, but their profiling coverage are different: *tracing* focuses on off-CPU events, *sampling* focuses on on-CPU events, and *bperf* covers both on- and off-CPU events. For the sampling methods, the sampling period is set to 1 ms, which is identical in all the experiments in the evaluation section.

Figure 16 shows the overhead of the three profilers with the workloads used in the experiments as well as additional workloads, *NPB-ep* [5] and *hackbench* [22] to cover on-CPU-intensive and off-CPU-intensive cases, respectively. Among the workloads, *RocksDB-X* indicates the RocksDB workload used in Optimization-*X* in Section 4.2. We measured two types of overhead. First, the performance overhead refers to the performance drop of profiled applications (runtime increase for hackbench and throughput decrease for the rest of applications) as compared to the baseline, which runs without any profilers (Figure 16a). Second, the extra CPU overhead refers to the additional CPU cycles consumed by using the profilers as compared to the baseline (Figure 16b). The values shown in the figures are the average of 10 runs.

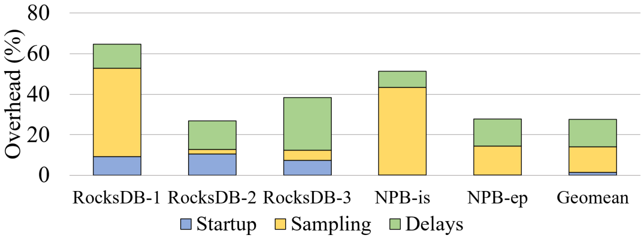


Figure 17: Overhead breakdown results of BCOZ.

Overall, the three profilers show acceptable performance drops, no more than 4% on average. Tracing, sampling and bperf have shown the average performance drop by 3.6%, 0.9% and 1.6%, respectively. Specifically, tracing shows notable performance drops with the workloads showing frequent off-CPU events (i.e., RocksDB-1, 2 and hackbench). Tracing records profiling information (i.e., IP and callchain) on every thread state transitions, leading to high overhead when off-CPU events are frequent. In contrast, bperf hooks into all the state transitions like tracing but only records timestamps for each transition. Profiling information is recorded only if an off-CPU interval overlaps with sampling points, resulting in low profiling overhead.

As compared to sampling, bperf enables profiling of off-CPU events at a low cost. bperf shows the additional performance overhead by only 0.7% (1.6% for bperf – 0.9% for perf) and extra CPU cycles by 1.4% (3.7% for bperf – 2.3% for perf). Considering that the profiling capability of bperf is greater than perf, we believe these overheads are acceptable.

As the mechanism of bperf inherits from perf, it can be attached and detached at any time while the profiling target application is running. As the overhead of bperf is low, we believe it can be an online tool for collecting statistical overheads of applications in production.

BCOZ. Figure 17 illustrates the overhead of profiling applications with BCOZ. The BCOZ overhead is categorized into three parts: startup, sampling, and delays. Startup represents the overhead of collecting debug information, which is the duration between BCOZ's bootstrapping and the application's main function (i.e., `libc_start_main()`), on average 1.4%. Sampling encompasses the overhead incurred when there's no virtual speedup delay (i.e., 0% line speedup) consisting of the bperf's sampling overhead and BCOZ's intervention to read samples and verify whether they include speedup targets, on average 12.6%. Finally, delays entail additional overhead when BCOZ is fully enabled, averaging 13.6%. The delays overhead does not refer to the amount of delays injected for virtual speedup, but the increase in the end-to-end execution time of the application.

The overhead of BCOZ is not light considering its end-to-end overhead of 27.6% on average and up to 64.7%. However, such profilers show similar performance overheads. For example, COZ has demonstrated its overhead of 17.5% on average and up to 65% [15]. As these profilers insert additional delays while the application is running, the end-to-end execution time can be increased. These overheads can be reduced when the inserted delays are limited, cooling-off times are inserted between virtual speedup experiments, etc [15]. Such remedies can be effective in reducing the profiling overhead, but it remains uncertain whether the results provided are sufficient to identify bottlenecks and their potential for performance gain.

5 Related Work

On-CPU Event Profilers. Conventional profilers [17, 19–21, 33] that rely on existing on-CPU events (such as CPU usage and execution time) face challenges when identifying bottlenecks in modern applications. This is primarily because the event with the longest execution time in a multi-threaded application does not necessarily represent the critical performance path, and they do not account for off-CPU events. In the context of multi-threaded applications, there are causal profiling studies aimed at analyzing the impact of optimizing each individual event on overall application performance [1, 4, 7, 15, 45, 53, 54]. COZ [15], for instance, provides performance improvement predictions by applying virtual speedup to each event using the sampling results from the Linux perf subsystem. However, COZ's virtual speedup is limited to on-CPU events sampled by the Linux perf subsystem. It is not capable of estimating virtual speedup of events that include off-CPU events.

Off-CPU Event Profilers. Existing studies have focused on analyzing off-CPU event bottlenecks [27,35,38,39,55,57,58]. Some studies analyze application bottlenecks by measuring the duration of off-CPU events [27,39,55]. However, in multi-threaded applications, the longest event may not always represent the critical path of the application [15, 58]. Furthermore, nested off-CPU events can have varying performance impact on event duration and overall application performance [58]. Therefore, analyzing performance using the duration of off-CPU events leads to incorrect conclusions.

Other studies identify application bottlenecks by specifically targeting off-CPU events related to synchronization [35, 57]. However, as mentioned earlier, the off-CPU bottlenecks in modern applications are diverse and encompass various aspects, including device I/O. Therefore, relying on profiling specific off-CPU events has limitation of supporting the various applications.

wPerf [58] is a state-of-the-art study focused on analyzing off-CPU bottlenecks in applications, wait-for graphs are constructed to identify off-CPU events that act as bottlenecks. However, as discussed in Section 2.2, wPerf has several limitations. wPerf does not precisely pinpoint the performance bottleneck of applications. Also, wPerf lacks the capability of causality analysis, so it could not analyze the actual impact on application performance when optimizing a performance bottleneck. Finally, wPerf identifies bottlenecks but misses detailed information, requiring additional efforts from developers to understand the exact performance bottleneck.

6 Conclusion

Existing profilers face limitations when it comes to identifying modern application bottlenecks that involve a mix of on- and off-CPU events. These profilers treat on- and off-CPU events as separate dimensions, making it difficult to perform comprehensive profiling and interpret the results. Moreover, even if the bottleneck of an application is identified, it remains uncertain whether optimizing the bottleneck will result in actual performance improvements. To address this problem, this paper introduces a sampling technique called blocked samples, which enables the identification of application bottlenecks by integrating on- and off-CPU events within the same dimension. We present bperf, a Linux perf tool that utilizes the proposed blocked samples technique to identify application bottlenecks based on event execution time, and BCOZ, a causal profiler that offers a virtual speedup for off-CPU events. By profiling the RocksDB application using these two profilers, we are able to uncover previously unidentified bottlenecks related to I/O and synchronization tasks. Furthermore, by virtually speeding up these tasks, we identify optimization possibilities that were overlooked in existing RocksDB optimization studies.

We plan to extend blocked samples to include richer information for profiling. The current blocked samples consider the operations inside an I/O device as a black box. However, I/O devices may have their internal operations, which can be the hint of performance optimization opportunities for applications. For example, disk-internal events, such as garbage collection, and valid page copying, are important events for storage applications to establish their optimization strategies. In this regard, we plan to augment blocked samples with I/O device-internal operations thereby allowing applications to employ expanded optimization strategies.

A Artifact Appendix

A.1 Abstract

Blocked samples is a profiling technique based on sampling, that encompasses both on- and off-CPU events simultaneously. Based on blocked samples, we present two profilers: *bperf*, an easy to-use sampling-based profiler and *BCOZ*, a causal profiler that profiles both on- and off-CPU events simultaneously and estimates potential speedup of optimizations.

A.2 Scope

Our artifact can be used to identify bottlenecks across various applications and pinpoint code lines in need of optimization. Particularly, our approach is an efficient profiling technique for applications where both on- and off-CPU events are mixed.

A.3 Contents

Our artifact consists of three subdirectories: `blocked_samples` (source code of Linux kernel with bperf), `bcoz` (source code of BCOZ), and `osdi24_ae` (OSDI'24 artifacts evaluation). Descriptions of each subdirectory are as follows.

blocked_samples. This directory includes an extended Linux perf subsystem for blocked samples. Blocked samples is a profiling technique based on sampling, that encompasses both on- and off-CPU events simultaneously. Furthermore, the original Linux perf tool is replaced with our bperf (`blocked_samples/tools/perf`).

bcoz. This directory includes source code of BCOZ. BCOZ is a causal profiler that leverages the concept of virtual speedup for both on-CPU and off-CPU events using blocked samples. At its core, BCOZ profiles on-/off-CPU events (i.e., blocked samples) collected by our extended Linux perf subsystem and estimates performance improvement through virtual speedup. BCOZ is extended from COZ [15], a causal profiler for only on-CPU events.

osdi24_ae. This directory is for the OSDI '24 artifacts evaluation. It includes instructions for reproducing the experimental results in the paper.

The instructions in the *Getting Started with Blocked Samples* section of `README.md` in the root directory help verify whether blocked samples functions correctly.

A.4 Hosting

The GitHub repository for the artifacts is available on https://github.com/s3yonsei/blocked_samples.

A.5 Requirements

The Linux kernel version for blocked samples is 5.3.7 and we have verified that blocked samples operates correctly on the Ubuntu 20.04 LTS server. We will soon release the support for blocked samples on the latest Linux kernel version in the repository.

dLoRA: Dynamically Orchestrating Requests and Adapters for LoRA LLM Serving

Abstract

Low-rank adaptation (LoRA) is a popular approach to finetune pre-trained large language models (LLMs) to specific domains. This paper introduces dLoRA, an inference serving system for LoRA models. dLoRA achieves high serving efficiency by dynamically orchestrating requests and LoRA adapters in terms of two aspects: (*i*) dynamically *merge* and *unmerge* adapters with the base model; and (*ii*) dynamically *migrate* requests and adapters between different worker replicas. These capabilities are designed based on two insights. First, despite the allure of batching without merging a LoRA adapter into the base model, it is not always beneficial to unmerge, especially when the types of requests are skewed. Second, the autoregressive nature of LLM requests introduces load imbalance between worker replicas due to varying input and output lengths, even if the input requests are distributed uniformly to the replicas. We design a credit-based batching algorithm to decide when to merge and unmerge, and a request-adapter co-migration algorithm to decide when to migrate. The experimental results show that dLoRA improves the throughput by up to 57.9× and 26.0×, compared to vLLM and HugginFace PEFT, respectively. Compared to the concurrent work S-LoRA, dLoRA achieves up to 1.8× lower average latency.

1 Introduction

Large language models (LLMs) are changing the landscape of modern applications. LLMs such as GPT4 [1] and Llama-2 [2] are pre-trained on a large corpus to achieve outstanding capabilities on generic tasks. These pre-trained LLMs (a.k.a. base LLMs) can be fine-tuned to a specific domain to optimize particular application scenarios, e.g., fine-tuning Llama-2 for better code generation [3]. LLM platforms [4–7] provide fine-tuning APIs and services for developers to fine-tune LLMs and build domain-specific applications. For example, OpenAI provides fine-tuning APIs for fine-tuning GPT-4 and Completions API to access these fine-tuned LLMs [4].

Low-rank adaptation (LoRA) [8, 9] is a popular approach to fine-tuning LLMs. It is a type of parameter-efficient fine-tuning [10] that reduces fine-tuning costs by updating only a small portion of model parameters. LoRA exploits the low dimensionality of parameter updates in fine-tuning and represents them with pairs of two small matrices called LoRA adapters. Fine-tuning a base LLM amounts to training a LoRA adapter for a specific domain while keeping the base LLM unchanged. Compared to the fully fine-tuning GPT-3 175B, LoRA can reduce the number of updated parameters by 10,000× and the GPU consumption by 3× while achieving comparable model quality [8]. At inference time, the LoRA adapter can be merged with the base LLM thus introducing no extra inference overhead.

Serving a set of LoRA model fine-tuned on a base LLM (i.e., LoRA as a service) introduces new challenges to LLM inference serving. Existing LLM inference systems such as Orca [11] and vLLM [12] focus on serving a single model, while in the scenario of LoRA as a service, there are multiple models. Conceivably, one can use Orca or vLLM to serve each LoRA model and adopt an existing model serving orchestrators like SHEPHERD [13] and AlpaServe [14] to manage multiple LoRA models. This simple approach does not consider the characteristics of LoRA model serving and has the following two fundamental problems.

First, serving each LoRA model separately introduces a high memory footprint, and suffers from low GPU utilization as the GPUs cannot be efficiently multiplexed across models. The problem is particularly acute for LLMs as LLMs have large sizes. An alternative approach is to directly use *unmerged* LoRA adapters, i.e., keeping the base LLM unchanged and storing the set of LoRA adapters alongside. When serving different types of requests, it can batch the shared base LLM computation across requests to increase efficiency. This unmerged approach, however, does not work well when the requests are skewed on a particular LoRA adapter, whereas the merged approach can further reduce computational costs to increase efficiency.

Second, LLM tasks have variable input and output lengths, which naturally introduces load imbalance between different worker replicas. Due to the autoregressive pattern of LLMs, simply dispatching requests to different worker replicas uniformly does not work well, as the execution time and GPU memory consumption of requests are diverse [11, 12]. The LoRA as a service scenario further exacerbates the problem, as LoRA adapter orchestration across worker replicas also needs to be taken into consideration. The dependency between LoRA adapters and requests as well as the GPU memory competition between them make the problem even harder than traditional load balancing problems.

We introduce dLoRA, a new inference serving system for LoRA models to address these two problems. Compared to previous practices in LoRA serving, dLoRA further improves efficiency with two special capabilities. First, dLoRA can dynamically *merge* and *unmerge* LoRA adapters with the base model in each worker replica. Second, dLoRA can dynamically *migrate* LoRA adapters and requests between worker replicas. Exploiting the capabilities of dLoRA efficiently has two technical challenges. The first one is how to decide when to merge and unmerge adapters. The second one is how to decide which adapters and requests to migrate. We propose two techniques to address these two problems.

To address the first problem, we propose a dynamic cross-adapter batching technique. Based on the request arrival pattern and current state, dLoRA dynamically switches between merged and unmerged inference with different batching strategies to reduce the end-to-end latency. To decide an appropriate switching time, dLoRA dynamically adjusts the switching threshold with the thresholds tuning according to the request pattern to reduce switching overhead. dLoRA adopts a credit-based batch generator to generate potentially efficient batching plans without harming the fairness of requests. A final decision is made by taking all factors into account, including execution time, queuing delay, and switching overhead.

To address the second problem, we propose a request-adapter co-migration technique. Except for proactively dispatching requests based on current requests and adapter distribution, it also dynamically migrates requests and replicates adapters to handle unpredictable load imbalance across replicas. We formulate the problem as an integer linear programming (ILP) problem and compute an optimal solution to minimize the load imbalance. To address the high overhead of ILP, we amortize the overhead by reducing the frequency of ILP solving and relaxing the problem to a selective migration problem inspired by selective replication [15–17].

In summary, we make the following contributions.

- We identify the inefficiencies of current LLM serving systems in the LoRA model serving scenario, and articulate the challenges of serving LoRA models.
- At the worker level, we propose a dynamic cross-adapter batching technique to dynamically switch between merged and unmerged modes to reduce the end-to-end latency.
- At the cluster level, we propose a request-adapter co-migration technique to dynamically migrate requests and adapters to balance the load across the cluster.
- We design and implement dLoRA with the preceding two techniques. The evaluation results based on real-world workload traces show that dLoRA achieves up to 57.9× and 26.0× higher throughput than vLLM [12] and HuggingFace PEFT library [10], respectively. By leveraging dynamic orchestration mechanisms, dLoRA also achieves up to 1.8× lower average latency compared to the concurrent work S-LoRA [18].

Figure 1: LoRA optimization.

2 Background and Motivation

2.1 Parameter-Efficient Large Language Models

Large language models. Large language models (LLMs) try to maximize the next token predictability given the previous tokens. At the inference time, LLMs show an autoregressive pattern. For each request, an LLM iteratively generates tokens based on the prompt (i.e., input tokens) and previous output tokens once a time until it generates an end-of-sentence marker. This autoregressive nature makes LLM inference exhibit two characteristics. The first one is variable inference latency depending on the input and output lengths [12, 19]. The second one is significant GPU memory consumption of intermediate states of requests. To reduce redundant computation, LLMs cache the intermediate states of previous tokens, called key-value (KV) cache, in the GPU memory [20]. Similar to prior work [12], we use intermediate states to refer to the key-value cache. As the size of the KV cache is proportional to the number of input and output tokens, the memory consumption of LLM inference is also variable. The KV cache consumes a large amount of GPU memory and may bound the performance of LLM inference due to the limited GPU memory capacity [12, 19].

Low-rank adaptation. Fine-tuning adapts a pre-trained LLM to a specific domain without training an LLM from scratch. Low-rank adaptation (LoRA) [8, 9, 21] is a popular class of parameter-efficient fine-tuning methods [10], as it can achieve competent performance by only fine-tuning a small number of trainable parameters, called the *adapter*. Furthermore, LoRA does not introduce extra inference latency. Inspired by the phenomenon of low "intrinsic rank" of weight updates, the core of LoRA is to represent each weight update as two rank composition matrices with much smaller ranks. During fine-tuning, LoRA only needs to optimize these two rank composition matrices, while keeping the pre-trained weights frozen. Figure 1 shows an example. For a pre-trained weight W with the shape of $d \times d$, LoRA represents weight updates ΔW as two smaller matrices A and B with the shape of $r \times d$ and $d \times r$ respectively, where r is much smaller than d. During fine-tuning, as shown in Figure 1(a), LoRA only updates A and B and keeps W frozen, which significantly reduces computation and memory consumption. At the inference time, as shown in Figure 1(b), LoRA can merge the multiplied matrix $B \times A$ (i.e., ΔW) into W to eliminate extra inference overhead. Given the benefits of LoRA, it is widely adopted to enhance the capability of LLMs, such as long sequence [22] and multimodal input [23]. It can be used in all dense layers of LLMs, but it is typically used to adapt attention weights [8].

2.2 Inference Serving Systems

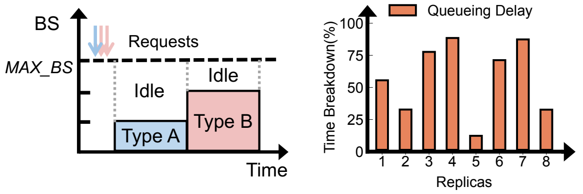
LLM serving systems. Many techniques have been developed to improve the efficiency of LLM inference by leveraging the characteristics of LLMs. Orca [11] proposes iteration-level scheduling to batch requests of different lengths at the granularity of iterations. Completed requests can be removed immediately and newly arrived requests can be inserted into the batch without waiting for the completion of the current batch. The state-of-the-art solution vLLM [12] further introduces an on-demand block-based GPU allocation mechanism called PagedAttention to reduce GPU memory fragmentation caused by variable and unpredictable KV cache, thereby increasing the maximum batch size. However, they only focus on the single LLM serving scenario. When serving multiple LoRA LLMs, they cannot share the common base model and thus cause severe redundant memory consumption.

HuggingFace PEFT [10] is a popular library for parameter-efficient fine-tuning. It can also be used to serve multiple LoRA LLMs shared with the same base LLM. However, it can only serve requests destined to the same adapter once at a time by swapping between different adapters, leading to low efficiency. Besides, it lacks support for cluster-level management for requests and adapters.

Traditional DNN serving systems. Many DNN serving systems can orchestrate multiple DNN models in a cluster, such as SHEPHERD [13] and AlpaServe [14]. However, they also do not support sharing the base model among different models and do not target autoregressive LLMs. PetS [24] can serve multiple parameter-efficient non-autoregressive transformer models in a single server, but it cannot serve autoregressive LLMs and does not consider LoRA. Besides, it does not support cluster-level management for requests and models. In short, existing DNN serving systems also cannot serve multiple LoRA LLMs in the cluster wide efficiently.

2.3 Challenges

To serve a large number of requests, a serving system usually deploys multiple replicas of the same base LLM, with each handling a subset of the requests. Nevertheless, when employing existing systems (such as vLLM and PEFT) to serve LoRA LLMs, we identify two primary challenges.



(a) Challenge within replicas. (b) Challenge across replicas.

Figure 2: Challenges in existing LoRA serving.

GPU underutilization within a replica. In a model replica, a single base model is accompanied by multiple LoRA adapters for different types of requests. The aforementioned PEFT only accommodates batching requests with the same LoRA adapter (i.e., the same type of requests). When serving one type of request, PEFT forces other types of requests to wait until the completion of the current batch. The serving system has to handle low-frequency types of requests one by one, which cause severe GPU underutilization. Figure 2(a) illustrates an example. When three requests arrive simultaneously, even if the max batch size is three, PEFT has to process these three requests separately: one batch for a request destined to the type A adapter and another batch for two requests destined for the type B adapter. As a result, the serving system only utilizes 50% of the total GPU resources and doubles the total latency for the requests destined to the type B adapter. This example indicates that although LoRA does not introduce extra inference latency for a single request, it is still challenging to serve multiple LoRA LLMs efficiently.

Load imbalance across replicas. To manage multiple replicas in a cluster, a serving system usually adopts a global scheduler to dispatch each incoming request to a specific replica. However, there exists load imbalance across replicas from two aspects. First, due to the limited GPU memory, one adapter type may only reside in a subset of replicas. When a burst of requests destined for this adapter type arrives, only a few replicas are utilized, while other replicas are idle. Figure 2(b) shows an example that sending requests based on the Azure trace [25] adopted by a previous DNN serving work [14] to a cluster with eight replicas, where 32 types of adapters are uniformly loaded in the eight replicas. In this case, the burst of requests leads to severe load imbalance across replicas. The difference in queuing delay between replicas can be up to 8.0×. Second, even if the requests are dispatched uniformly across replicas, the variable input and output lengths of requests still lead to load imbalance inevitably. The statistics of ShareGPT [26], the datasets collected from real-world conversations with ChatGPT [27], show that the input and output lengths of requests are highly variable. The longest input length and output length of requests are longer than the average lengths by 636.7× and 163.9× respectively, which implies extremely diverse execution time and GPU memory consumption among requests. The load imbalance caused by variable input and output lengths undermines the system's

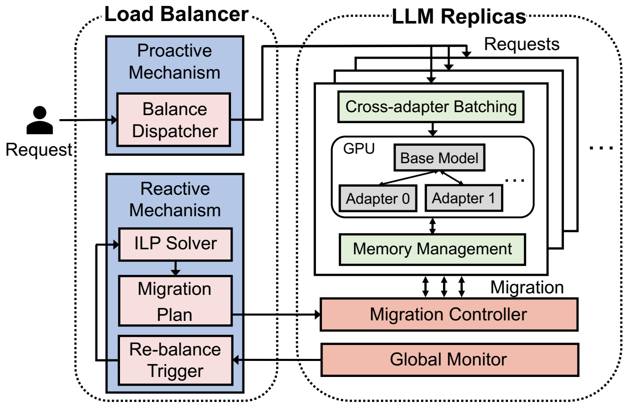


Figure 3: dLoRA architecture.

overall inference efficiency and significantly increases latencies for requests on the overloaded replica.

3 Overview

dLoRA is an inference serving system that serves multiple LoRA models in a cluster. Within a replica, dLoRA employs a novel cross-adapter batching technique to process requests to different LoRA adapters in a single batch and improves the GPU utilization (§4). Across replicas, dLoRA dynamically migrates LoRA adapters and requests in the cluster to achieve better load balancing (§5). Figure 3 shows the overall architecture of dLoRA.

Intra-replica. dLoRA deploys a set of worker replicas in a cluster. Each replica contains a subset of LoRA adapters and one base model on several GPUs.

Dynamic batching. Within a replica, dLoRA uses a local *cross-adapter batching* technique to process requests from the global scheduler. The replica maintains a queue to buffer incoming requests and schedules a batch of requests to the execution engine with dynamic batching to achieve optimal tradeoff between merged and unmerged inference.

Memory management. dLoRA efficiently manages the GPU memory of LoRA adapters and requests within a single replica. The memory manager allocates the GPU memory to the LoRA adapters and the intermediate states of requests. The two different types of memory may race for the limited GPU memory, which harms the serving performance. To mitigate this, the memory manager dynamically adjusts the memory allocation for adapters and requests based on the current GPU memory usage and workload pattern. Besides, the memory manager also swaps the unused adapters and requests to the host memory.

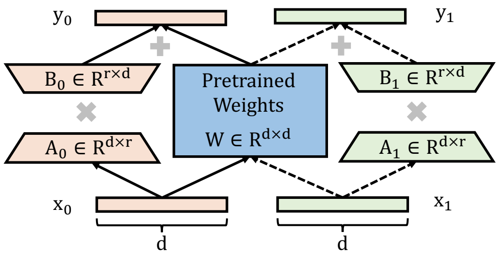

Figure 4: Unmerged inference.

Inter-replica. To manage multiple replicas in the cluster, dLoRA uses a load balancer to solve the aforementioned load imbalance problem. Due to the variable input and output lengths of LLM requests, dLoRA introduces proactive and reactive mechanisms to solve the imbalance problem before and after it occurs, respectively.

Proactive mechanism. The proactive mechanism, upon receiving user requests, directs them to a specific replica based on a two-fold dispatching policy. For short-term load dynamics, the mechanism proactively selects the replica with the most available resources to load the corresponding adapter and process the request. For long-term load dynamics, the mechanism proactively loads and replicates adapters for future predictable load spikes.

Reactive mechanism. The proactive mechanism alone is not sufficient since the resource usage (i.e., input and output length) of a request is variable. The load imbalance problem still occurs. To address this issue, dLoRA introduces a reactive mechanism to handle such a situation. Specifically, there is a global monitor that periodically collects the resource usage of each replica. Once the monitor detects a replica with a heavy load, it notifies the re-balance trigger. The reactive mechanism then employs a request-adapter co-migration algorithm to find the optimal migration plan and sends the plan to the cluster's migration controller. The controller then migrates requests' intermediate states and loads LoRA adapters across different replicas to achieve load balancing.

4 Dynamic Batching

4.1 Unmerged Inference

In §2.3, we discuss the limitations of merged inference in terms of significant queuing delay and poor GPU utilization when serving multiple LoRA LLMs. However, the characteristics of LoRA LLMs provides an opportunity.

Unmerged inference. Figure 1(b) shows that the fine-tuned weights and the pre-trained weights are merged to serve a request (i.e., $y = (W + BA)x$), as initially suggested in the LoRA paper [8]. This approach is termed *merged inference*. An alternative approach is *unmerged inference* to process requests with different types in a single batch. Specifically, unmerged inference separates the computation of the pre-trained LLM weights and each LoRA adapter weights. During inference, different types of requests can be batched together to share the same computation with the pre-trained LLM

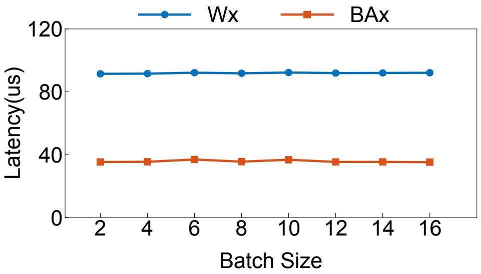

Figure 5: Non-negligible adapter computation overhead.

weights and process different computation with LoRA adapter weights at parallel.

Figure 4 demonstrates unmerged inference. Consider two different requests, x_0 and x_1, with their respective LoRA adapters, $adapter_0$ and $adapter_1$. During inference, the base model inference Wx is batched together as $W \times [x_0, x_1]$. Simultaneously, the LoRA adapter inference BAx is computed separately for each request as $B_0A_0x_0$ and $B_1A_1x_1$ in parallel. Finally, the base model inference and the LoRA adapter inference are aggregated to obtain the final results $y_0 = Wx_0 + B_0A_0x_0$ and $y_1 = Wx_1 + B_1A_1x_1$. Unmerged inference improves the GPU computation efficiency by improving the batch size. However, this solution poses a new challenge.

Extra Computation Overhead. Although unmerged inference accelerates the requests processing with different types, the benefit of unmerged inference technique is not a free lunch. Unmerged inference requires computing three matrix multiplications for each request, i.e., Wx, Ax and BAx, and a matrix addition for result aggregation. As a result, unmerged inference introduces extra computation overhead of two additional matrix multiplications (i.e., separate computation for adapter inference) and one additional matrix addition in each layer.

Figure 5 illustrates the overhead associated with unmerged inference. We conduct an experiment to compare the execution time of the base LLM computation, denoted as Wx (equivalent to original LoRA LLM inference), with the LoRA adapter computation BAx. The experimental setup follows §7. The results, depicted in the figure, reveal that the execution time for the LoRA adapter computation BAx is 38.9% of the baseline LLM computation Wx. This finding suggests that unmerged inference might not always yield performance benefits. On the contrary, performance may degrades when only processing few types of requests.

4.2 Dynamic Batching with Thresholds Tuning

In the preceding discussion, we highlight how unmerged inference incurs additional computational overhead, while merged inference leads to significant queuing delays and low GPU efficiency. A combined approach of these two batching methods can potentially offer a more balanced tradeoff between queuing delay and computational overhead. Yet, determining the optimal batching strategy, within a constrained scheduling time frame, is challenging. First, the decision needs to be made at the granularity of the iteration while each iteration of LLM inference is typically around tens or hundreds of milliseconds [11, 19]. To avoid the performance degradation, the decision must be made swiftly. Second, the unpredictability of request arrival patterns and request execution time further complicates this decision-making [13, 14, 26]. Last but not least, switching between the two inference methods introduces non-negligible overhead (i.e., an additional matrix multiplication BA and a matrix addition/subtraction between base LLM and adapter). We propose a dynamic batching technique to choose the inference method at runtime.

Algorithm 1 Dynamic Batching

```
 1: function DYNAMICBATCHING($B_{fcfs}, R, S, L$)
 2:     Input: FCFS requests $B_{fcfs}$, Request $R = \{r_1, r_2, ..., r_n\}$
 3:            Replica state $S$, LoRA adapters $L = \{l_1, l_2, ..., l_m\}$
 4:     Output: The batch of requests to be executed $B_{next}$
 5:     // Adaptive switching between different modes
 6:     if $S.state ==$ unmerge then
 7:         $R_{merge} = \arg\max_{l_i \in L} |\{r_i \in R \mid r_i.type == l_i\}|$
 8:         if $|R_{merge}|/|B_{fcfs}| > \alpha_{switch}$ then
 9:             $S.state$, $S.type =$ merge, $R_{merge}.type$
10:             return $B_{next} = R_{merge}[: max\_bs]$
11:         else
12:             return $B_{next} = B_{fcfs}$
13:     else
14:         $R_{merge} = \{r_i \in R \mid r_i.type == S.type\}|$
15:         if $|R_{merge}|/|B_{fcfs}| < \beta_{switch}$ then
16:             $S.state =$ unmerge
17:             return $B_{next} = B_{fcfs}$
18:         else
19:             return $B_{next} = R_{merge}[: max\_bs]$
```

Algorithm. Algorithm 1 outlines the pseudo-code. Each iteration begins by assessing the replica's state (line 6). In the unmerged state, the algorithm estimates potential performance gains from merged inference. It selects the LoRA adapter with the most requests (line 7) and evaluates its performance against the default first-come-first-serve (FCFS) order (line 8). We use the (FCFS) as the default scheduling choice. Dynamic batching is orthogonal to the underlying scheduling policy; other policies can also be used. If the size ratio exceeds the switching threshold α_{switch}, indicating a performance enhancement, the algorithm switches to merged inference (line 9) and processes the requests from the corresponding adapter type (line 10). If not, it continues with the FCFS batch (lines 11–12). In scenarios of merged inference, the algorithm first batches requests matching the active adapter, i.e., R_{merge} (line 14). If the FCFS batch size ratio to R_{merge} is smaller than the threshold β_{switch} or the active LoRA adapter is not in the set of legal adapters L (line 15), the unmerged state (i.e., processing B_{fcfs}) is deemed advantageous (lines 16–17). Otherwise, the algorithm remains the merged state (lines 19).

Adaptive threshold tuning. The switching threshold α_{switch} and β_{switch} are the key parameters of the algorithm. Figure 6

α_{switch}

Figure 6: Thresholds demonstration.

illustrates the two thresholds between merged and unmerged inference. The horizontal axis represents the ratio between $|R_{merge}|$ and $|B_{fcfs}|$.

Our first insight is that the switching overhead can be amortized across multiple future iterations. For example, assume that the switching overhead from unmerged to merged inference is 100 ms, and assume that merged inference of one iteration is 50 ms and unmerged inference of one iteration is 100 ms. Let the number of iterations in current processing is three, and the overall execution time is 300 ms if the status is unmerged inference. However, if we switch to merged inference at the beginning, the overall execution time is 250 ms for three iterations, i.e., switching overhead 100ms plus three iterations of 150 ms. In this case, the switching overhead is amortized across the three iterations. Our second insight is that leveraging historical retrospection is possible, despite the unavailability of future knowledge. Continuing with the example, at the beginning of the first iteration, the total number of iterations remains unknown. If requests are finished in one iteration, merging inferences offers no advantage. However, if processing spans two or more iterations, it becomes plausible to anticipate additional future iterations. Under such circumstance, switching to merged inference is still timely.

Based on the two insights, we propose an adaptive threshold tuning algorithm. The algorithm first introduces the break point on iteration granularity, which is marked by events such as replica switching, changes in R_{merge}, or after processing a set number of iterations. Upon reaching a break point, the algorithm tunes the thresholds based on the data collected from the preceding period, stretching from the current to the previous break point. The pseudo-code is outlined in Algorithm 2. In cases where the previous period's replica state is *unmerge*, we focus on tuning α_{switch}. Let the number of the iterations in the previous period be N_I and the merged requests, $R_{merged}[: max_{bs}]$, in the i_{th} iteration be B_i and B_{fcfs} in the i_{th} iteration be B_i'. The throughput of the merged inference T_{merge} and the throughput of the unmerged inference $T_{unmerge}$ are calculated in lines 4–5. The iteration time can be profiled accurately [19]. A higher T_{merge} leads to a reduction in α_{switch} by a decrement factor γ_{dec}. Otherwise, it is increased by a multiplication factor γ_{mul}. If the replica state in the previous period is *merge*, the algorithm tries to tune β_{switch}. The tuning is similar to the case of α_{switch}, and we omit the details for brevity. This method ensures the adaptability of the two thresholds to varying request characteristics.

Algorithm 2 Adaptive Threshold Tuning

```
1: Input: Candidate period $N_I$, Merged batches $B_1, B_2, ..., B_I$,
   Switching overhead $t_M$, Current switching threshold $\alpha_{switch}$
2: Output: New switching threshold $\alpha_{switch}$
3: function ADAPTIVETUNING($N_I$, $\{B_i\}$, $t_M$, $\alpha_{switch}$)
4:     $T_{merge} = \frac{\sum_{i=1}^{N_I} |B_i|}{\sum_{i=1}^{N_I} IterationTime(B_i) + t_M}$
5:     $T_{unmerge} = \frac{\sum_{i=1}^{N_I} |B_i'|}{\sum_{i=1}^{N_I} IterationTime(B_i')}$
6:     if $T_{merge} > T_{unmerge}$ then
7:         $\alpha_{switch} = \alpha_{switch} - \gamma_{dec}$
8:     else
9:         $\alpha_{switch} = \alpha_{switch} \times \gamma_{mul}$
10:    return $\alpha_{switch}$
```

Starvation prevention. Although dynamic batching accelerates LoRA LLM serving, it may cause starvation. Specifically, because dynamic batching prefers processing requests with the most loaded LoRA adapter type, it may starve other types of requests. To address this problem, we use a credit-based mechanism to prevent starvation. The basic idea involves allocating a credit to each LoRA adapter. This credit is then transferred to any preempted adapter. When the credits of certain adapters exceed a threshold, the algorithm prioritizes processing requests with these adapters. Detailed explanations are provided in §A.1.

4.3 LoRA Adapter Offloading

Besides GPU computational resources, GPU memory resources are also heavily used by LLM inference workloads. Sharing a base LLM across LoRA LLMs mitigates the GPU memory footprint, yet memory scarcity persists, especially when storing multiple LoRA adapters. For instance, a single LoRA adapter for Llama-7B requires 56 MB of GPU memory, which is comparable to the intermediate states (i.e., key-value cache) of 7 tokens. As the number of LoRA adapters increases, only a small fraction of GPU memory is available for storing intermediate states of requests. To this end, we employ a swapping mechanism that swaps LoRA adapters and intermediate request states between GPU and host memory. The compact size of LoRA adapter facilitates rapid swapping. Such process is further accelerated by overlapping the swapping with execution using prefetching techniques [19]. Regarding GPU memory distribution, dLoRA adopts a workload-aware allocation algorithm for balancing LoRA adapters and intermediate request states, as detailed in §5.

5 Dynamic Load Balancing

To address the load imbalance problem across replicas for LoRA serving, we combine proactive and reactive mechanisms. Specifically, we follow the existing approach [13, 14] to adopt a proactive mechanism that dispatches requests to replicas. The challenge of LoRA serving as discussed in §2.3 is that the variable input and output lengths of LLM requests cause load imbalance even if the proactive mechanism bal-

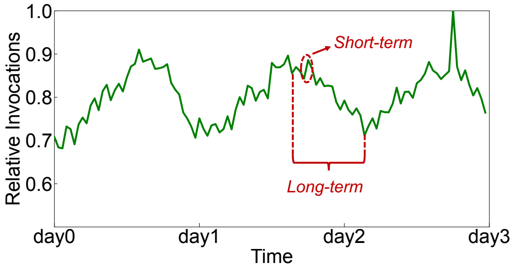

Figure 7: Workload pattern.

ances the load when dispatching requests. Therefore, we design a reactive mechanism that migrates requests and adapters between replicas to reactively address such load imbalance.

5.1 Proactive Mechanism

We first introduce the dispatcher that proactively dispatches requests to replicas and loads LoRA adapters to GPUs according to the workload patterns (i.e., the arrival pattern of requests). Figure 7 shows a production trace used by prior works on inference serving [13, 14]. The workload pattern of this trace can be examined from both long-term and short-term perspectives. In the long term, the pattern exhibits predictability and periodicity, e.g., low load at midnight and high load during daytime. On the other hand, in the short term, the pattern is marked by unpredictability and burstiness. We follow existing work [13, 14] to adopt a proactive mechanism based on these characteristics for LoRA serving.

Guided by the predictable long-term workload, it is possible to preload LoRA adapters to GPU memory to reduce the adapter loading time. During the adapter preload process, we follow the existing work [13] to maximize the minimum burst tolerance of LoRA adapters. The burst tolerance of an adapter in our scenario is defined as the ratio of the peak capacity to the average load of the adapter, where the average load can be obtained from the historical long-term workload. Different from the previous DNN serving scenarios, we find that the peak capacity of a LoRA adapter is dominated by the GPU memory allocation between LoRA adapters and requests' intermediate states. As more LoRA adapter is preloaded into the GPU memory, more replicas can serve this type of request immediately. However, it leaves less GPU memory for requests' intermediate states, which limits the peak serving throughput. Therefore, we define the peak capacity of a LoRA adapter as the number of requests that can be served by the unallocated GPU memory where the corresponding LoRA adapter resides. Based on this metric, the dispatcher of dLoRA greedily preloads the LoRA adapter with the lowest burst tolerance to a replica without this adapter until the minimum burst tolerance decreases to find an optimal placement plan.

Due to the unpredictable short-term pattern of the workload, there also exists a short-term burst of certain LoRA adapters' requests. Such short bursts may cause the burst requests to be dispatched to a small set of replicas with the corresponding LoRA adapters. This leads to severe load imbalance and long queuing delay od requests. On the contrary, if the burst requests are dispatched to other replicas without the corresponding adapter, it incurs additional loading time and consequently harms the serving performance. To address this problem, dLoRA use an adapter-aware dispatch policy with dynamic LoRA loading to consider all these factors. Specifically, dLoRA calculates an estimated pending time for each replica, which includes the time to load the LoRA adapter (if not already loaded) and the estimated queuing time on this replica. Based on this metric, dLoRA dispatches requests to the replica with the shortest estimated pending time to balance the load across replicas. This is especially effective in mitigating issues caused by sudden bursts of requests and consequent queuing delays in heavily loaded replicas.

5.2 Reactive Migration

Although proactive dispatching can mitigate the load imbalance problem, the system still suffers from load imbalance caused by variable input and output lengths of LoRA requests (§2.1). Therefore, even if the workload arrival pattern is stable and entirely predictable, the load imbalance still occurs when some requests in some replicas have longer execution times than others. The GPU memory consumption of requests also suffers from the same load imbalance problem. Some replicas may hold substantial intermediate states of requests even larger than the GPU memory capacity, which causes frequent swapping between GPU memory and host memory. Other replicas may hold a smaller amount of intermediate states of requests. Such load imbalance harms the serving performance and cannot be solved by only proactively dispatching.

Dynamic adapter-request co-migration. To address the load imbalance problem, we propose a adapter-request co-migration technique. The main idea is to migrate LoRA adapters and requests (with intermediate states) from overloaded replicas to others. Such migration reactively balances the load across replicas. As shown in Figure 8, replica 0 is overloaded with long-context requests while replica i is underloaded with short-context requests. The load imbalance can be mitigated by migrating some requests from replica 0 to replica i and loading corresponding adapters. However, it is not trivial to decide the optimal migration plan. Before introducing the algorithm in detail, we first model the reactive migration problem. The key notations are listed in Table 1.

Objective: overall running time. The goal of the migration algorithm is to minimize the overall running time among all replicas. The overall running time is determined by the placement of requests and LoRA adapters. We define two 0-1 matrices x and y to represent the placement of requests and LoRA adapters, respectively. Specifically, $x_{i,j}$ and $y_{k,j}$ are 0-1 variables that indicate whether request i or adapter k is in the replica j. Furthermore, we break x into two matrices x^G and x^H to represent the placement of requests in the GPU memory and host memory, respectively. The request with its

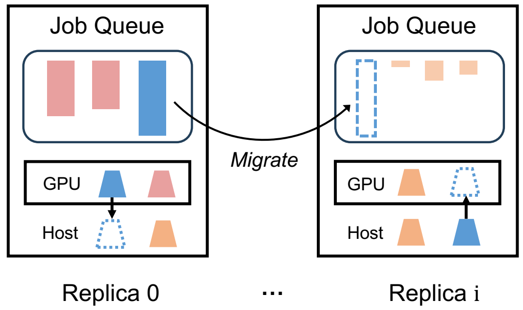

Figure 8: Dynamic migration.

Symbol	Description
$x^G_{i,j}$	Whether requests i is in the replica j's GPU memory.
$x^H_{i,j}$	Whether requests i is in the replica j's host memory.
$x_{i,j}$	Whether requests i is in the replica j.
$y_{k,j}$	Whether adapter k is in the replica j.
M^R_i	The memory consumption of request i.
M^A_k	The memory consumption of adapter k.
M^G_j	GPU memory capacity of replica j.
M^H_j	Host memory capacity of replica j.
L_i	Average exec time of requests with request i's adapter.
γ	Migration factor to control the request migration frequency.
η	Affinity factor to control the affinity between requests.

Table 1: Key notations in the migration problem.

intermediate results is either resident in the GPU memory or host memory (i.e., $x_{i,j} = x^G_{i,j} + x^H_{i,j} \leq 1$).

The overall running time of requests on each replica includes execution time and swapping overhead. On replica j, the execution time of request i is $L_i x_{i,j}$, where L_i is the average execution time of requests i. We scale the execution time by multiplying a migration factor γ to account for the migration time of request i. γ is calculated as the ratio of total executed time, including the migration time, to the total executed time without migration, inhibiting the frequent migration between replicas. As for swapping overhead, it is represented as $M^R_i x^H_{i,j}/B$, where M^R_i is the memory consumption and B is the PCIe bandwidth. As a result, the overall running time of replica j is estimated as $\sum_i \left(\gamma \times L_i x_{i,j} + M^R_i x^H_{i,j}/B\right)$. Because the dynamic batching algorithm prefers to batch requests with the same type, we also add a penalty term $\eta \sum_k y_{k,j}$ to represent the affinity among the same type of requests, where η is a hyperparameter. For all parallel replicas, the overall running time is the maximum running time of all replicas:

$$Min.\ \big(\max_j \sum_i (\gamma \times L_i x_{i,j} + M^R_i x^H_{i,j}/B) + \eta \sum_k y_{k,j}\big)$$

Adapter-request matching constraints. Different from classical load balancing problems [15–17], the adapter-request co-migration algorithm needs to consider both the migration of requests and the loading of LoRA adapters at the same time. One request can only be migrated to the replica only if there is a corresponding adapter available, which is formulated as following adapter-request matching constraints:

$$\forall i, j,\ y_{i,j} \geq x_{i,j}$$

Memory constraints. For each replica, the GPU memory consumption cannot exceed the GPU memory capacity. We define M^G_j as the GPU memory capacity and M^H_j as the host memory capacity of replica j. We get two constraints for GPU and Host memory, respectively:

$$\begin{cases} \forall j,\ \sum_i M^R_i \cdot x^G_{i,j} + \sum_k M^A_k \cdot y_{k,j} \leq M^G_j \\ \forall j,\ \sum_i M^R_i \cdot x^H_{i,j} \leq M^H_j \end{cases}$$

Existence constraints. Last but not least, the existence constraints ensure that each request is only placed in one replica, which is represented as:

$$\forall i,\ \sum_j x_{i,j} = 1$$

ILP formulation. Given the above objective and constraints, we formulate the co-migration problem as an ILP problem, where matrices x^G, x^H, and y are the variables. dLoRA solves the problem with the off-the-shelf ILP solver [28] and gets the optimal placement plan (i.e., x^G, x^H, and y). According to this plan, dLoRA migrates the intermediate states of requests and loads LoRA adapters simultaneously. dLoRA also reserves a chunk of memory in each replica, which is utilized to replicate additional LoRA adapters to maximize the burst tolerance as described in the proactive mechanism (§5.1). With this approach, dLoRA's co-migration algorithm effectively achieves load balancing across replicas with optimal performance.

Selective migration with constraints relaxation. The above ILP formulation offers an optimal migration plan, but its large decision space introduces computation overhead. As the GPU cluster and request number expand, the ILP's complexity increases exponentially. To address this, dLoRA employs two domain-specific heuristics to accelerate such solving process.

Our first insight is that migration is necessary primarily during extreme load imbalance. Therefore, dLoRA only triggers the migration algorithm when the available GPU memory of a replica is beyond a memory threshold or the queuing delay of requests in a replica is beyond a computation threshold. This approach effectively minimizes the migration frequency, thereby amortizing the migration overhead. Besides, similar to selective replication [15–17], dLoRA only considers migration between top K overloaded replicas and top K underloaded replicas. As a result, the complexity of the selective migration only depends on K rather than the cluster scale.

Our second insight is that the ILP problem can be simplified by relaxing the constraints. In practice, migration is implemented as token transfer and subsequent intermediate state reconstruction, which is much faster than direct intermediate state migration [12]. As a result, dLoRA does not differentiate the requests on the GPU memory and host memory. Instead, dLoRA only considers the total memory consumption of requests and LoRA adapters. We assume that additional memory consumption is swapped out to the host memory which is always sufficient in practice. Therefore, memory constraints are negligible, with only the swapping overhead added to the total execution time.

Last, to reduce the complexity of the ILP problem, the variable matrix x is relaxed to the real number. Given the real number matrix x, the placement of each request is determined by the largest element in the corresponding row of x. For instance, request i is placed in replica j' if $x_{i,j'} = \max_j x_{i,j}$. With these techniques, dLoRA is able to solve the optimal adapter-request co-migration plan within milliseconds.

6 Implementation

We implement a prototype of dLoRA based on vLLM [12] with about 6.2K LOC. We use vLLM to build dLoRA as vLLM is the state-of-the-art serving system with advanced features such as PagedAttention and iteration-level scheduling. The prototype includes a FastAPI [29] frontend, a global scheduler, and GPU-based execution engines. The frontend of dLoRA extends the vLLM FastAPI [29] frontend, enables client-specific LoRA adapter selection per request. dLoRA's global load balancer is responsible for dispatching requests to LLM replicas and dynamically migrating requests. It uses Ray [30] actor to interact with execution engines in the cluster and utilizes Pulp [28] to solve the ILP problem defined in §5. The execution engine also uses Ray [30] actor for key-value cache management and LoRA adapter management. To support *unmerged inference* in §4, we transform the LoRA type of each request into a one-hot vector and generate a request-type mapping matrix of the current batch. We then utilize the `einsum` function provided by PyTorch to achieve parallel matrix multiplication and integrate it into the execution engine. We add LoRA adapters to the vLLM execution engine and swap adapters between GPU and host memory asynchronously to reduce overhead. As for model executor, we implement LoRA inference for popular LLMs, including OPT [31] and Llama-2 [2]. dLoRA also accomplishes Megatron-LM [32] style tensor parallelism on LoRA adapters to support distributed execution of large models which can not fit in a single GPU, e.g., Llama-2-70B. dLoRA can be integrated with other frameworks, such as Ray Serve [33]. On the server side, similar to HuggingFace PEFT [10], the cluster administrator needs to provide additional LoRA information, including LoRA adapter weights, LoRA adapter name and its dependency on the base LLM, before launching the service. dLoRA takes charge of other things. When sending a request to dLoRA, the client side specifies the LoRA adapter name in the request. dLoRA dispatches the request to the corresponding LoRA adapter and returns the result.

Model	Size	# of Layers	# of Heads	Hidden Size
Llama-2-7B	13GB	32	32	4096
Llama-2-13B	26GB	40	40	5120
Llama-2-70B	132GB	80	64	8192

Table 2: Model configurations.

7 Evaluation

In this section, we first demonstrate the end-to-end performance improvements of dLoRA over state-of-the-art LLM serving systems under diverse workloads and models. Then, we evaluate the design choices of dLoRA and show the effectiveness of each component.

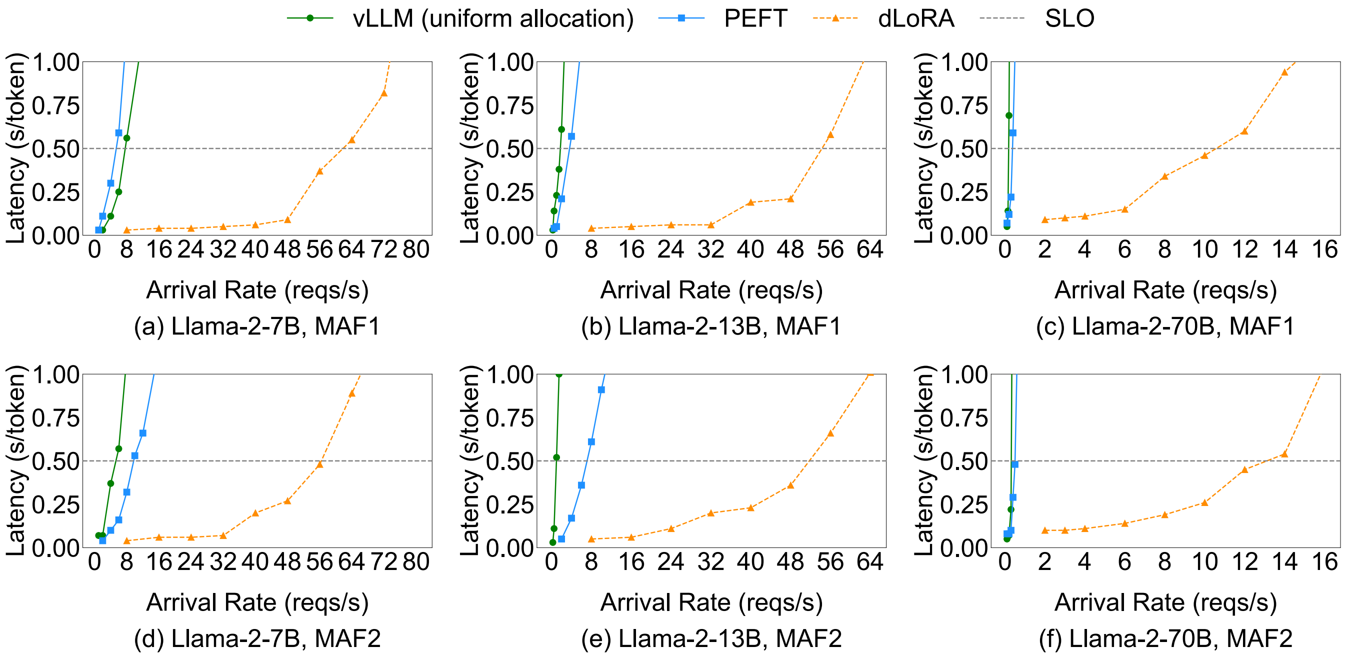
7.1 Experiment Setup

Testbed. We evaluate dLoRA on a four-node GPU cluster, each with eight NVIDIA A800 80GB GPUs, i.e., 32 GPUs in total. Each node is equipped with 128 CPUs, 2048 GB of host memory, and a 200 Gbps InfiniBand NIC. We use PyTorch 12.1.0 and NVIDIA CUDA 12.2 for our evaluation.

Models. We choose the widely-used open-sourced LLMs, Llama-2 model series [2], as the pre-trained LLMs (i.e., base LLMs) for our evaluation. We use various Llama-2 models with different sizes, including Llama-2-7B, Llama-2-13B, and Llama-2-70B. The details of these models are shown in Table 2. The rank of LoRA adapters is set to 8, as used in the evaluation of prior work [8, 9].

Workloads. Similar to prior work [12], we generate workloads based on the ShareGPT dataset [26]. ShareGPT is a dataset collected from real-world conversations with OpenAI ChatGPT shared by users. We sample the arrival pattern of requests based on the production traces, Microsoft Azure function trace 2019 (MAF1) [34] and 2021 (MAF2) [25]. Although these traces are collected from Azure serverless functions, they are also widely used as the proxy of the LLM inference traces by prior work on model serving [13, 14]. Because the number of functions is larger than that of LLMs, we sort the functions based on the function invocation frequencies and map the functions to LoRA LLMs in a round-robin manner. To demonstrate different load patterns, we define the skewness as the number of each round-robin mapping. For example, if we map the first 10 functions to the first LoRA LLM, the second 10 functions to the second LoRA LLM, and so on, the skewness is 10. The larger the skewness, the more skewed the workload. To illustrate the impact of increasingly longer requests [35], we also scale the input and output length of requests by a scale ratio factor in §7.4.

Metrics. We use the average latency as the primary metric to evaluate the performance of dLoRA. Following prior work on LLM serving [11, 12], the average latency is calculated by dividing the sum of each request's end-to-end latency by the total number of output tokens. To compare different systems,



(a) Llama-2-7B, MAF1
(b) Llama-2-13B, MAF1
(c) Llama-2-70B, MAF1
(d) Llama-2-7B, MAF2
(e) Llama-2-13B, MAF2
(f) Llama-2-70B, MAF2

Figure 9: Average latency of different serving systems with Llama-2 models.

we set a latency service level objective (SLO) and compare the maximum throughput achieved by each system under the SLO. Similar to prior work, we set the latency SLO to 10× of the latency of a single iteration in the decoding phase. Specifically, SLO is 0.5 seconds based on our profiling.

Baselines. Because there is no existing system that specifically targets LoRA LLM serving. We compare dLoRA with two state-of-the-art LLM serving systems.

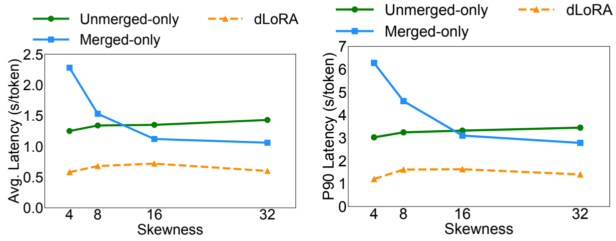
- **vLLM (uniform allocation)** [12]: vLLM is the state-of-the-art LLM serving system. It is a general-purpose LLM serving system, and ignores the multi-LLM serving scenario. To evaluate the performance of vLLM in the LoRA serving setting, we deploy multiple vLLM instances on the same cluster and uniformly allocate resources between them.
- **PEFT** [10]: PEFT is a HuggingFace library for parameter-efficient fine-tuning models. Although it can be used to serve LLMs, it does not support advanced features like selective batching [11] and PagedAttention [12]. To conduct a fair comparison, we implement these features for PEFT. PEFT batches requests based on their types and swap adapters between batches if necessary.

7.2 End-to-End Performance

We first compare end-to-end performance of dLoRA with vLLM (uniform allocation) and PEFT under MAF1 and MAF2 workload traces on Llama-2-7B, Llama-2-13B and Llama-2-70B models. The first column of Figure 9 shows the performance of these LLM serving systems when serving 128 Llama-2-7B models. Since Llama-7B is relatively small, the total GPU memory can accommodate full parameters of all models. However, vLLM (uniform allocation) and PEFT cannot dynamically batch different types of requests (i.e., unmerged inference) based on different workload patterns. In this case, dLoRA improves the throughput by up to 10.6× compared to vLLM (uniform allocation) and up to 11.5× compared to PEFT under the SLO requirement.

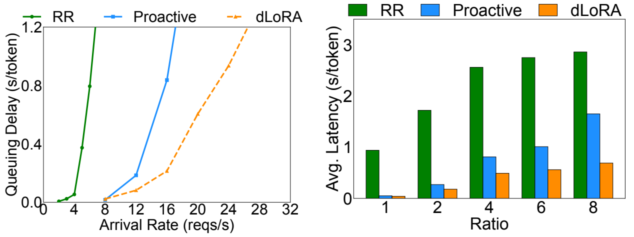
The second column of Figure 9 shows the performance of these LLM serving systems when serving 128 Llama-2-13B models. Since Llama-13B is larger than Llama-7B, the total GPU memory cannot accommodate full parameters of all models. As a result, vLLM (uniform allocation) which treats each LoRA LLM as an individual LLM has to swap the model parameters between host and GPU memory. Thus, dLoRA improves the throughput by up to 53.0× compared to vLLM (uniform allocation) under the SLO requirement. PEFT shares the base LLM between different LoRA LLMs to reduce memory footprint, but it does not have adapter-request migration. This significantly degrades the performance of PEFT. As a result, dLoRA improves the throughput by up to 15.0× compared to PEFT under the SLO requirement.

The third column of Figure 9 shows the performance improvement of dLoRA when serving 32 Llama-2-70B models in the cluster. Llama-2-70B is even larger than the GPU memory capacity of a single NVIDIA A800 80GB GPU. Therefore, the Llama-2-70B is partitioned across 4 GPUs with the tensor parallelism. As shown in Figure 9, the techniques employed by dLoRA integrate effectively with existing parallelism strategies and dLoRA improves the throughput by up



(a) Average Latency. (b) P90 Latency.

Figure 10: Effectiveness of the credit-based dynamic batching algorithm.



(a) Reduction in Queuing Delay. (b) Stability under Different Ratios.

Figure 11: Effectiveness of the adapter-request co-migration algorithm.

to 57.9× compared to vLLM (uniform allocation) and up to 26.0× compared to PEFT under the SLO requirement.

7.3 Effectiveness of Dynamic Batching

To show the effectiveness of dynamic batching with thresholds tuning, we compare the performance of dLoRA with strawman solutions described in §4. The experiments are conducted in a single NVIDIA A800 80GB GPU to serve 8 LoRA Llama-2-7B models, which avoids the effect of the adapter-request co-migration algorithm.

Figure 10(a) shows the average latency under diverse skewness. The arrival rate is set to make the average latency of dLoRA approximately equal to the SLO requirement. The first strawman solution, Merged-only, which always uses merged inference, performs poorly when the skewness is low, i.e., the type of requests is diverse, since it cannot serve different requests at the same time. Therefore, dLoRA improves the latency by up to 3.9×. The other strawman solution, Unmerged-only, which always uses unmerged inference, performs similarly no matter how the skewness changes. However, when the skewness is high, i.e., a few types of requests are dominant, Unmerged-only cannot take advantages of merged inference to avoid extra computation overhead caused by the adapter computation. Consequently, dLoRA improves the latency by up to 2.4× compared to Unmerged-only. In short, dLoRA dynamically switches between merged and unmerged inference based on the runtime workload, and always outperforms the two strawman solutions and achieves the optimal tradeoff.

In addition to the average latency, we also record the P90 latency of the three solutions with the same setting. As shown in Figure 10(b), dLoRA outperforms Merged-only and Unmerged-only by up to 5.2× and 2.5×, respectively. This consistent performance improvement indicates that although dLoRA may preempt some requests to serve other requests, the credit-based starvation prevention mechanism of dynamic batching improve performance while avoiding starvation.

7.4 Effectiveness of Dynamic Load Balancing

To show the effectiveness of the proactive and reactive dynamic load balancing, we compare the performance of dLoRA with two strawman solutions. We measure the average queuing delay of requests, an important indicator of load imbalance. Due to the limited budget, this experiment is conducted on a server with 8 NVIDIA A800 80GB GPUs. Figure 11(a) shows the experiment result. The first strawman solution is *RR* that directly dispatches requests to the corresponding LoRA LLMs preloaded by the workload-aware adapter placement in a round-robin manner without considering the bursty load imbalance (§5). Since RR does not consider the bursty load imbalance at all, dLoRA outperforms RR by 3.6× under the SLO requirement. The second strawman solution is *Proactive Dispatch* which only supports proactive mechanism in §5.1 without reactive migration. However, due to the variable and unpredictable length of requests, Proactive Dispatch cannot handle this unpredictable run-time load imbalance. In contrast, dLoRA dynamically migrates requests between replicas to balance the load and outperforms Proactive Dispatch by 1.4× under the SLO requirement.

We also evaluate the stability of the dynamic load balancing algorithm under different scale ratio factors of input and output length of requests. Figure 11(b) shows the average latency of requests under different ratios. Because RR cannot dynamically change LoRA adapter distribution across replicas as the ratio increases, the average latency of requests increases rapidly, and thus the average latency of RR is up to 23.5× higher than dLoRA. Although Proactive Dispatch Only is able to dynamically load LoRA adapters and dispatch the requests to mitigate load imbalance (i.e., it outperforms RR by up to 6.5×), it is not able to migrate requests between replicas to handle increasingly variable requests, leading to unpredictable load imbalance. As a result, the average latency of Proactive Dispatch is up to 2.39× higher than dLoRA.

7.5 Scalability and Overhead

For a cluster-scale serving system, we conduct evaluations to analyze the scalability of dLoRA. Figure 12 shows the throughput of dLoRA under different numbers of adapters. We increase the number of adapters increases while keeping the arrival rate constant. As the number of adapters increase, dLoRA achieves stable throughput. However, vLLM (uniform allocation) faces scalability challenges because it has to main-

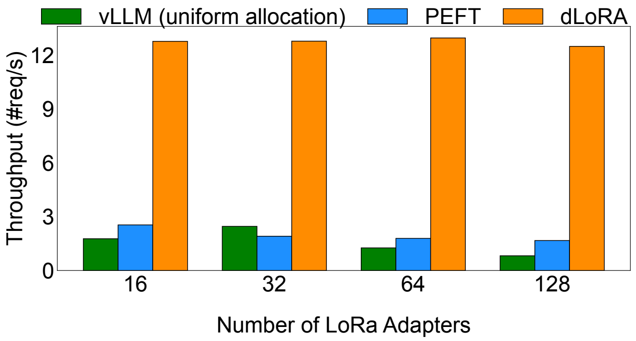


Figure 12: Scalability of dLoRA.

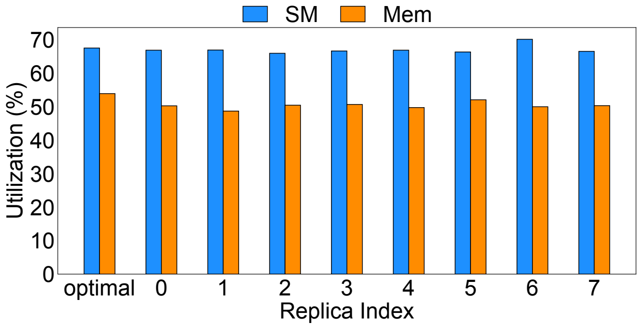

Figure 13: GPU utilization of dLoRA.

tain separate instances of full LLM weights for each LoRA LLM whcih incurs high memory footprint. PEFT struggles to scale efficiently as well because it cannot dynamically batch different types of requests. Moreover, the two baselines cannot manage the load imbalance between replicas. As a result, the throughput of vLLM (uniform allocation) and PEFT decreases by up to 3.0× and 1.5× respectively, as the number of adapters increases to 128.

We also evaluate the runtime overhead of dLoRA. Figure 15 breaks down the total latency of dLoRA's inference into three parts: the solving time of the ILP solver for the dynamic co-migration algorithm, the switching overhead of the dynamic batching algorithm, and the actual inference time. As shown in this figure, the overhead introcduced by dLoRA, i.e., ILP solving time and the switching overhead, are negligible compared to the actual inference time. The actual inference time consistently accounts for over 96.7% of the total latency, regardless of the arrival rate. The negligible runtime overhead of dLoRA mainly comes from the fact that dLoRA migrates requests or switches inference mode occasionally and the overhead is amortized by a number of iterations.

7.6 GPU Utilization

To show the GPU utilization, we measure the streaming multiprocessor (SM) utilization and GPU memory utilization of each replica in the cluster.The setup is the same as §7.4. dLoRA serves the Llama-2-13B model. The request rate is set to make the average latency of dLoRA approximately equal to the SLO requirement. We also measure the optimal SM utilization and GPU memory utilization when all requests belong to the same type, and vLLM always uses merged inference. As shown in Figure 13, although requests belong to different LoRA types, dLoRA achieves nearly the same SM utilization and GPU memory utilization compared to the optimal utilization, which indicates that dLoRA effectively utilizes the GPU resources and avoids resource waste as shown in Figure 2(a). Besides, the SM utilization and GPU memory utilization among replicas are balanced, which shows the effectiveness of the dynamic load balancing algorithm.

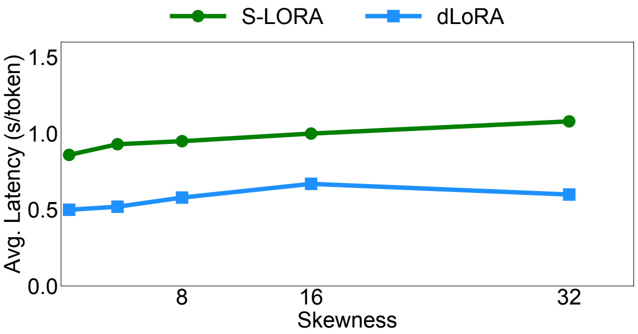

Figure 14: Comparison with SLoRA.

7.7 Comparison with Concurrent Work

S-LoRA [18] is a concurrent work for serving multiple LoRA LLMs. S-LORA also tries to batch requests destined for different LoRA adapters. However, S-LoRA does not consider the load imbalance between replicas and is not able to dynamically switch between merged and unmerged inference. The parallelism strategy proposed by S-LoRA is also orthogonal to dLoRA. Figure 14 compares dLoRA with S-LoRA using the same setting as §7.3. As shown in the figure, no matter how the skewness changes, dLoRA consistently outperforms S-LoRA by up to 1.8× in terms of average latency. The reason is that S-LoRA statically serves requests by unmerged-only inference, which ignores the opportunity of using merged inference to reduce the computation overhead. In contrast, dLoRA exploits this opportunity and is more effective in handling diverse requests with different LoRA types.

8 Related Work

LLM serving systems. Recently, many works have been proposed for LLM serving. Orca [11] proposes iteration-level scheduling to continuously batch requests with different lengths at the iteration level. vLLM [12] proposes a PagedAttention operator and a block-based KV cache management mechanism to reduce GPU memory fragmentation. FastServe [19], DeepSpeed-FastGen [36], and SARATHI [37] leverage the characteristics of LLM serving to schedule requests with different lengths. Nvidia FasterTransformer [38],

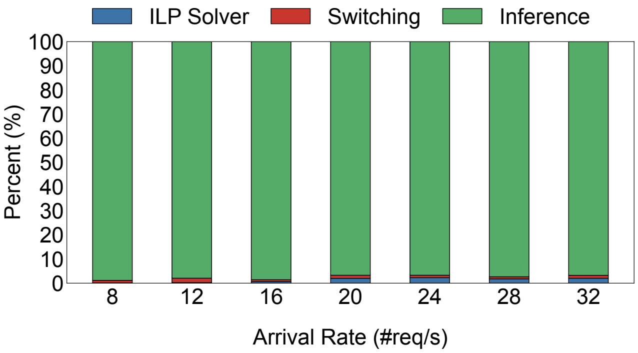

Figure 15: Overhead of dLoRA.

DeepSpeed Inference [39], and the Google serving system for PaLM [40] optimize the GPU/TPU implementation and parallelism specifically for LLM inference. FlexGen [41] uses offloading to improve the throughput of LLM serving. SpecInfer [42] uses speculative decoding to reduce the latency of LLM serving systems. SpotServe [43] tries to leverage spot instances to reduce the cost of LLM serving. These works focus on the optimization of a single LLM. In contrast, dLoRA is a serving system for multiple LoRA LLMs in a GPU cluster.

S-LoRA [18] and Punica [44] are concurrent works that also propose to serve multiple LoRA LLMs by batching requests destined for different adapters. S-LoRA proposes a new parallelism strategy, which is orthogonal to dLoRA. Punica uses an ad-hoc migration strategy to reduce the number of used GPUs, which is also different from dLoRA. dLoRA proposes dynamic load balancing algorithms to balance the load among GPUs, which is not considered in Punica and S-LoRA. They also overlook the opportunity of using merged inference to further reduce the latency of LLM serving by only adopting a merged-only inference strategy.

Traditional DNN serving systems. Many production-ready DNN serving systems have been developed, such as Tensorflow Serving [45] and Triton Inference Server [46], but they do not have LLM-specific optimizations. Some recent DNN serving systems, such as Clipper [47], ClockWork [48], SHEPHERD [13], Tabi [49], and Paella [50] serves multiple DNN models in cluster wide, but they mainly focus on small DNN models, such as ResNet and BERT. AlpaServe [14] leverages diverse parallelism strategies to accelerate serving multiple large DNN models in a GPU cluster, but it does not target autoregressive LLM serving and LoRA models. PetS [24] considers the scenario of serving multiple parameter-efficient DNN models in a GPU server, but it does not consider serving autoregressive LLMs in a GPU cluster and the unique system characteristics of LoRA adapters. DVABatch [51] uses multi-entry multi-exit batching to serve diverse models simultaneously, but it does not target either LLMs or LoRA.

Load balancing. Load balancing has been studied in many research fields, such as networking and cloud computing. Many load balancers, such as Ananta [52], Beamer [53] and Maglev [54], try to improve the performance of dispatching packets, but as discussed above, it is not sufficient to solve load imbalance in our scenario. Other kinds of load balancers, such as Pegasus [15], Scarlett [16] and E-Store [55], adopt selective replication or migration to balance the load. However, they are not suitable for our scenario, and the dependency between requests and adapters makes the load imbalance in our scenario even more complicated.

9 Conclusion

We present dLoRA, an inference serving system for LoRA models. dLoRA dynamically orchestrates requests and adapters for efficient LLM serving in each worker replica and across worker replicas. For each replica, dLoRA employs a dynamic batching technique to leverage both merged and unmerged inference to improve the efficiency of LLM serving. For the cluster, dLoRA employs a dynamic load balancing technique to migrate both requests and adapters to balance the load among worker replicas. Based on these techniques, we build a system prototype of dLoRA. Evaluation on production traces shows that dLoRA achieves up to 57.9× and 26.0× higher throughput than vLLM and HugginFace PEFT. dLoRA also achieves up to 1.8× lower average latency than the concurrent work S-LoRA.

A Appendix

A.1 Starvation Prevention of Algorithm 1

Algorithm 3 shows the pseudo-code of the credit-based dynamic batching algorithm to prevent starvation. Initially, we assign the same credit to each LoRA adapter, which guarantees the fairness in the beginning. Whenever a request is not served in the FCFS order, the credit of the corresponding LoRA adapter needs to be transferred to the requests that orignially should be served in the FCFS order (line 14 and line 21). In this, way, if a LoRA adapter is not served for a long time, it will accumulate enough credit and our algorithm always serves them first (lines 11–15). We also prevent the LoRA adapter to merge into the base LLM weights when it does not have sufficient credit (line 18). To mitigate the oscillation of starvation prevention between different LoRA adapters, we set a threshold T_{starve} to decide the starvation (lines 6–10). This parameter can be tuned to make a tradeoff between performance and fairness.

Algorithm 3 Credit-based Dynamic Batching

```
 1: function CREDITBATCHING($B_{fcfs}, R, S, L$)
 2:     Input: FCFS requests $B_{fcfs}$, Request $R = \{r_1, r_2, ..., r_n\}$
 3:            Replica state $S$, LoRA adapters $L = \{l_1, l_2, ..., l_m\}$
 4:     Output: The batch of requests to be executed $B_{next}$
 5:     // Stavation Prevention
 6:     for $l \in L$ do
 7:         if $l_i.state == S_{starve} \wedge l_i.credit < T_{normal}$ then
 8:             $l_i.state = S_{normal}$
 9:         else if $l_i.credit > T_{starve}$ then
10:             $l_i.state = S_{starve}$
11:     $L_{starve} = \{l_i \in L \mid l_i.state == S_{starve}\}$
12:     $B_{starve} = \{r_i \in R \mid r_i.type \in L_{starve}\}[: max\_bs]$
13:     if $|B_{starve}| > 0$ then
14:         $transfer\_credit(B_{starve}, B_{fcfs})$
15:         return $B_{next} = B_{starve}$
16:
17:     // Adaptive switching between different modes
18:     $L_{eligible} = \{l_i \mid l_i.creidt \geq credit(\{r_i \mid r_i.type == l_i\}, B_{fcfs})\}$
19:     $RET$ =DYNAMICBATCHING($B_{fcfs}, R, S, L_{eligible}$)
20:     if $RET\ != \ B_{fcfs}$ then
21:         $transfer\_credit(RET, B_{fcfs})$
22:     return $B_{next} = RET$
```

Parrot: Efficient Serving of LLM-based Applications with Semantic Variable

Chaofan Lin[1]*, Zhenhua Han[2], Chengruidong Zhang[2], Yuqing Yang[2]
Fan Yang[2], Chen Chen[1]*, Lili Qiu[2]
[1]*Shanghai Jiao Tong University,* [2]*Microsoft Research*

Abstract

The rise of large language models (LLMs) has enabled LLM-based applications (a.k.a. AI agents or co-pilots), a new software paradigm that combines the strength of LLM and conventional software. Diverse LLM applications from different tenants could design complex workflows using multiple LLM requests to accomplish one task. However, they have to use the over-simplified request-level API provided by today's public LLM services, losing essential application-level information. Public LLM services have to blindly optimize individual LLM requests, leading to sub-optimal end-to-end performance of LLM applications.

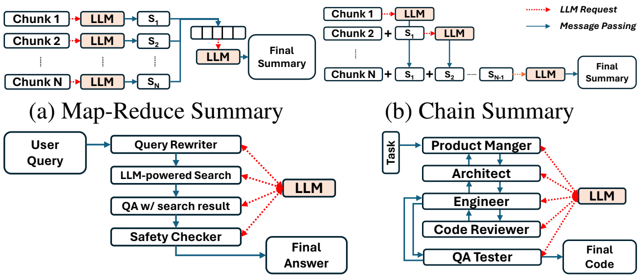
This paper introduces Parrot, an LLM service system that focuses on the end-to-end experience of LLM-based applications. Parrot proposes *Semantic Variable*, a unified abstraction to expose application-level knowledge to public LLM services. A Semantic Variable annotates an input/output variable in the prompt of a request, and creates the data pipeline when connecting multiple LLM requests, providing a natural way to program LLM applications. Exposing Semantic Variables to the public LLM service allows it to perform conventional data flow analysis to uncover the correlation across multiple LLM requests. This correlation opens a brand-new optimization space for the end-to-end performance of LLM-based applications. Extensive evaluations demonstrate that Parrot can achieve up to an order-of-magnitude improvement for popular and practical use cases of LLM applications.

1 Introduction

Large language models (LLMs) have demonstrated a remarkable language understanding capability [7, 41]. This enables a paradigm shift in application development. In this new paradigm, one or multiple application entities, known as AI agents or co-pilots, communicate with LLMs via natural language, known as "prompts", to accomplish a task collaboratively. For example, Meeting applications like Microsoft Teams or Google Meet can summarize meeting discussions through LLMs [33]. Search engines like Google and Bing can be enhanced with Chat ability through LLMs [14, 34]. It is believed such LLM-based applications will become the mainstream applications in the near future [13].

To accomplish a task, LLM-based applications typically require multiple rounds of conversation. The conversation, implemented through multiple API calls to LLM, demonstrates complex workflow patterns. Figure 1 illustrates several popular conversation patterns. For example, a meeting summary application [8, 33] often divides a lengthy document into multiple shorter sections, each satisfying the length constraint of the LLM conversation and thus can be summarized and combined into the final summary through the Map-Reduce or chaining summary patterns. Chat-based applications, e.g., Bing Copilot [34], call LLM APIs multiple times to generate answers based on user queries. Multiple agents, each representing a different role played by different LLM calls, can collaborate to achieve a task [22, 47, 54].

Public LLM service providers have to face diverse tenants and applications, each with different workflows and performance preference. However, existing API design for LLM service provision is still request-centric. Public LLM services only observe tons of individual requests, without knowing any



(a) Map-Reduce Summary (b) Chain Summary

(c) LLM-Powered Search (d) Multi-agent Coding

Figure 1: The workflow of popular LLM-based applications. The final result requires multiple LLM requests.

*This work is partially done while Chaofan Lin's internship and Dr. Chen Chen's visting scholar in Microsoft Research.

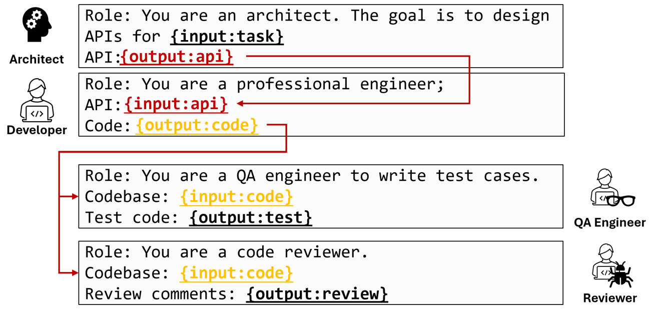
application-level information, e.g., which requests belong to the same application, how different requests are connected, or whether there are any similarities. The lost application-level information makes public LLM service blindly optimize the performance of individual requests, leading to sub-optimal *end-to-end* performance of LLM applications. In this paper, we observe there exist significant opportunities to improve the *end-to-end* experience of LLM applications by exploiting the application-level information, especially the *correlation* of multiple LLM requests.

First, multiple consecutive LLM requests may be dependent: the result of one request could be the direct input of the next request. Therefore, it is desirable to colocate those requests together and execute them consecutively on the LLM service side. However, unaware of their dependencies, these requests have to be executed interactively between the client side of LLM-based applications and the public LLM services. These clients, often located on the other end of the Internet, can only issue the second request after they receive the result of the first request. This unnecessarily incurs *extra overhead of consecutive requests* on network latency as well as losing the opportunity of co-scheduling these consecutive requests (§3).

Second, LLM requests may have *diverse scheduling preference*, even within a single application. For example, in Figure 1a, to reduce the end-to-end latency, the requests representing multiple Map tasks should be batched more aggressively to increase the throughput of the Map tasks; while the Reduce task, due to its scarcity, should be optimized for latency. Unfortunately, public LLM services cannot discriminate the difference between the two types of tasks. As a result, the current practice is to blindly optimize the latency for individual requests, which might not be desirable for the end-to-end experience.

Third, there exists a high degree of *commonality* across LLM requests. Popular LLM applications (e.g., Bing Copilot [32], GPTs [42]) use a long system prompt, including task definitions, examples, and safety rules, to guide the behavior of LLM applications. The long system prompt is usually static and common for all users. As existing public LLM services treat each request individually, these common prefix prompts are provided repeatedly in each request, leading to a great waste of storage, computation, and memory bandwidth. Our analysis of a production LLM-based search engine shows that over 94% of tokens in the requests are repeated across different users.

Although we have seen some emerging engine-level techniques [25,56,63] proposed to optimize the above three cases, they all work based on certain application-level knowledge, which is lost in nowadays public LLM services. In a nutshell, due to the lack of understanding of the correlations of LLM requests, existing LLM services cannot leverage the three opportunities, leading to high end-to-end service latency and reduced throughput. Based on the above facts and insights, we introduce Parrot, an LLM service system that treats LLM applications as first-class citizens. Parrot retains most of application-level information by a simple abstraction Semantic Variable, achieving a perfect balance between increasing system complexity and bringing new information for optimization. A Semantic Variable is a text region in the prompt with a specific semantic purpose, such as a task instruction, a list of few-shot examples, an input, or an output. A Semantic Variable can also work as the data pipeline that connects multiple LLM requests. Semantic Variable naturally exposes the information of prompt structures and correlations of requests to LLM services. By inspecting Semantic Variable at runtime, Parrot can perform conventional data flow analysis to derive the data dependency between LLM requests just-in-time.



```

Figure 2: The communication of consecutive LLM requests in multi-agent applications.

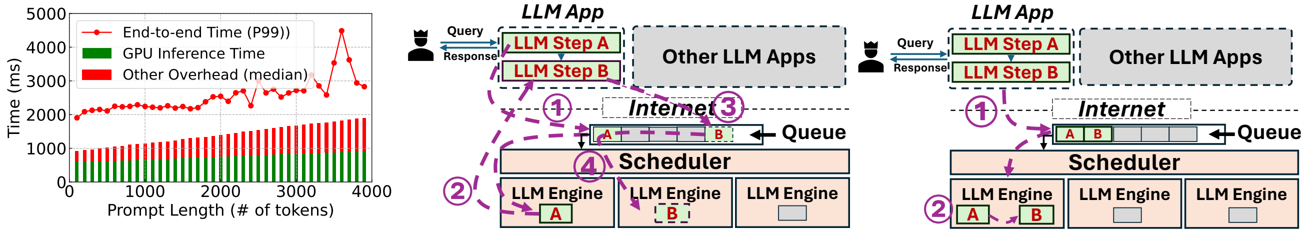
By analyzing the application-level information, Parrot's unified abstraction naturally enables joint optimizations, which bring better global optimality. The same data pipeline built by Semantic Variables can enable multiple optimizations simultaneously, including hiding data pipeline's latency, objective deduction for a better scheduling and commonality analysis to perform de-duplication. Parrot's scheduling also takes different opportunities into accounts under the unified abstraction. Our extensive evaluation of Parrot on popular LLM-based applications, including the production and open-source projects, shows Parrot achieves up to 11.7× speedup or 12× higher throughput compared with the state-of-the-art solutions. Parrot is open-sourced at `https://github.com/microsoft/ParrotServe`, including the code for artifact evaluations to reproduce our experiment results.

2 Background

LLM Service. Most LLM services are provisioned as a conditional generation service via a text completion API.

$$Completion(\text{prompt}:\text{str}) \rightarrow \text{generated\_text}:\text{str}.$$

The application client provides a text prompt, and the LLM service responds with the generated text. Behind the API, an LLM service provider runs one or multiple clusters of LLM inference engines. A request scheduler dispatches LLM



(a) Latency Breakdown

(b) Current LLM Services

(c) Our system: Parrot

Figure 3: The end-to-end latency breakdown of current LLM services. The source of the overhead comes from network and queuing due to chatty interaction between LLM application and LLM services, which is eliminated in our system Parrot.

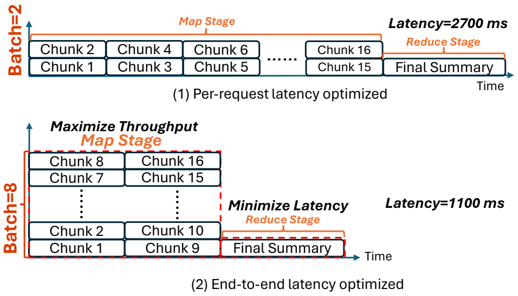
requests from a queue to an LLM inference engine, which uses a set of GPUs to conduct the LLM inference.

LLM-based Applications. Figure 1 highlights the representative workflows of how LLM is used in the applications. Due to the limited context window of LLMs (e.g., 4,096 for GPT-3.5-Turbo [40]), data analytics on long documents follow a *map-reduce style* (Figure 1a) or *chain style* (Figure 1b) workflow to generate the final results. It splits the long transcript into chunks, uses multiple requests to generate partial results for each chunk (the Map task), and combines them altogether (a Reduce task) or incrementally (the chain style) to generate the final result. Chat-based search engine in Figure 1c may use consecutive LLM requests to discern query intention, enrich the query with supplementary information, retrieve related data, undergo a safety check, and finally generate the response. Multi-agent in Figure 1d and Figure 2 is another type of workflow using multiple LLM requests, each with a designated role. Different roles work collaboratively on the same task, e.g., AutoGen [54] and MetaGPT [22] use the roles like product manager, architect, engineer, and QA tester. They communicate with each other on a software project. Each role is supported by one or multiple LLM requests to act as the designed role to generate their responses.

3 Problems of Serving LLM Applications

Although LLM's text completion API provides a flexible way of building LLM applications, it loses the application-level information to public LLM services, leading to the following challenges.

Excessive Overhead of Consecutive Requests. As demonstrated in Figure 1, LLM applications frequently make multiple LLM calls to complete a single task. Due to the request-centric design of existing public LLM services, which generate responses for each request individually, developers have to parse the output of an LLM request and compose the prompts for subsequent LLM requests on the client side. Figure 3a shows our empirical study of the latency breakdown of the LLM calls from a popular LLM application in our production, which uses a chain-style workflow. The prompt lengths range from 150 to 4000 tokens and the output length is around 50 tokens. We find there is a significant portion of the latency of LLM API call originates outside the LLM engine (30 ∼ 50% on average and over 70% in the worst cases). The overhead increases with the growing length of prompts. The high latency can sometimes result in API timeouts and resubmissions.



(1) Per-request latency optimized

(2) End-to-end latency optimized

Figure 4: Request-centric scheduling v.s. application-centric scheduling for the map-reduce style document summary task.

Such overhead is due to the chatty interaction between LLM services and clients. Figure 3b illustrates the overhead of a simple two-step LLM application (e.g., *chain-style* summary of two text chunks). Existing LLM services are unaware of the dependency among such requests, where the output of the previous request may be the direct input of the next one. For such consecutive and dependent requests, the client has to wait for the arrival of the response to the first LLM request (②) before submitting the next LLM request (③). This unnecessarily incurs heavy network latency because clients and LLM services are typically in different data centers. Moreover, the next LLM request has to suffer extra queuing delays (④), because requests from other applications may arrive between the consecutive LLM requests.

LLM-based App.	# Calls	Tokens	Repeated (%)*
Long Doc. Analytics	$2 \sim 40$	$3.5k \sim 80k$	3%
Chat Search	$2 \sim 10$	$5k$	94%
MetaGPT [22]	14	$17k$	72%
AutoGen [54]	17	$57k$	99%

*We count a paragraph as repeated if it appears in at least two LLM requests.

Figure 5: The prompt structure of search copilot shows a long prompt reused by different user queries.

In Table 1, we evaluated four popular LLM applications. The first two are from our production, and the last two are popular open-source projects. They all require tens of LLM calls to complete a single task, which results in high user-perceived latency. Our evaluation in §8.2 shows LLM services that treat requests individually could slow down the end-to-end latency by over 2×. An LLM service can eliminate the overhead if it can handle consecutive requests in a batch. Parrot adopts such an approach. As shown in Figure 3c, the two steps of the same application are scheduled together, thus allowing the output of Step A to be fed directly into Step B—with the network and queuing overhead bypassed.

Misaligned Scheduling Objectives. Due to the lost application information (workflow and application performance objective), existing public LLM services have to blindly use a universal treatment for all requests, e.g., optimizing per-request latency [44]. However, LLM-based applications are more concerned about the end-to-end experience, rather than individual requests. This misaligned optimization objectives may negatively impact end-to-end performance. Considering the map-reduce document summary in Figure 1a, the system should minimize the end-to-end time it takes to receive the final summary, rather than the latency of individual requests. The LLM services optimized for individual requests are not optimal for end-to-end latency.

As depicted in Figure 4, current LLM services must limit the number of concurrent requests running on each LLM engine to control the latency of individual requests. However, there is a trade-off between latency and throughput in LLM inference. Increasing the batch size can bring up to 8.2× higher throughput but lead to 95% higher latency [9]. Yet, if we understand the application-level performance objective, which in this case is the end-to-end latency, we can determine that the ideal scheduling strategy should maximize the throughput (using higher batch sizes) during the map stage and minimize request latency during the reduce stage. This strategy reduces end-to-end latency by 2.4×. Moreover, it uncovers the potential to enhance cluster throughput without compromising the end-to-end latency of LLM applications. This insight is essential for addressing the conflict between rising demand and limited hardware resources. It underscores the necessity of scheduling LLM requests from the perspective of LLM applications, but it also presents the challenge of managing diverse LLM requests with varying performance objectives.

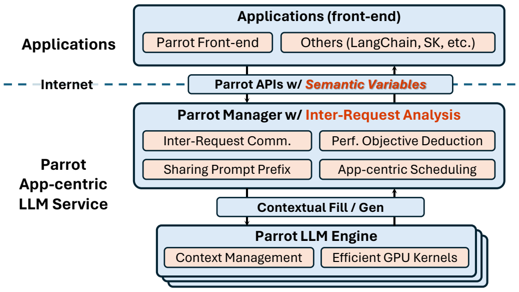

Figure 6: Parrot system overview.

Redundant Computations. Currently, most LLM-based applications exhibit a high degree of redundancy in the prompts of their requests. For instance, Bing Chat [32] has handled more than 1 billion chat prompts. These prompts share the same system prompts that defines the functionality of Bing Chat. OpenAI introduces GPTs [42] to let users customize a ChatGPT for a specific purpose whose prompt template is the same across users. The commonality in prompts is crucial as it delineates the functionality and restrictions of LLM-based applications. The prompt structure in Figure 5 [52] includes a role definition, several examples to enhance the precision of LLM's behaviors and user query details. While the user input is dynamic, the task role is always fixed, and the few-shot examples could be quasi-static in that the same type of tasks use the same examples. This is why more than 94% of prefix tokens could be repetitively used across LLM requests for various users (Table 1). Such commonality also exists in multi-agent applications. For example, MetaGPT [22] and AutoGen [54] recurrently incorporate conversation history into the prompt over several rounds of LLM requests, leading to 72% and 99% redundancy respectively. These redundant sections excessively utilize GPU memory bandwidth and are computed for multiple times. Earlier results have proposed optimizations in LLM engines to avoid redundant GPU memory of shared prompt [25]. However, it is hard for public LLM services to swiftly detect and co-locate the prompt-sharing requests, which be dynamically generated, from tons of diverse requests from diverse applications. Without knowledge about the prompt structure, extensive token-by-token matching for every LLM request is expensive at the cluster level. Hence, if the cluster scheduler of public LLM service cannot dispatch prompt-sharing requests to the same engine, the engine-level redundancy avoidance optimizations would be hard to take effect.

4 Parrot Design

Figure 6 depicts the overview of Parrot's design. Parrot provides a natural way of programming LLM applications with Semantic Variable annotations (§4.1), which is compatible of existing LLM orchestration frameworks, e.g., LangChain [8]. Centering on this abstraction, Parrot Manager is designed

```
import Parrot as P
from Parrot.PerformanceCriteria import LATENCY

@P.SemanticFunction
def WritePythonCode(task: P.SemanticVariable):
""" You are an expert software engineer.
    Write python code of {{input:task}}.
    Code: {{output:code}}
"""

@P.SemanticFunction
def WriteTestCode(
    task: P.SemanticVariable,
    code: P.SemanticVariable):
""" You are an experienced QA engineer.
    You write test code for {{input:task}}.
    Code: {{input:code}}.
    Your test code: {{output:test}}
"""

def WriteSnakeGame():
  task = P.SemanticVariable("a snake game")
  code = WritePythonCode(task)
  test = WriteTestCode(task, code)
  return code.get(perf=LATENCY), test.get(perf=LATENCY)
```

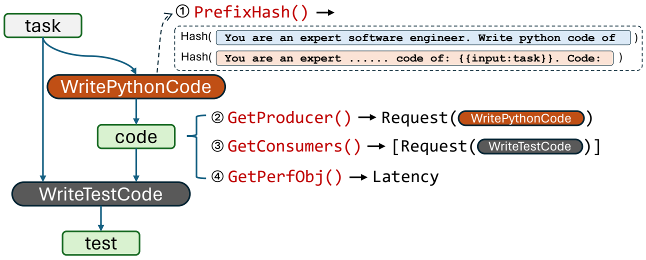
Figure 7: Example: a multi-agent application in Parrot.

to schedule LLM requests at a cluster-level, by deriving the application-level knowledge (§4.2) and optimizing end-to-end performance of application (§5). The manager will schedule the LLM requests to LLM `Engine`, which is formed by a GPU server (or a group of servers) in the cluster that can serve LLM requests independently.

4.1 Semantic Variable

Parrot treats an LLM request as a semantic function[1] implemented using natural language and executed by LLMs. A Semantic Variable is defined as a input or output variable of a semantic function, which is referred as a placeholder in the prompt. Figure 7 shows a simplified example of multi-agent application like MetaGPT [22]. It contains two `SemanticFunctions`, one for the software engineer to write code and one for the QA engineer to write test code. It has three Semantic Variables: `task`, `code`, and `test`, for task description, the code to be developed by the software engineer, and the test code to be developed by the QA engineer, respectively. Although existing LLM orchestration frameworks (e.g., LangChain [8]) also allow placeholders in a prompt, however, the placeholders are rendered with real data before the submission, hence public LLM services cannot detect such a structure. Instead, Parrot relies on Semantic Variables to preserve the prompt structure for further inter-request analysis in public LLM services side.

In addition to the semantic functions, LLM application developers can further define orchestration functions that connect multiple semantic functions (e.g., `WriteSnakeGame` in Figure 7). The Semantic Variables connecting multiple semantic functions form the data pipeline of multiple LLM requests in the public LLM service. A simple data flow analysis of the semantic functions can be done to reveals the connections of multiple LLM requests. E.g., in Figure 7, the `code` variable connects the two LLM requests originating from `WritePythonCode` and `WriteTestCode`, showing their sequential dependency. Different from traditional completion API, Parrot splits a completion request to `submit` operation and `get` operation (§7). A function calling of `SemanticFunction` will trigger the `submit` API to submit a LLM request with its prompt and input Semantic Variables. The execution of a `SemanticFunction` is asynchronous thus it returns the futures of the output Semantic Variables. Through the `get` API, applications can fetch the value of an output Semantic Variable from the public LLM service in an on-demand manner. This asynchronous design allows Parrot-powered LLM service to receive all LLM requests not blocked by native functions and analyze their relationships just-in-time.



task
① PrefixHash() →
Hash(You are an expert software engineer. Write python code of)
Hash(You are an expert ...... code of: {{input:task}}. Code:)
WritePythonCode
code
② GetProducer() → Request(WritePythonCode)
③ GetConsumers() → [Request(WriteTestCode)]
④ GetPerfObj() → Latency
WriteTestCode
test

Figure 8: Primitives (selected) for Inter-Request Analysis.

The `get` operation supports annotation of performance criteria, showing the end-to-end performance requirement of an application, which can be end-to-end latency or throughput (extensible to more criteria like per-token latency when streaming, and time-to-first-token). For example, the final outputs, `code` and `test` in Figure 7, are fetched using `get` with an objective of end-to-end latency. Criteria of middle variables will be automatically deduced and propagated from final outputs (§5.2). After propagation, each variable is attached to a criterion, which finally works by serving as a hint to Parrot's scheduler (§5.4).

4.2 Primitives of Inter-Request Analysis

In general, Parrot perform inter-request analysis mainly by two types of application-level information deduced from Semantic Variable: DAG of requests and prompt structure. Figure 8 illustrates the DAG workflow of the example shown in Figure 7 and the primitives used for inter-request analysis and optimizations.

DAG-based analysis. As requests, or `SemanticFunctions`, are submitted beforehand, Parrot can receive them all at once and analyze their correlations just-in-time on the service side. Parrot maintains a DAG-like data structure in each user's

[1] The term *semantic function* is borrowed from Semantic Kernel [36].

registered session. Each node is either a request or a Semantic Variable that connects different requests. When a request comes, Parrot inserts it to DAG by linking edges with Semantic Variables it refers through placeholders in the prompts. Parrot can perform conventional dataflow analysis [1, 38] using the primitives to get the producer and consumers of Semantic Variables (i.e., `GetProducer` and `GetConsumers`) to recover dependency of LLM requests. Using the request DAG and the annotated performance criteria (via `GetPerfObj`) of final output Semantic Variables, Parrot can deduct the request-level scheduling preference by analyzing the DAG and the performance objective of final outputs (§5.2).

Prompt structure-based analysis. Based on the prompt structure declared by Semantic Variables, Parrot supports extracting the hash values of an LLM request at multiple positions split by Semantic Variables (i.e., `PrefixHash`). For example, the prompt of `WritePythonCode` has two potential sharing prefix: the text before `{{input:task}}` and the text before `{{output:code}}`, thus there will be two prefix hash values generated. The prefix hashes of LLM requests will be used by swift detection of commonality across multiple requests, supporting both static and dynamically generated contents, as well as within the same type of application or even across applications (§5.3).

5 Optimizations with Semantic Variable

5.1 Serving Dependent Requests

To avoid the unnecessary client-side execution, it requires the dependency of requests at the application level, which is lost in today's public LLM services. With the DAG and primitives illustrated in §4.2, Parrot serves dependent requests efficiently through a graph-based executor. The executor polls constantly and sends it to corresponding engine once ready (i.e. producer requests are all finished), which allows instant execution and maximizes batching opportunities. For consecutive execution of dependent requests, materialized value is transmitted through a message queue allocated for corresponding Semantic Variable, avoiding unnecessary chatty communication between clients and LLM services.

The value of a Semantic Variable in a request may require transformation before being exchanged, e.g., the value of a Semantic Variable is extracted from the JSON-formatted output of an LLM request, which is then fed into consecutive LLM requests. Similar to existing message queue systems that support message transformation (e.g., Kafka [5]), Parrot also supports string transformation to manipulate Semantic Variables during value exchanging among LLM requests. Parrot supports most output parsing methods of LangChain [8], which covers most use cases of LLM applications.

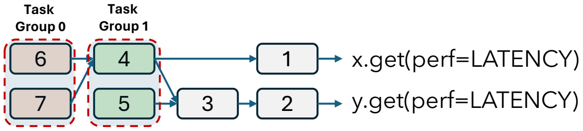


Figure 9: Performance deduction for an LLM-based application generating two latency-sensitive Semantic Variable.

5.2 Performance Objective Deduction

To optimize the end-to-end performance of applications, we need to know the application-level performance criteria. To help deriving the request-level scheduling preference from the end-to-end application's performance requirement, we need to understand the workflow of the LLM application, which is the DAG of LLM requests derived by Parrot's primitives.

When an application annotates a Semantic Variable to prefer higher throughput, all requests generating this Semantic Variable (both directly or indirectly) will be marked as throughput-preferred when scheduling. This scheduling preference is usually beneficial for offline data processing, such as bulk document analysis.

Handling latency-sensitive applications is more intricate. As demonstrated in Figure 4, achieving low end-to-end latency may sometimes require prioritizing throughput at the Mapping stage. The latency of individual requests can sacrificed so as to reduce the completion time of the entire DAG of requests. Parrot analyzes LLM requests in reverse topological order, beginning with those linked to latency-critical Semantic Variable, as depicted in Figure 9. With the extracted DAG, LLM requests that directly result in latency-critical Semantic Variables are labeled as latency-sensitive (Request 1 and 2), as are their immediate predecessors (Request 3). Parallel LLM requests at the same stage are grouped into a *task group* (Task Groups 0 and 1). The scheduler should minimize the latency of the entire task group, often leading to a higher batch capacity for higher throughput of token generation.

5.3 Sharing Prompt Prefix

When an LLM request is scheduled to an LLM engine, a context on the engine is created to store the state of the model execution for this request (mainly KV cache). Existing works have proposed to share the KV cache of common prefix of prompts in LLM engines to save the GPU memory. However, as we have explained in §3, today's public LLM service face diverse applications and requests, which is hard to identify the commonality at the cluster level. Token-by-token comparison is impractical due to high time complexity, especially for very long context with massive requests. In Parrot, by exposing Semantic Variables to LLM service, we can understand the prompt structure to automatically detect the commonality more efficiently at the granularity of Semantic Variables. Using Parrot's primitive of `PrefixHash`, Parrot only needs to check the hash value at positions after each Semantic Variable in a request's prompt. Parrot maintains a key-value store, where each entry maps a (hashed) prefix of tokens to a list of requests, thus the scheduler can quickly check the opportunity in an online manner, supporting both static and dynamically-generated prompt within one application or even across different applications.

Furthermore, we propose better GPU kernel for the attention computation of the requests with a common prefix. We first leverage vLLM's paged memory management [25] to save the redundent GPU memory. But vLLM's kernel still suffers from redundant computation and memory loading of the shared tokens. Therefore, we design a new Attention decoding algorithm by combining FlashAttenation [12] and PagedAttention [25] that treat the shared and non-shared token separately. This significantly accelerates the attention of shared contexts (implementation details in §7).

5.4 Application-Centric Scheduling

Parrot's scheduling is a problem that matches LLM requests to LLM engines, i.e. the cluster-level scheduling, while the engine-level scheduling will be covered in the implementation details of the engine in §7. To fix the problem of existing public LLM service that blindly optimize diverse individual requests, Parrot's scheduling policy leverages the application-level knowledge to optimize the end-to-end performance. Specifically, the primary goal of Parrot's scheduler is to meet the varied performance goals of LLM applications while optimizing GPU cluster utilization. As explained in §3, a conflict arises when combining throughput and latency oriented requests: large batch sizes increase throughput and GPU efficiency but degrade latency, and vice versa. Transformer-based LLM inference is largely memory-bound, with latency influenced by the count of concurrent tokens within the engine. To meet performance targets of LLM applications, particularly latency, an LLM engine must regulate the token count below a specified threshold, which is determined by the LLM request with the most strict latency constraint. Therefore, Parrot's scheduling principles are twofold: (1) group LLM requests with similar performance requirements to circumvent the conflict, and (2) maximize opportunities for sharing across requests.

Algorithm 1 outlines the scheduling process of Parrot. With the extracted DAG, the system arranges the LLM requests according to their topological order (line 1). Parrot tends to schedule requests belonging to the same application together to avoid the slowing down of interleaved scheduling (§8.2). For requests identified as part of a task group through Parrot's performance objective deduction, the scheduler attempts to allocate the entire task group together (line 4-line 5). Additionally, if Parrot detects other queued requests or running contexts with a common prefix, it tries to assign them to the same LLM engine (line 3, line 6-line 9), to utilize Parrot's context fork to reduce the redundant computation and GPU memory transactions. For an LLM request without the above opportunity, Parrot schedules the request independently (line 10-line 11). Due to limited space, we omit the details of how Parrot chooses LLM engines (i.e., `FindEngine`). Briefly, Parrot finds the engine that satisfies the scheduling preference of a request while minimizing the negative impacts. For instance, if a latency-sensitive request is scheduled to an LLM engine that can run up to 64,000 tokens of throughput-driven requests, its capacity will be significantly reduced to 2,000 to satisfy its strict latency requirement. But, if it is scheduled to an engine that has already been running a latency-sensitive request, the capacity reduction is negligible.

Algorithm 1: Parrot's Request Scheduling.

```
   Data: Q: the request queue
1  Q.sort() ; /* Topological order                */
2  for $r \in Q$ do
3      SharedReqsInQueue, CtxInEngine =
         FindSharedPrefix($r$);
4      if $r.TaskGroup \neq \varnothing$ then
5          $r^*$ = FindEngine(r.TaskGroup);
6      else if $SharedReqsInQueue \neq \varnothing$ then
7          $r^*$ = FindEngine(SharedReqsInQueue);
8      else if $CtxInEngine \neq \varnothing$ then
9          $r^*$ = FindEngine(r, filter=CtxInEngine);
10     if $r^* = \varnothing$ then
11         $r^*$ = FindEngine($r$);
12     Q.remove($r^*$);
```

6 Discussion

Dynamic Applications and Function Calling. Currently, Parrot only supports cloud-side orchestration of LLM requests without involving dynamic control flow and native functions (e.g., Python Code). They still require client-side execution. We intentionally disable the offloading of these functions to public LLM services to minimize the security risks of malicious injection. For private LLM services whose LLM applications are trusted or there is a trusted zone to execute these functions, Parrot's APIs can be easily extended with conditional connections and native code submission. Moreover, these extensions further enable new optimizations, e.g., we can speculatively pre-launch high-probability branches in dynamic applications based on past profiles. This also proves the potential of Parrot's design when facing new types of applications. We leave these extensions as future works.

Other Applications of Inter-Request Analysis. The inter-request analysis in Parrot enables a new optimization space not limited to the ones we introduced in §5. A large-scale service has more scheduling features to consider, including handling outliers [3], job failures [58], delay scheduling [57], fairness [15, 61], starvation [17], or supporting heterogeneous clusters [24, 37], which have been widely studied in other systems. Parrot provides a new view from the perspective of LLM-based applications: we need to understand the interconnection and commonality of LLM requests to optimize applications' end-to-end performance. These features can be revisited in the LLM service system by considering the new characteristics of LLM applications. In this paper, we focus on Parrot's mechanisms and a few use cases, leaving other optimizations as promising future works.

Parrot with LLM Orchestration Frameworks. There have been several frameworks for developers to build LLM-based applications, e.g., LangChain [8], SemanticKernel [36], and PromptFlow [35]. The key function of these frameworks is to "glue" different LLM calls to accomplish a complex task (aka. LLM orchestration). Parrot can be integrated with these frameworks by extending their calling of LLM service APIs with Semantic Variables. Most of these frameworks have already used a template-based approach in which developers can design a template with placeholders, and render the placeholders at runtime. These placeholders naturally have the same concept as Parrot's Semantic Variable. However, because these frameworks will render the template prompt before the submission, LLM services lose the information on the prompt structure. To make these frameworks compatible with Parrot, both the template itself and the variables to render the template (using Semantic Variable in Parrot) need to be wrapped as a `SemanticFunction` so the necessary information is exposed to Parrot's LLM service.

7 Implementation

Parrot is an end-to-end LLM service for LLM applications, implemented on Python with about 14,000 lines of code. Its front-end provides the abstraction of Semantic Variable, and `SemanticFunction`, which is transformed into Parrot's APIs (implemented with FastAPI [48]) to be submitted as LLM requests. A centralized Parrot manager handles the management of LLM requests, including Semantic Variables, communication, and scheduling. We also build an LLM engine based on efficient kernels from vLLM [25], xFormers [26], and ourselves. The engine supports advanced features for LLM serving, including paged memory management [25] and continues batching [56]. Parrot's front-end and manager are implemented in 1,600 and 3,200 lines of Python, respectively. Parrot's LLM engine is implemented in 5,400 lines of Python and 1,600 lines of CUDA. We have implemented OPT [60] and LLaMA [51] with PyTorch [45] and Transformers [53].

APIs. Applications programmed by `SemanticFunctions` or other frontends are finally lowered to requests to universal APIs through different adapters. Parrot provides OpenAI-like APIs with the extension of Semantic Variables. The request body of two operations mentioned in §4.1 is shown as follows:

```
(submit) {"prompt": str, "placeholders": [{"name":
↪  str, "in_out": bool, "semantic_var_id": str,
↪  "transforms": str}, ...], "session_id": str}

(get) {"semantic_var_id": str, "criteria": str,
↪  "session_id": str}
```

In addition to the static string prompt, Parrot preserves the input and output placeholders. A placeholder is associated with a semantic variable either for rendering the input or parsing the output. As introduced in §5.1. Parrot supports transformations before the input or after the output. Parrot also supports other APIs for setting and fetching the value of Semantic Variables. The error message will be returned when fetching an Semantic Variable, whose intermediate steps fail (including engine, communication, and string transformation).

Kernel Optimization. vLLM's GPU kernel, while capable of reusing results cached in GPU memory for shared prefix tokens in a prompt, sometimes excessively reloads these tokens from global to shared memory, impeding attention score computations. Using OpenAI Triton [43] and CUDA, we have developed a novel GPU kernel, integrating concepts from PagedAttention [25] and FlashAttention [11, 12], to accelerate attention decoding computation involving shared prefixes. This kernel retains PagedAttention's approach of storing the key-value (KV) cache in disparate memory segments and utilizes a page table per request to monitor block status and placement. Furthermore, employing FlashAttention principles, the kernel maximizes data reuse within shared memory. Unlike reloading tiles repeatedly in the PagedAttention's implementation, it loads KV cache tiles for the shared prefix to shared memory only once, diminishing memory transactions between the L2 Cache and Shared Memory. The kernel initially calculates interim attention metrics (including attention scores, `qk_max`, `exp_sum`) for the shared prefix using the loaded tiles and records these back to HBM. Subsequently, it processes the new tokens' partial attention beyond the prefix, amalgamating this with the prefix's interim results to derive the ultimate attention output.

Universal Engine Abstraction. Parrot's cluster manager controls multiple engines running various models, tokenizers, KV cache layouts, etc. To enable Parrot's optimizations, LLM engines need to support (1) stateful generation (e.g., guidance [18]) and (2) sharing KV cache states across different requests. Hence we propose a universal abstraction to describe the minimal capability required to LLM engines to be integrated into Parrot.

```
def Fill(token_ids: List[int], context_id: int,
 ↪  parent_context_id: int)
def Generate(sampling_configs: Dict, context_id:
 ↪  int, parent_context_id: int)
def FreeContext(context_id: int)
```

These three methods not only cover the basic completion functionality of LLM inference engine, but also provide a flexible context management interface. The `Fill` method processes the initial prompt tokens, calculates and fills the KV cache into corresponding context. The `Generate` method produces tokens via generative decoding that produces one token per iteration until it reaches the length limit, user-defined termination character or EOS (end-of-sequence) token, under certain sampling configurations (e.g. temperature). `Fills` and `Generates` are scheduled and batched by engine's scheduler per iteration using continuous batching [56]. Creating and forking contexts can also be realized with these two methods by setting `context_id` and `parent_context_id`, respectively. The `FreeContext` method explicitly frees a context (i.e. free its KV cache in GPU memory). Separating `Fill` and `Generate` not only fits Semantic Variable naturally: constant text and input values are processed by `Fill`; the output values are generated by `Generate`, but also breaks the request-level dependency into a finer granularity, enabling more parallel execution opportunities [2, 21, 46, 64].

8 Evaluation

8.1 Experimental Setup

Testbed. We evaluate Parrot with two separate setups for single-GPU and multi-GPU experiments. The single-GPU evaluations use a server with a 24-core AMD-EPYC-7V13 CPUs equipped with one NVIDIA A100 (80GB) GPU. The multi-GPU evaluations use a server with 64-core EPYC AMD CPU and four NVIDIA A6000 (48GB) GPUs. Both servers run CUDA 12.1 and cuDNN 8.9.2.

Workloads. Our evaluations are performed to run four representative LLM applications. Each LLM engine uses one GPU and runs a LLaMA 13B or LLaMA 7B model [51] . For LLM-based data analytics on long documents, we use the Arxiv dataset [27], executing chain and map-reduce summarizations on an extensive collection of academic papers. To investigate the sharing opportunities of LLM-based applications with many users, we run the prompts from Bing Copilot and GPTs [42] with synthesized user queries. For multi-agent applications, we build a multi-agent programming application using MetaGPT [22], which contains a system architect to design APIs, multiple programmers to write code for different files, reviewers to share review comments. The programmers will also revise the code based on comments. For chat service workloads, we derived scenarios from the ShareGPT dataset [50], which mirrors real LLM chat conversations. According to the distribution of our measurement, we introduced a random delay of 200 $\sim$ 300 ms to LLM requests to emulate typical network overhead seen over the Internet. To create realistic workloads, we documented the LLM responses using GPT-4 [41], ensuring the LLaMA models generated text of similar length for system performance analysis. Table 2 presents the workloads and their optimizations in Parrot.

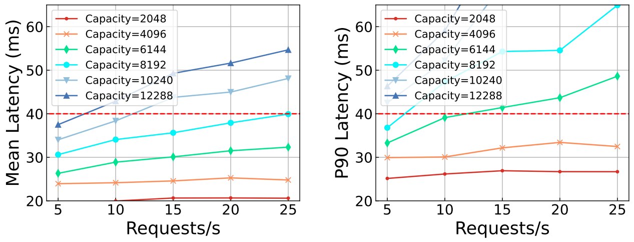
Table 2: The workloads and the optimizations taking effect.

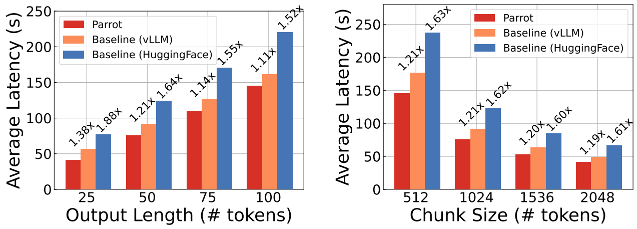


(a) Mean Latency

(b) P90 Latency

Figure 10: Latency (per output token) of vLLM with varying token capacities and request rates. Requests are sampled from ShareGPT [50] and their arrival time follows Poisson distributions.

Baseline. We benchmark Parrot against sate-of-the-art solutions for building LLM applications and serving LLM requests. The majority of LLM applications used in our baseline comparisons are developed using LangChain [8], which is the predominant framework for LLM application development. The LLM applications in baselines leverage OpenAI-style chat completion APIs as provided by FastChat [62]. FastChat is a widely recognized open-source LLM serving system with over 30,000 stars on its repository. Incoming requests to FastChat are allocated to LLM engines that run either HuggingFace's Transformers library [53] or vLLM [25], both of which incorporate cutting-edge enhancements for LLM execution, such as FlashAttention [12], PagedAttention [25], and continuous batching techniques [56]. The default scheduling strategy employed by FastChat assigns incoming requests to the LLM engine with the smallest current queue. Since existing LLM services typically expose their functionality through "chat" completion APIs, baseline assessments treat all requests as independent and assume a high sensitivity to latency. To manage token generation response times, each LLM engine is subject to a capacity threshold, which is the



(a) Output lengths

(b) Chunk sizes

Figure 11: Average E2E latency of chain summarization with varying output lengths and chunk sizes.

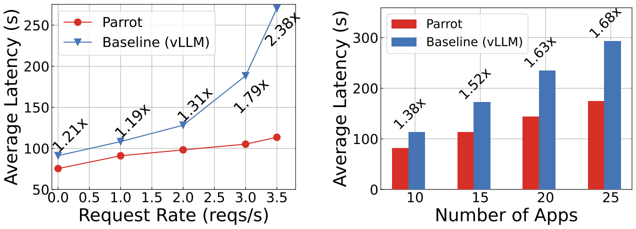
aggregate token count from all active requests on the engine.

Since existing LLM token generation is usually bound by memory bandwidth, the per-token generation latency of an engine is mainly affected by the number of running tokens in a batch. As depicted in Figure 10, our experiments indicate that the latency per output token, i.e. TPOT (Time-per-output-token) for vLLM, with continuous batching enabled, experiences a notable uptick when the engine's workload using a batch capacity beyond 6144. In our evaluation, we use the setting that an LLM engine can keep its generation latency under 40 ms/s for latency-sensitive requests, consistent with our experience of OpenAI's LLM services. When all LLM engines hit their maximum capacity, any additional LLM requests are queued in a FIFO (First In, First Out) manner, awaiting the completion and release of resources by ongoing tasks. Serving longer context (e.g., 32k or even 1M tokens) within a satisfactory latency require either more GPUs using tensor-parallel [49] or sequence-parallel [6] approaches, or approximate attention (e.g., StreamingLLM [55]), which is beyond the scope of this paper.

8.2 Data Analytics on Long Documents

Our experimental analysis within data analytics randomly picks ten long documents from the Arxiv-March dataset [27], using chain-summary and map-reduce summary. Each document has over 20,000 tokens. The results measures the mean end-to-end latency across all documents.

Chain-style Applications. Our evaluation demonstrates how Parrot enhances chain summarization by mitigating the excessive communication overhead stemming from client interactions. Figure 11 presents the average end-to-end latency for summarizing a single document using one LLM engine (A100, LLaMA 13B) . We adjust the chunk size (the count of tokens per chunk) and the output length, with results shown in Figure 11a and Figure 11b, respectively. Parrot achieves a reduction in end-to-end latency by as much as 1.38× and 1.88× compared to the baselines employing vLLM and HuggingFace, respectively. The efficiency of Parrot primarily stems from the decreased network latency, which is a consequence of reduced client interaction. As the output length increases, the time spent on generation becomes more significant, leading to a diminishing advantage for Parrot over the baseline. By increasing the chunk size, we decrease the number of chunks, yet the extent of the speedup is contingent upon the network latency savings for each chunk. Given that token generation is substantially more time-consuming than prompt processing, we observe a consistent speedup with variable chunk sizes and a fixed output length (1.2× and 1.66× relative to vLLM and HuggingFace, respectively). This indicates that Parrot's optimization for dependent LLM requests is particularly beneficial for shorter outputs, which are prevalent in various LLM applications such as summarization, short answer generation, scoring, and choice provision. Due to HuggingFace's slower performance relative to vLLM, subsequent evaluations focus solely on the comparison between Parrot and vLLM.



(a) With background requests

(b) Multiple summary apps.

Figure 12: Average E2E latency of chain-summary with background requests or other chain-summary applications.

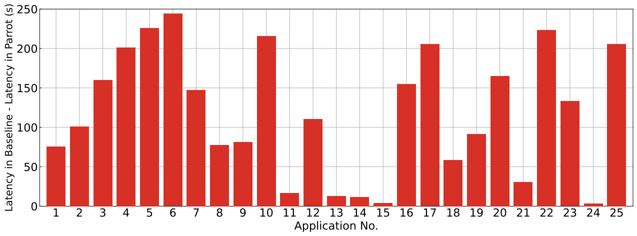


Figure 13: The difference in E2E latency of the 25 chain-summary application between Baseline and Parrot. All applications finish earlier in Parrot.

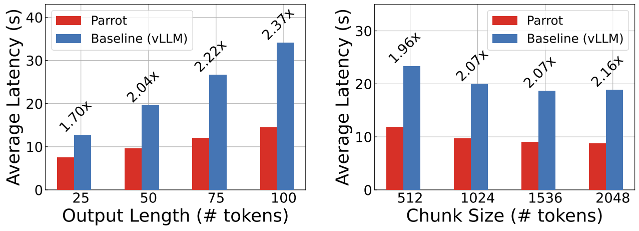
Figure 12a extends the evaluation by introducing background LLM requests at varying rates to examine the capability of Parrot in mitigating additional queuing delays for dependent requests. Parrot slashes the end-to-end latency by a factor of 2.38× in comparison to the baseline (vLLM). With Parrot, as soon as the summary for the first chunk is completed, the subsequent chunk is processed immediately by incorporating the summaries of previous chunks into the prompt, which aids in generating the summary for the next chunk. In contrast, the baseline treats all LLM requests individually. As a result, in addition to the network latency from client interactions, subsequent requests must re-enter the queue, leading



(a) Output lengths

(b) Chunk sizes

Figure 14: Average E2E latency of Map-Reduce document summary with varying output lengths and chunk sizes.

to added queuing delays. Figure 12b further illustrates the end-to-end latency when multiple chain-summary applications are submitted concurrently, with each application tasked with generating a summary for a separate document. Parrot manages to reduce the average end-to-end latency for all applications by 1.68× without slowing down any applications compared to the baseline according to Figure 13. The baseline, by interleaving the execution of different applications, exacerbates the slowdown of the end-to-end latency for all applications. These experiments validate that recognizing the interconnections of LLM requests can significantly enhance end-to-end performance, as opposed to processing requests in isolation.

Map-Reduce Applications. An alternative implementation of the document summarization application follows the map-reduce paradigm as depicted in Figure 1a. This approach consists of multiple parallel mapping LLM requests, where each request summarizes a distinct segment of the document, followed by a reducing LLM request that aggregates these individual summaries into a final summary. As shown in Figure 14, Parrot realizes a 2.37× acceleration over the baseline with one LLM engine (A100, LLaMA 13B). Since the mapping LLM requests are independent, they are dispatched concurrently by both Parrot and the baseline. The primary advantage of Parrot stems from its deduction of a performance objective that identifies the mapping tasks as a task group. By recognizing this relationship, Parrot is capable of optimizing the latency of the entire task group through larger batch sizes, which in turn enhances throughput. In contrast, the baseline processes each LLM request in isolation, operating under the presumption that they are all sensitive to latency. This constrains the baseline to utilize a limited token capacity (4096 tokens) on the LLM engine to achieve optimal latency for individual tasks, which is detrimental to the end-to-end performance of applications. It underscores the necessity for LLM services to distinguish LLM requests to optimize the end-to-end performance of varied LLM applications.

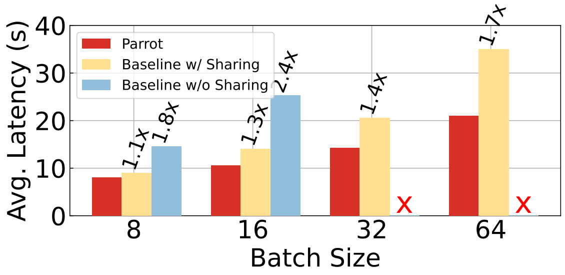


Figure 15: Latency of Bing Copilot with varying batch sizes.

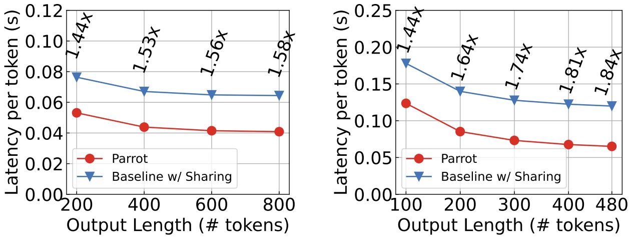
8.3 Serving Popular LLM Applications

Production applications need to face massive users. As explained in Figure 5, developers often need to use a very long system prompt to define the behavior of LLMs. Therefore, users of the same LLM application often use the shared prompt, which can benefit from Parrot's context fork mechanism and Parrot's scheduling policy that co-locates LLM requests sharing a long prompt prefix. Because we do not have access to the intermediate steps of Bing Copilot, we only evaluate the final request generating the response to users. We synthesized 64 requests from the length distribution we measured using Bing Copilot. The system prompt length is about 6000 tokens. The output lengths ranges from 180 to 800 tokens. Figure 15 shows the average request latency of Bing Copilot of Parrot and the baselines. Because the LLM service in the baseline system does not know the prompt structure, it is hard to infer the shared prompt from massive LLM requests. Compared to the baseline without sharing prompt, Parrot achieves 1.8× $\sim$ 2.4× speedup for batch sizes of 8 and 16. Further increasing the batch size leads to out-of-memory due to the massive KV cache of shared system prompt. We also build an advanced baseline using vLLM's paged attention to support sharing the prompt with a static prefix. Both Parrot and vLLM use the paged memory management [25], thus both systems can hold the same number of tokens in an LLM engine (A100, LLaMA 7B). Parrot further achieves 1.1× $\sim$ 1.7× speedup over vLLM because of the better GPU kernel. Although vLLM can save extra memory usage of the shared prompt, its GPU kernel still has to reload the tokens repeatedly. Given that the token generation of LLMs is bound by memory bandwidth, such redundant memory loading slows down the end-to-end inference. By combining FlashAttention and PagedAttention, Parrot only needs to load the tokens of the shared prompt once, when computing the attention from the diverged tokens of different users. Parrot's speedup of shared prompt mainly comes from the token generation, thus the longer output length leads to higher improvement. Figure 16 shows Parrot achieves 1.58× and 1.84× speedup compared to vLLM using paged attention, showing 40 *ms* per-output-token latency at a batch size of 32.

In Figure 17, we further evaluated the serving of multiple GPTs applications [42], each of which has multiple users, in



(a) Batch Size = 32

(b) Batch Size = 64

Figure 16: Latency per output token of Bing Copilot.

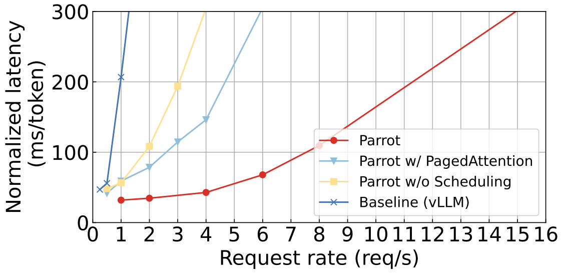


Figure 17: Serving multiple GPTs applications.

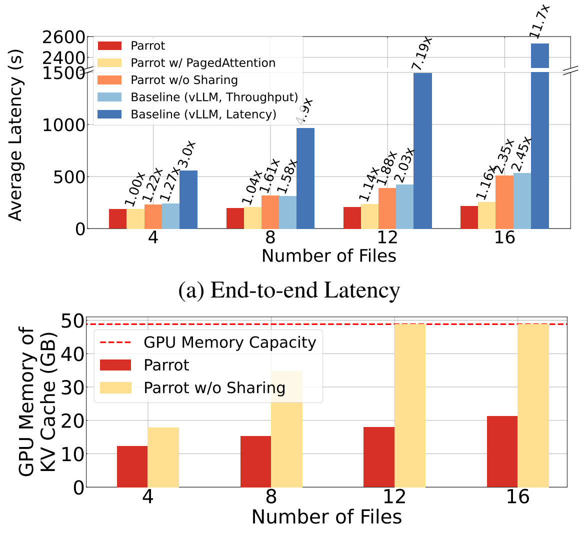
a multi-GPU cluster. Four A6000 (48GB) GPUs are deployed with four LLM engines (LLaMA 7B). We select four GPTs applications in four popular categories including productivity, programming, image generation, and data analysis. The LLM requests are randomly generated from the four categories with equal probability. LLM requests arrive at fixed rates following Poisson distribution. Parrot can sustain 12× higher request rates compared to the baseline without sharing. Because the baseline's scheduling policy is not aware of the shared prompt within each LLM application, the requests are mixed in all LLM engines making it impossible to reuse the common prompt prefix. Parrot's scheduling policy co-locates LLM requests of the same applications to maximize the sharing opportunity, achieving both lower inference latency and higher cluster throughput. After turning off such affinity scheduling policy, Parrot only exhibits 3× higher request rates compared to the baseline, because the requests with shared prefix are often dispatched to different engines thus reduced the sharing opportunities. Moreover, Parrot's attention kernel helps Parrot to achieve 2.4× higher rate compared to Parrot using vLLM's PagedAttention, by avoiding the redundant memory loading for attention of shared prompts.

8.4 Multi-agent Applications

We assess the performance of multi-agent systems utilizing MetaGPT [22] within Parrot. A workflow is constructed with three distinct roles. Initially, the Architect outlines the project's file structures and specifies APIs within each file for a given task. Subsequently, multiple Coders undertake the project implementation, with each focusing on a specific file. Following the integration of the code from all files, several Reviewers engage in the process, each examining and commenting on a single file. The Coders then revise their code based on these comments. This review-and-revision cycle is iterated three times to produce the final code. Figure 18 illustrates the latency and memory consumption of Parrot compared to baseline systems on one A100 running LLaMA 13B. Parrot achieves a speedup of up to 11.7× compared with the latency-centric baseline. The primary improvement is attributed to Parrot's capability to deduct the performance objectives for LLM requests based on the end-to-end performance criteria. For this specific multi-agent scenario, the goal is to minimize the time taken to deliver the final code. Parrot identifies multiple task groups within the parallel processes of coding, reviewing, and revising, facilitating larger batch sizes to enhance throughput and reduce the completion time of task groups. We also contrast Parrot with an throughput-centric baseline that uses larger batch on purpose to optimize cluster throughput, which also shows higher concurrency and better completion time than the latency-centric baseline.



(a) End-to-end Latency

(b) GPU Memory of KV Cache

Figure 18: The latency and memory usage for multi-agent programming, with varying number of files to program.

Even when compared to the throughput-centric baseline, Parrot demonstrates superiority, being faster by up to 2.45×. This enhancement mainly stems from Parrot's ability to decrease redundancy through its prompt structure analysis, which contributes a 2.35× acceleration. Given the interactive nature of the roles in MetaGPT, there is considerable overlap in the context among different roles, which Parrot capitalizes on by sharing this common context as a prompt prefix. The static prefix sharing mechanism from vLLM does not work in this dynamic scenario. Without a grasp of the prompt's structure, it cannot identify dynamically generated Semantic

Variables that could also be shared during runtime. As depicted in Figure 18b, Parrot without this sharing capability would hit the GPU memory ceiling. Additionally, Parrot's specialized GPU kernel for processing the shared prefix achieves a further 1.2× speedup when there are 16 files, compared to using vLLM's PagedAttention, due to the reduced memory transactions.

8.5 Scheduling of Mixed Workloads

To assess the performance of Parrot on a multi-GPU setup, we configure a cluster with four A6000 (48GB) GPUs, each hosting a separate LLM engine (LLaMA 7B), resulting in a total of four LLM engines. We emulate a real-world scenario where LLM services encounter a variety of demands by injecting a mix of requests from chat applications at a rate of 1 req/s and from data analytic tasks (i.e., map-reduce applications) previously analyzed in §8.2. Requests from the chat applications are characterized by their need for low latency, whereas the map-reduce applications prioritize high throughput, creating a challenge when they are concurrently processed by the same LLM engine. We benchmark Parrot against two reference implementations: one tailored for latency, limiting engine capacity to reduce decoding time, and another for throughput, utilizing full engine capacity to maximize GPU utilization.

The results depicted in Figure 19 demonstrate that Parrot attains a 5.5× and 1.23× improvement in normalized latency (measured as request latency per number of output tokens) [25, 56] for chat applications in comparison to the latency-focused and throughput-focused baselines, respectively. In terms of token generation speed for chat applications, Parrot delivers performance on par with the latency-centric baseline and outperforms the throughput-centric baseline by 1.72×. For map-reduce applications, Parrot reaches a 3.7× speedup over the latency-centric baseline and is 1.05× more efficient than the throughput-centric baseline. Parrot excels by providing both low latency for chat applications and high throughput for map-reduce applications. It mitigates the contention between chat and map-reduce workloads by intelligently scheduling them on separate engines. These findings underscore the significance of specialized handling for diverse requests to enhance the overall performance of LLM services.

9 Related Works

Deep Learning Serving Systems. The field of model serving has seen a surge of research activity in recent years, with many systems developed to address the different challenges of deep learning model deployment. The systems include Clipper [10], TensorFlow Serving [39], Clockwork [19], REEF [20], AlpaServe [28], which have explored many aspects including batching, caching, placement, scheduling, model parallelism for the serving of single or multiple models.

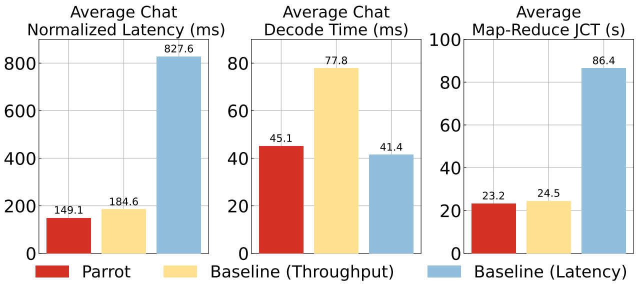


Figure 19: The mixture of chat and map-reduce applications.

These systems were proposed for serving general deep learning models, which have less consideration about the unique requirements of large language models, e.g., autoregressive decoding. Orca [56] proposed a fine-grained scheduling mechanism that can batch multiple LLM requests at the iteration level, which is also known as continuous batching. vLLM proposes PagedAttention [25] allows the batching of LLM requests with different lengths using non-contiguous memory, increasing memory utilization. These systems for LLM serving still treat LLM requests separately, missing the opportunities to understand the interconnections within an application and exploit the commonality of different requests. Parrot is orthogonal to them. With more application-level knowledge exposed by Semantic Variables, Parrot can do data flow analysis on LLM requests, which enables a brand new optimization space with the final goal of optimizing the end-to-end performance of applications, rather than individual requests.

LLM Orchestrator Frameworks. LLM orchestration frameworks help developers create and manage applications powered by LLMs. They simplify the process of prompt design, and orchestration of multiple LLM requests, which enable developers to interact with LLMs easily. LangChain [8] is a Python framework that provides many workflow patterns, e.g., chain, map-reduce so that developers can easily customize their own LLM applications. Semantic Kernel [36] introduces Planners are semantic agents that can automatically generate plans based on the needs of the users. PromptFlow [35] supports chains of native and semantic functions and visualizes them as a graph. LlamaIndex [29] allows developers to use natural language queries to retrieve relevant documents. Parrot is orthogonal to these frameworks and can be easily integrated with these frameworks to support Parrot's APIs with Semantic Variable abstraction, as discussed in §6.

DAG-aware System Optimizations. Dependency graphs or DAGs (Directed Acyclic Graphs) widely exist in many kinds of systems, and many optimizations have been proposed to optimize the systems by exploiting the DAG information. Tez [4], Dryad [23], and Graphene [16] use the task dependency to optimize the scheduling and packing of parallel data analytic workloads. SONIC [30], Caerus [59], and Orion [31] optimize serverless functions from the aspects of communication, latency, and cost. Parrot learns from the previous system works and realizes the importance of correlations of LLM requests to optimize the end-to-end performance of LLM applications. This motivates Parrot to build APIs for exposing such dependency information. Moreover, it is unique to LLM applications to understand the prompt structure in addition to request-level dependency, which is necessary for communication and identifying commonality across LLM requests. This motivates us to propose the Semantic Variable abstraction, instead of just using a DAG of requests.

10 Conclusion

This paper proposes Parrot that treats LLM applications as first-class citizens and targets to optimize the end-to-end performance of LLM applications, instead of only optimizing individual LLM requests. We propose Semantic Variable as the key abstraction that exposes the dependency and commonality of LLM requests, enabling a new optimization space. Our evaluation shows Parrot can optimize LLM-based applications by up to 11.7×. We envision this new angle of efficiency improvement of LLM applications brings a broad future direction to study other scheduling features like the fairness of *end-to-end* performance of LLM applications.

Abstract

Minimizing monetary cost and maximizing the goodput of inference serving systems are increasingly important with the ever-increasing popularity of deep learning models. While it is desirable to spatially multiplex GPU resources to improve utilization, existing techniques suffer from inter-model interference, which prevents them from achieving both high computation and memory utilizations. We present USHER, a system that maximizes resource utilization in a holistic fashion while being interference-aware. USHER consists of three key components: 1) a cost-efficient and fast GPU kernel-based model resource requirement estimator, 2) a lightweight heuristic-based interference-aware resource utilization-maximizing scheduler that decides the batch size, model replication degree, and model placement to minimize monetary cost while satisfying latency SLOs or maximize the goodput, and 3) a novel operator graph merger to merge multiple models to minimize interference in GPU cache. Large-scale experiments using production workloads show that USHER achieves up to 2.6× higher goodput and 3.5× better cost-efficiency compared to existing methods, while scaling to thousands of GPUs.

1 INTRODUCTION

Driven by the breakthroughs achieved by Deep Learning (DL) models in a wide variety of domains [1–3], machine learning (ML) inference has emerged as the dominant workload that underpins many real-world applications. Our quest for improving the capability and accuracy of DL models has led to models growing in size rapidly [4]. While the success of DL models has been celebrated, it has come with a significant monetary cost: the increase in model sizes and popularity of ML model-based applications demand the use of expensive and power-hungry GPUs, leading to ML inference accounting for more than 90% of production costs [5]. Forecasts paint a gloomy picture: annual data center infrastructure and operating costs are projected to increase to over $76 billion by 2028 due to the rapid increase of the number of GPUs in the data centers, which is more than twice the estimated annual operating cost of Amazon AWS [6].

The exorbitant operating cost requirement has led to several systems innovations; state-of-the-art ML inference systems incorporate several optimizations that increase the *utilization* of GPUs. The fundamental technique to improve the utilization of a GPU is to use *batching*, where multiple inputs are combined and passed together through the model. Batching inputs together results in an increase in the compute requirements and thus improves the utilization of the GPU, albeit at the expense of increased latency. Unfortunately, batching is insufficient to optimally utilize a GPU because it is a *single knob* that influences two GPU resources: memory and compute, and thus is unable to saturate both resources at the same time. Moreover, since real-world batch sizes are not continuous in nature, there is no fine-grained control over the resources—while one batch size may severely underutilize the GPU in terms of memory or compute, the next possible batch size may not fit in the given resources or violate the strict latency Service-Level-Objective (SLO) (§2.1). When combined with the fact that request rates vary over time [3], real-world deployments have reported low GPU utilization averaging between 25% to below 50%, which has become a thorny pain point in reducing the total operational cost of large GPU clusters [7–10].

A natural solution to this problem is to place and simultaneously execute multiple models in a GPU. Unfortunately, previous research works have shown that this could result in *interference* between models due to resource contention which could introduce significant increase in inference latency, thus leading to SLO violation [11, 12]. An alternative is to leverage virtualization technologies that can divide the GPU resources; sadly GPU virtualization technologies available today are rudimentary and inflexible at best. NVIDIA Multi-Process Service (MPS) [13] facilitates simultaneous execution of multiple spatially multiplexed models by logically partitioning the computation space of the GPU among the models. Several scheduling systems [4, 14] have been proposed that leverage MPS and decide how much GPU computation space to allocate to each model to satisfy the latency SLO of the model requests based on offline profiling and place the models to the GPUs in such a manner that maximizes the utilization of the computation space of the GPUs. However, these works solely focus on compute utilization and largely overlook the maximization of memory space utilization. NVIDIA multi-instance GPU (MIG) addresses the problem of inter-model interference by physically partitioning the computation and memory spaces of the GPU [15]. However, MIG only provides rigid partitioning, leading to GPU overprovisioning, and hence underutilization, and is only available in the latest generation of GPUs.

In this paper, we propose USHER, an end-to-end inference serving system that optimizes both GPU computation and memory utilizations by spatially multiplexing its resources in an interference-aware fashion. We design USHER from first-principles, based on a systematic analysis of performance and interference characteristics of the state-of-the-art solutions on real-world data traces (§2). Our analysis reveals several key observations. First, we may need to divide the workload of a model into multiple GPUs even when one GPU is enough to complete the workload within the latency SLO. Also, we need to perform this workload division holistically for all models. Second, not only the model parameter size, but also the intricate relationship between batch size, batch size-dependent resource requirements, and SLO contributes to making a model computation-heavy or memory-heavy. USHER leverages such observations in designing its three key components.

To accurately estimate the computation and memory requirements of a new model without incurring the prohibitive cost of offline profiling, USHER proposes a novel low-level GPU kernel analysis-based approach that first estimates which GPU kernels of the model will be executed concurrently and then sums up the resource requirements of those kernels. Finally, it takes the maximum sum across all sets of concurrent kernels as the highest resource requirement of the model (§3.2).

Based on the estimation, USHER needs to decide on the placement of each model that maximizes resource utilization without interference in both computation and memory spaces. Towards this, USHER incorporates a novel variant of a multi-dimensional bin packing scheduler [16–20]. To address the exponential complexity of holistic workload division, the scheduler first creates moderate-sized groups of models to maximize the probability of spatially multiplexing computation-heavy models with memory-heavy models within a group. Then, the scheduler decides the optimal workload division, batch size, and GPU placement decisions holistically for all models within a group by a heuristic algorithm (§3.3).

Finally, to minimize the cache interference among multiple spatially multiplexed models, USHER proposes a novel method that merges the computation graphs of multiple DL models to maximize the usage of GPU cache contents. Existing works [21–23] on computation graph merging reduce memory requirements by sharing weights across multiple models, which cannot maximize GPU cache usage. To this end, USHER merges the graphs in a manner that when the weight submatrix that is similar across different models is present in the GPU cache, the matrix multiplications of the different models associated with the submatrix are performed at the same time (§3.4).

We implemented USHER on Tensorflow (§4) and evaluated it on a wide variety of models and workloads using both real testbed and simulations. Our evaluation shows that USHER achieves up to 2.6× higher goodput and 3.5× better cost-efficiency against Shepherd [3], GPUlet [14], and AlpaServe [4], three representative state-of-the-art baselines (§5).

Overall, we make the following contributions in this paper:

1. We systematically analyze the underutilization of resources and inter-model interference in the state-of-the-art inference serving systems.
2. We propose USHER, a system that spatially multiplexes the inference serving of multiple DL models in an interference-aware and resource utilization-maximizing manner.
3. We evaluate USHER against the state-of-the-art baselines and show that it significantly outperforms them.

2 Experimental Analysis

We use *Cuti* and *Muti* to denote GPU computation and memory utilization, respectively, and use *Creq* and *Mreq* to denote their requirement from a model. Creq (or Mreq) of a model is the highest percentage of the total computation (or memory) space of a GPU consumed by the model at any point during its execution. We further use *Rreq* to denote the sum of *Mreq* and *Creq*. We use *C-heavy* and *M-heavy* to denote computation-heavy and memory-heavy, respectively. We use

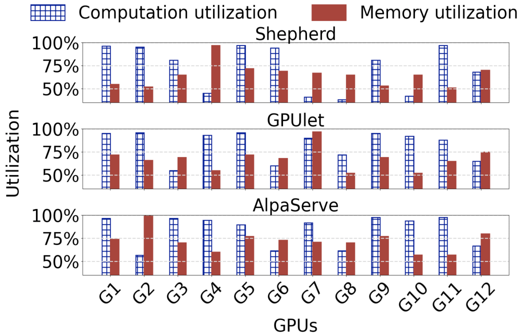

Figure 1: Performance of existing systems.

GPU# to denote the total number of GPUs required to satisfy the SLOs, and use *model#* to denote the number of models in a GPU. We use *C-space* and *M-space* to denote the available capacity of a GPU in computation and memory, respectively.

As [3, 14], we conducted analytical experiments using a mix of convolutional neural network (CNN) and Transformer models, which are typically the most widely used DL models in production deployments [3]. The 20 models used in our experiments are shown in Table 1. We got the trained models from HuggingFace repository [45]. The inference requests are also taken from the datasets. As [4, 14], the SLO of a model is taken as double the average inference latency of a single request in a Nvidia V100 GPU. As [3], the experiments were conducted on a GPU cluster formed by 12 Amazon EC2 servers of type p3.2xlarge. Each server has one Nvidia V100 GPU with 5760 computation cores, 16 GB GPU memory, one 2.3 GHz processor with 8 CPU cores, and 61 GB host memory. For the large model Llama-2, we utilized the DeepSpeed library [46] to partition the model into multiple partitions, allowing each partition to be loaded onto a GPU. Throughout the remainder of the paper, when referring to a model, it denotes the entire model for small models and a model partition for large models. Also, multiplexing refers to spatial multiplexing. As [3,4], we used the Microsoft Azure Function trace 2019 [47] for the inference request rates and assigned the 46,000 function streams from the trace to the 20 models in a round-robin manner.

2.1 Performance of Existing Systems

We used Shepherd [3] to represent systems that do not allow spatial multiplexing and use GPUlet [14] and AlpaServe [4] to represent systems that allow spatial multiplexing. They aim to maximize GPU computation utilization and goodput. Goodput is defined as the number of inference requests completed within their latency SLOs per unit time.

Fig. 1 shows the average Cuti and Muti of each GPU. Shepherd achieves 41%-97% and 51%-97% Cuti and Muti, respectively. Though Shepherd uses batching to increase utilization (Ruti), it also increases the inference latency and memory requirement, which may become a bottleneck and limit the Cuti. GPUlet and AlpaServe increase the Cuti and Muti to 55%-97% and 54%-99%, respectively, due to their spatial multiplexing. However, there is still room for improvement. Also, Shepherd, GPUlet, and AlpaServe produce 14.2%-52%, 7%-40.1%, and 5.3%-44.9% $|Cuti - Muti|$ values, respectively. This is because the Creq and Mreq of a model are not necessarily correlated and hence, maximizing Cuti does not necessarily maximize Muti. Next, to study interference among models, we measured the goodput of each model with and without multiplexing in GPUlet and AlpaServe, and calculated their ratios. Fig. 2 shows the CDF of models versus the ratio. We see that 87% and 100% of the models have a ratio $\leq$ 0.55 in GPUlet and AlpaServe, respectively, meaning their goodputs are decreased by almost half due to the interference. GPUlet tries not to place the models in one GPU if their interference estimated by a regressor is high. However, it does not capture the interference among three or more models, and also does not address the cache interference problem.

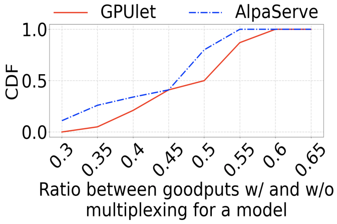

Figure 2: Impact of inter-model interference on goodput.

Observation 1. *The existing inference serving systems cannot maximize Cuti or Muti, and their model multiplexing significantly reduces the goodput due to model interference. In addition, maximizing Cuti does not necessarily maximize Muti.*

2.2 Opportunity of Workload Division

By equally dividing the workload (i.e., number of incoming requests per unit time) of a model into multiple GPUs, we essentially replicate the whole model in those GPUs. We use replication degree (RD) to denote the number of replicas of a model. In the example in Fig. 3a, models M1, M2, and M3 have 70%, 65%, and 40% Mreq (with 10%, 5%, and 10% for parameters, and the rest for intermediate data), respectively, to meet their SLOs with BS (batch size) = 8. Hence, the average Muti equals $\frac{70\%+65\%+40\%}{3} = 58.33\%$. Though the three GPUs have 30%, 35%, and 60% of the GPU memory unused, they are not enough to host any other model. Now, due to the strict latency SLO requirement, it is not possible to increase the BS of any model any further to increase the memory utilization since increasing the BS also increases the per-batch inference latency. Reducing the BS of M1 by half essentially conducts a workload division and lowers the intermediate data amount by half in each GPU where M1 is hosted, resulting in 40% Mreq in such a GPU. Fig. 3b shows a multiplexing schedule. The total number of GPUs (GPU#) is still 3 with 61.66% average Muti. Fig. 3c shows another multiplexing schedule, which performs workload division also for M2 and M3, and results in 2 GPU# and 100% Muti. This example shows that to increase Ruti in multiplexing, we may need to divide the workload to more GPUs than the minimum required and we need to decide the optimal workload division schedule *holistically* (instead of independently) for all models.

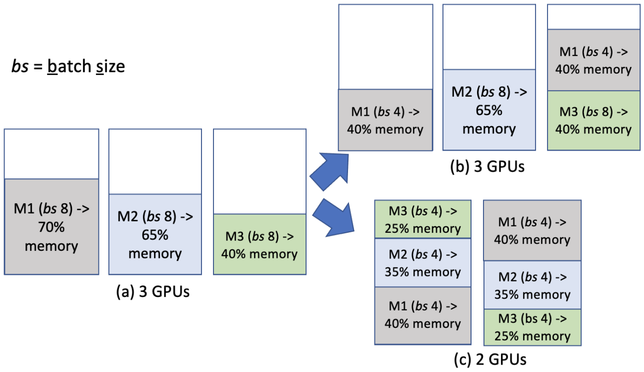

Figure 3: Performing workload division holistically for all models increases resource utilization.

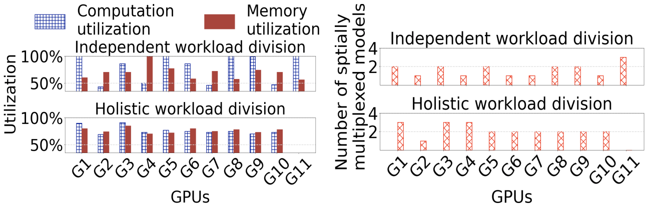


(a) Resource utilization of each GPU by workload divison.

(b) Number of spatially multiplexed models in each GPU using workload division.

Figure 4: Effectiveness of holistic workload division.

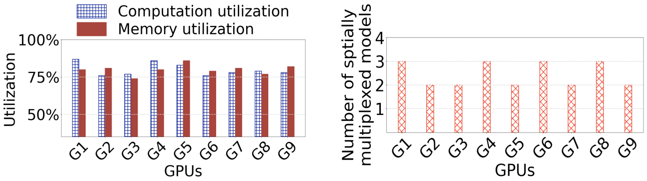
We then experimented to test the impact of workload division. We first used Shepherd to decide the BS (b_i^s) and the minimum RD (r_i^d) of each model i to complete its workload within the SLO. Then, for each model i independently, we created $2r_i^d$ replicas of each model with BS=$\frac{b_i^s}{2}$ and placed them to randomly selected GPUs with enough available C-spaces and M-spaces to host the model replicas. In our next experiment, to perform holistic workload division, we created all possible configurations, i.e., {(BS, RD) for each model i within range $[b_i^s, \frac{b_i^s}{2}]$ and $[r_i^d, 2r_i^d]$}. Then, for each configuration, we placed the model replicas to randomly selected GPUs having enough resources. Finally, we chose the best configuration that resulted in the lowest GPU#. Fig. 4 shows the average Cuti and Muti, and model# in each GPU for both experiments. Independent workload division increases the average Cuti and Muti by 3.5% and 3.8%, respectively, compared to Shepherd shown in Fig. 1 and the GPU# is decreased from 12 to 11. The holistic workload division further increases the average Cuti and Muti by 4.7% and 5.1%, respectively, leading to another decrease of GPU# by 1, even with a simple strategy of random GPU placement.

Observation 2. *In spatial multiplexing-based inference serving, unlike existing systems, we may need to divide the workload of a model even when one GPU is enough to complete the workload within SLO in order to increase the overall resource utilization.*

Observation 3. *Optimal workload division should not be decided independently for each model. Instead, a holistic approach that considers all models simultaneously is essential.*

2.3 Study on C-heavy and M-heavy Models

In this experiment, we did the same holistic workload division experiment described above, except that, for each configuration, we first ordered the models in descending order of Creq+Mreq and followed this order of models to place the model replicas to randomly selected GPUs with enough spare resources. Fig. 5 shows the results. The average Cuti and Muti increase by 5.3% and 4.9%, respectively, compared to the holistic approach in Fig. 4a, leading to a further decrease of GPU# by 1. Also, the average model# in a GPU increases by 0.24 compared to the holistic approach in Fig. 4b. Due to the ordering of the models, less spare resources remain in the GPUs after the model placement, leading to less resource fragmentation and better utilization.



(a) Resource utilization of each GPU by sorting the models according to total resource requirements.

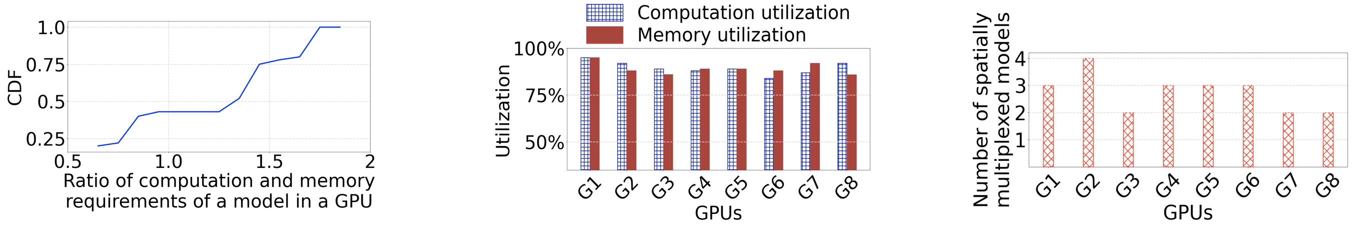
(b) Number of spatially multiplexed models in each GPU using the sorting approach.

Figure 5: Considering a model's total resource requirement in model replica placement.

The general notion assumes large models have high Creq and Mreq, while small models have low Creq and Mreq. However, this distinction overlooks the impact of BS in inference serving. Increasing BS may boost resource use but risks latency violations and memory overflow. This highlights the delicate balance of Cuti and Muti in workload scheduling.

For example, when we executed LlaMA-2 (with 13 billion parameters) with BS=4 in a Nvidia H100 GPU, it takes up almost all GPU memory, but has 45% Cuti unused. Increasing BS any further overflows the memory. Hence, it is M-heavy instead of C-heavy, despite being a large model. On the other hand, MobileNetV2 (only 3.4 million parameters) with BS=128 reaches up to 93% Cuti but has 30% Muti. Increasing BS any further violates its 64ms SLO. Hence, it is a C-heavy model instead of M-heavy model.

Fig. 6a shows the CDF of models versus the ratio $Creq/Mreq$ of a model. We see that 22% of the models have ratios $\leq$0.75, indicating they are M-heavy. Also, 28% of the models have ratios in (1.35,1.65], indicating they are C-heavy. Llama-2 is an M-heavy model (i.e., Mreq/Creq$\geq$1.2). Among the other small models, 39% are M-heavy, 2% have comparable Creq and Mreq, and the rest are C-heavy (i.e., Creq/Mreq$\geq$1.2).

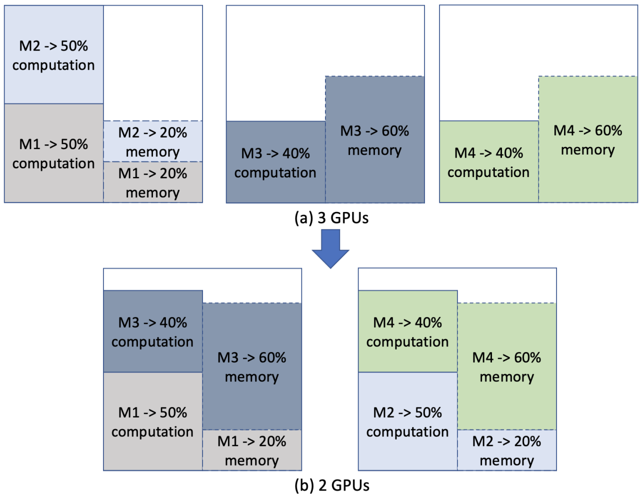


(a) CDF of models vs. Creq/Mreq.

(b) Resource utilization by multiplexing C-heavy and M-heavy models.

(c) Model# by multiplexing C-heavy and M-heavy models.

Figure 6: Computation-heavy and memory-heavy models.



(a) 3 GPUs

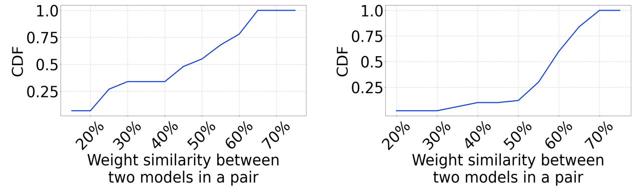
(b) 2 GPUs

Figure 7: Spatially multiplexing a computation-heavy model with a memory-heavy model increases resource utilization.

> **Observation 4.** *Unlike common belief, model parameter size alone cannot dictate whether a model is C-heavy or M-heavy. Even a small model can surpass a larger one in Creq, driven by the intricate relationship between BS, BS-dependent resource needs, and SLO.*

We next investigate whether multiplexing a C-heavy model with an M-heavy model improves Ruti. Let us consider 4 models M1, M2, M3, and M4 in Fig. 7 with BS=32. Their Creq are 50%, 20%, 40%, and 40%, and their Mreq are 20%, 20%, 60%, and 60% respectively. Hence, M1 and M2 are C-heavy and M3 and M4 are M-heavy. First, we multiplex M1 and M2 in the same GPU as shown in Fig. 7a, which results in 100% Cuti but 40% Muti. M3 and M4 cannot be multiplexed due to lack of memory, resulting in 3 GPU#, 60% average Cuti and 53.33% average Muti. Alternatively, if we multiplex M1 with M3 and M2 with M4 as shown in Fig. 7b, it results in 2 GPU#, 90% average Cuti and 80% average Muti. Hence, multiplexing a C-heavy model with a M-heavy model maximizes resource utilization.

To experimentally validate this, we did the same experiment described in §2.3, except that we interleave C-heavy models with M-heavy models in the ordered list. Figs. 6b and 6c show the results. The average Cuti and Muti increase by 12.1% and 11.8%, respectively, compared to the holistic approach in Fig. 4a, Also, the average model# increases by 0.6 compared to the holistic approach in Fig. 4b, and hence, GPU# is decreased by 2.



(a) Weight similarity across CNN models.

(b) Weight similarity across Transformer models.

Figure 8: Weight similarity across models.

> **Observation 5.** *Multiplexing C-heavy model with an M-heavy model increases both Cuti and Muti of a GPU.*

2.4 Models' Weight Overlapping

Previous studies [48, 49] have indicated that CNN models have significant weight overlapping (i.e., similar parameter values) in earlier layers because the first few convolutional layers function as feature-extractors [48] and are task-agnostic. Also, to reduce training cost, the task-specific transformer models are typically trained not from scratch, but from pre-trained task-agnostic foundation models using transfer learning. Additionally, for both models, people generally customize a task-specific pretrained model for their own datasets by fine-tuning only the last few layers. These indicate the potential for weight similarity across models. Motivated by these, we evaluated the weight similarity across models. Specifically, for each pair of CNN models and Transformer models, we measured the weight similarity between the two models in the pair.

Given CNN models A and B, we first find the weight similarity between every possible pair of convolutional layers across the two models. Then, we take the average weight similarity of all pairs of layers as the weight similarity between the two models. To find the weight similarity between layer $i \in L_A$ and layer $j \in L_B$, where L_x denotes the set of all convolutional layers in model x, we calculated $\frac{2\times|\max(W_A^i \cap W_B^j)|}{|W_A^i|+|W_B^j|}$, where $\max(W_A^i \cap W_B^j)$ denotes the longest common submatrix between weight matrices W_A^i and W_B^j. We consider two weight values as the same if their absolute difference is very low (i.e.,

$\leq 10^{-7}$). We did the same experiment for the attention layers of the Transformer models.

Fig. 8 shows the results for randomly chosen 1k CNN and 1k Transformer models from HuggingFace trained model repository [45]. For the CNN models, 52% model pairs have weight similarity within $(45\%, 65\%]$. For the Transformer models, 70% model pairs have weight similarity within $(55\%, 70\%]$ in between themselves.

Observation 6. *There are significant weight overlappings between different CNN models, and also between different Transformer models.*

3 System Design of Usher

3.1 Overview

Observation(O)1 motivates us to propose a new system to maximize both computation and memory utilizations of GPUs in an interference-aware manner to minimize the inference serving cost. We design USHER based on O2-O6.

Given models with request rates and a cluster of GPUs (that may be heterogeneous), USHER decides the *schedule* that includes the configuration (BS,RD), GPU allocation, and placement of the model replicas of each model. We consider two scenarios with different goals in this paper: (i) non-fixed cluster, where USHER aims to minimize the monetary cost while satisfying the SLOs of all models [12, 14, 50], and (ii) fixed-cluster, where USHER aims to maximize goodput [3, 4].

USHER has following major methods as shown in Fig. 9.

(1) **GPU Kernel based Resource Requirement Estimator (GK-Estimator)**(§3.2). The estimator quickly and correctly calculates the Creq and Mreq of a model in a GPU type based on a given configuration.

(2) **Interference-Aware Resource-Utilization-Maximizing Scheduler (IR-Scheduler)**(§3.3). Instead of solving an optimization problem, which has high complexity, USHER provides a lightweight heuristic to quickly derive the schedule. It first groups the models in a manner that maximizes the opportunity of multiplexing C-heavy and M-heavy models within a group. Then, within each group, it chooses the configuration that results in the placement with the best performance regarding the specific goal (by leveraging O2-5). The IR-Scheduler ensures each model replica gets its Creq and Mreq in the GPU where it is placed, thus ensuring there is no inter-model interference in C-space and M-space.

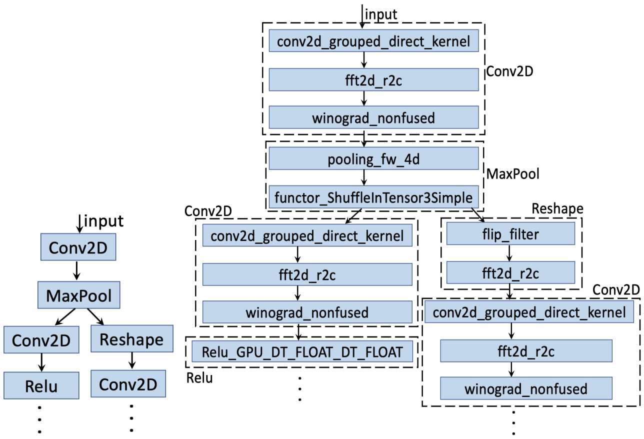
(3) **Operator Graph Merger (OG-Merger)**(§3.4). After deciding the placement, OG-Merger merges as many operator graphs of the models assigned to a GPU as possible to minimize inter-model interference in the GPU cache. After the merging, the merged graph is allocated the sum of the resources allocated to the models (decided by the IR-Scheduler) whose graphs have been merged. Note that the IR-Scheduler does not satisfy the cache requirements of the models, which we found to be almost 100% in the setup in §2. Hence, satisfying the cache requirement results in underutilization of C-space and M-space. That is why USHER addresses cache interference separately in OG-Merger.

In USHER, the input to the IR-Scheduler includes the request rate (i.e., workload) of each model and the types of GPUs in the system (①). During decision making, IR-Scheduler uses GK-Estimator (②) to estimate Creq and Mreq given a configuration (③), and finally outputs the optimal schedule (④). Then, OG-Merger merges the models placed to the same GPU (⑤). Then, the system starts serving the inference requests. As [14, 50], when a model's workload changes significantly, i.e., by 0.5k requests/second, (which may happen after 45s-300s as shown in §5.4), USHER is used again to adapt to the new workload pattern.

3.2 Kernel-based Resource Requirement Estimator

Offline profiling is a common approach for estimating the Creq and Mreq of each new model [3, 4, 12, 14, 50]. However, it is costly and time-consuming. To address this challenge, we propose the GK-Estimator that estimates the resource requirement of each model independently by analyzing its low-level GPU kernels without actually running the model in a GPU. We use Mreq as an example to explain how GK-Estimator works. Every model can be treated as a computational graph, in which a node is an operator and an edge is a tensor (i.e, multi-dimensional matrix) denoting model input or intermediate data generated by a model layer. Internally, each operator execution involves sequentially calling one or more GPU kernel APIs defined in the GPU programming framework (e.g., CUDA for Nvidia GPUs, ROCm for AMD GPUs). For each operator defined in ONNX [51], we found which GPU kernels are called by an ML framework during the execution of the operator by using Nvidia Profiling tool [52]. We noticed that 1, 2, 3, and 4 GPU kernels are called for 2%, 8%, 56%, and 34% of the operators, respectively.

The operators of a new model are usually from a pre-known set of operators [53, 54]. Therefore, GK-Estimator uses a regression model that quickly computes the memory required by the intermediate data generated by an operator based on the sizes of the input tensors and mathematical operations of the operator. Then, for a sequential DL model, its Mreq is the sum of the model parameter size and the highest memory required by an operator. The memory requirement for a model with parallel branches (e.g., Inception model, illustrated in Fig. 10a), the Mreq of the intermediate data is the sum of



(a) Operator-level computation graph **(b) Kernel-level computation graph**

Figure 10: Conversion of an operator-level computation graph for a CNN to its kernel-level computation graph.

Mreqs of the intermediate data from kernels that are executed concurrently. Then, as shown in Fig. 10, first, GK-Estimator converts the operator-level computation graph to a kernel-level computation graph by replacing each operator with the sequence of GPU kernels it calls. This sequence is found offline for each operator in ONNX. Then, it finds each set of kernels that will be executed concurrently. Next, for each set, it estimates the Mreq of the intermediate data generated by each kernel of the set by a regression model (called Mreq-Regressor) and then sums up the Mreqs of all the kernels in the set. Finally, it takes the sum of the model parameter size and the maximum memory requirement from all sets as the Mreq of the model.

The start time of the first kernel of the model (i.e., the kernel that directly gets the model input) is 0^{th}ms. To identify which kernels will be executed concurrently, GK-Estimator first finds the start time of each kernel. It uses another regression model to estimate the execution time duration of each kernel (called Time-Regressor). The kernels with a start time difference of no more than τms (e.g., 0.001ms) are considered to be potentially running concurrently.

To build Mreq-Regressor and Time-Regressor, we use a stacked model (a combination of lasso regression, kernel ridge regression, gradient boost regression, and XGBoost regression models) for higher accuracy [55]. The inputs to both the regressors include the following features that impact the resource requirement and execution time duration of a kernel: batch size, sizes of the kernel's parameter weight tensor and its input intermediate data tensor, the number of floating-point operations of the kernel, and GPU type. Note that none of the features depend on the kernels of the other models that the IR-Scheduler may potentially place to the same GPU. We trained the regression models offline using all the GPU kernels for all the operators defined in ONNX. The training takes 1.3hr in a V100 GPU. We conducted an experiment and found that this kernel analysis approach achieves 99.98% accuracy in estimating the Creq and Mreq of the models in Table 1 with BS 2. We also measured the accuracy of each of the constituting regression models in the stacked model and found that they provide 23%-40% less accuracy compared to the stacked model.

3.3 Interference-aware and Resource Utilization-maximizing Scheduler

USHER first groups the models such that the models inside a group are highly probable to be multiplexed in an interference-aware and resource utilization-maximizing manner. Then, inside each group, based on O3, USHER decides the GPU allocation and placement decisions *holistically* for all models of the group. Below, we first describe the grouping process (§3.3.1) and then the scheduling process (§3.3.2).

3.3.1 Model Grouping

Based on O4 and O5, multiplexing a C-heavy model with an M-heavy model maximizes Ruti. Such multiplexing makes the Cuti and Muti of a GPU comparable. If a GPU's C-space is much lower than its M-space or vice versa, it may not be able to host an additional model. Based on this, we follow one principle during multiplexing models. That is, the sum of the Creqs of the models is nearly equal to the sum of the Mreqs of the models in the GPU (i.e., $\sum_i Creq_i \approx \sum_i Mreq_i$). Based on this, USHER groups the models such that $\sum_i Creq_i \approx \sum_i Mreq_i$ for the models in each group.

Before conducting the grouping, USHER first finds the Creq and Mreq of each model. USHER calculates the average Rreq across all possible BS and GPU type combinations using GK-Estiamtor (described in §3.2). For a GPU type, USHER stops at the BS for which the Creq or Mreq exceeds the maximum C-space or M-space of the type, respectively.

Next, USHER performs the grouping using a variant of k-means clustering [56]. The algorithm clusters a set of elements into nearly equal-sized groups so that the sum of the distances between elements within each group is minimized, while the sum of the distances between groups is maximized.

At the beginning, each group consists of a single model. USHER calculates the distance between every two models as $D = |\sum_i Creq_i - \sum_i Mreq_i|$. Then, it uses the k-means algorithm to group the models into several groups, where each group consists of two models such that D is minimized, i.e., $\sum_i Creq_i \approx \sum_i Mreq_i$ for each group. Next, considering each group as an element, USHER executes another pass of the algorithm. This process merges two groups created by the previous pass to one and increases the number of models in each group by two times. As a result, if we decide to have at most 2^p (i.e., 4) models in each group, we need to perform p passes of the algorithm. Finally, the models are grouped into several groups and the set of the groups is denoted by $\mathbf{G} = \{\mathcal{G}_1, \mathcal{G}_2, ..., \mathcal{G}_n\}$.

3.3.2 Scheduling: Deciding Configuration and Placement

After grouping the models, for every model in each model group $\mathcal{G}_i$, IR-Scheduler decides the schedule. Below, we use

Algorithm 1 Interference-aware and resource utilization-maximizing scheduler for **G**.

```
1: for each $\mathcal{G}_i \in$ G do
2:     Generate all possible configurations={(BS, RD) for each
       model $M \in \mathcal{G}_i$}.
3:     for each configuration do:
4:         cost, total_goodput = PLACEMENT(configuration)
5:     Schedule as per the configuration for which all of the requests are
       completed within their latency SLOs, i.e., total_goodput =
       total_workload and the cost is minimum.
```

the non-fixed cluster as an example to present the method and then extend it for the fixed cluster. Based on O2, workload division (i.e., RD>1) may increase the utilization even when one model replica is enough to complete all of the inference requests within the latency SLO. During the scheduling, first, USHER takes all possible configurations, i.e., {(BS, RD) for each model in the group $\mathcal{G}_i$} (Algorithm 1). For each configuration, it finds the placement to minimize the cost (Algorithm 2). Finally, USHER chooses the configuration and placement that result in the minimum cost.

The placement algorithm tries to assign one group of models $\mathcal{G}_i$ to the same GPU set to maximize Cuti and Muti. Therefore, to assign the models in $\mathcal{G}_i$, the algorithm prioritizes the GPUs that are already assigned with the models in $\mathcal{G}_i$, and initializes a new GPU only when no used GPU can host a model. To avoid resource fragmentation and increase Ruti, it prioritizes the models $\mathcal{G}_i$ that have high Creq and Mreq and aims to place it to a GPU that leaves the lowest C-space and M-space after hosting it. Additionally, based on O5, USHER takes placement decisions alternatively between C-heavy and M-heavy models. The scheduling algorithm is shown in Algorithm 1. The algorithm finds the best placement decision for each possible configuration by calling the PLACEMENT() algorithm (Lines 1-4). The set of possible values of BS of a model is: {4, 8, 16, 32, 64, 128}, and the set of possible values of RD of a model is: $\{m \cdot c_M^l\}$, $m = 1,2,...,6$, where c_M^l is the minimum possible value of RD of model M to satisfy its SLO. It is calculated as the minimum number of GPUs of the highest GPU type required to complete all of the model M's requests within the SLO considering the highest possible BS in each GPU. The highest possible BS is taken as the minimum value between 128 and the BS beyond which its Mreq exceeds the memory capacity ($\max M$) of the highest capacity GPU type. This way, as the maximum possible value of RD of a model can be as much as 6 times the minimum possible value, the scheduling algorithm conducts workload division based on O2.

Algorithm 2 Placement algorithm for model group $\mathcal{G}_i$.

```
1: procedure PLACEMENT (configuration)
2:     $\mathcal{G}_{iGPU} \leftarrow$ GPU group for $\mathcal{G}_i$, initially empty
3:     for each $M \in \mathcal{G}_i$ do
4:         Calculate its $Creq$ and $Mreq$ in each type of GPU
5:         if $Creq > \max C$ or $Mreq > \max M$ (highest-capacity GPU) then
6:             return Infeasible_configuration
7:     Group the models into C-heavy and M-heavy models
8:     Sort two groups in descending order of $Creq + Mreq$:
       $\{M_1, M_2, \ldots, M_n\}$ and $\{M'_1, M'_2, \ldots, M'_m\}$
9:     final_model_list $\leftarrow \{(M_1, M'_1), (M_2, M'_2), \ldots, (M_n, M'_m)\}$
10:    for each $M \in$ final_model_list do
11:        MODEL_REPLICA_PLACEMENT_WITHIN_$\mathcal{G}_{iGPU}$()
12:        MODEL_REPLICA_PLACEMENT_OUTSIDE_$\mathcal{G}_{iGPU}$()
13:        for each model replica of $M$ do
14:            NEW_LOWEST_COST_GPU_INITIALIZATION()
15:            Assign the new GPU to $\mathcal{G}_{iGPU}$.
16:    for each $M \in \mathcal{G}_i$ do
17:        goodput$_M$ = min (achieved_goodput$_M$, workload$_M$)
18:    total_goodput = $\sum_M$goodput$_M$
19:    return additional costs for initializing new GPUs and
       total_goodput for the taken placement decision.
```

The placement algorithm is shown in Algorithm 2. USHER first calculates the Creq and Mreq for each model in each GPU type according to the configuration given as input using GK-Estimator (Lines 3-4). Then it further groups the models in the model group $\mathcal{G}_i$ into C-heavy and M-heavy models (Line 7). A model is C-heavy if its average C-req/M-req ≥ 1.2, and is M-heavy if M-req/C-req ≥ 1.2. Next, USHER sorts each of the two sub-groups in the descending order of the Creq+Mreq (Line 8). After that, USHER pairs up each two models from the two sub-groups to create final_model_list (Line 9). Finally, USHER inserts the models that are neither C-heavy nor M-heavy into the list while maintaining the descending order of Creq+Mreq.

Then, USHER picks up a pair or a model one by one from the list to be assigned to a GPU. Specifically, USHER calls the MODEL_REPLICA_PLACEMENT_WITHIN_$\mathcal{G}_{iGPU}$ function (Line 11). The function places as many model replicas of M as possible to the mode's GPU group (denoted by $\mathcal{G}_{iGPU}$). The GPU group of a model group is defined as the group of GPUs that hosts most of the model replicas of the model group. Basically, when USHER initializes a new GPU for any model replica of model group $\mathcal{G}_i$, the new GPU is added to the GPU group $\mathcal{G}_{iGPU}$. This way, USHER tries to place the model replicas in the same model group to the GPUs of the same GPU group. If multiple GPUs are available for a model or a pair, USHER chooses the one that leaves the lowest C-space+M-space after hosting it to avoid resource fragmentation.

After that, USHER calls MODEL_REPLICA_PLACEMENT_OUTSIDE_G_{iGPU} that places as many remaining model replicas of M as possible to the GPUs of the other GPU groups (Line 12). Finally, for each model replica that is not placed to any GPU yet, USHER calls NEW_LOWEST_COST_GPU_INITIALIZATION that initializes a new GPU of the GPU type that can host the model or pair with the minimum cost and assigns the GPU to G_{iGPU} (Lines 13-15). At last, the placement algorithm returns to the scheduling algorithm the additional costs for initializing the new GPUs and the total goodput across all the models (Line 19). As [14], goodput of a model is taken as the ratio between the batch size and the expected time (including in-queue wait time) to complete a batch. The execution time of a batch is calculated using the Time-Regressor in §3.2.

For the fixed cluster setup, the modifications are as follows. First, the maximum value of model replication degree is capped by the total number of GPUs in the cluster. Second, in Algorithm 1, USHER schedules as per the configuration for which the `total_goodput` is maximum.

3.4 Operator Graph Merging to Minimize Cache Interference

To minimize interference in GPU cache, among the models assigned to one GPU, USHER merges as many operator graphs of the models as possible into a single graph. To perform maximal operator graph merging, USHER first groups the models to sub-groups based on their architectural similarity (i.e., the structure and the constituting operators) (§3.4.1). Then, for each sub-group, motivated by O6, USHER decides which operators across multiple graphs to merge based on their weight similarity (§3.4.2). Finally, during the merging process, USHER extracts away the largest common weight submatrix between the operators that need to be merged and ensures that the matrix multiplications associated with the submatrix for different inputs of different models are processed at the same time, while the submatrix is in the GPU cache (§3.4.3).

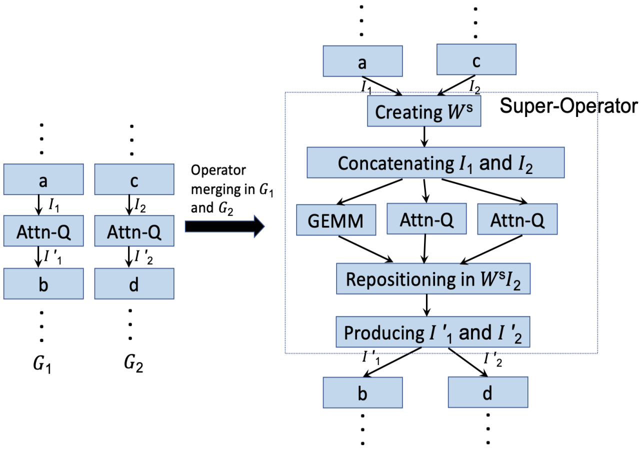


Figure 11: Operator merging in G_1 and G_2 to maximize GPU cache usage. Attn-Q refers to the Attention Query operator.

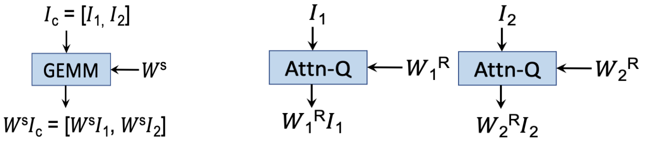


(a) Executing on W^s at the same time.

(b) Executing the remaining operations using separate operators.

Figure 12: Creating a new operator GEMM.

3.4.1 *Grouping Architectural-Similar Operator Graphs*

The models with architectural-similar operator graphs are more likely to have high similarity in their weights [54]. Based on this, USHER uses DBSCAN algorithm [57] to group the models assigned to a GPU based on architectural similarity. Given a set of elements, DBSCAN algorithm can cluster the elements with very little distance (i.e., 10^{-7}) between themselves within the same group, without requiring any predetermined number of groups or number of elements within a group. Inside DBSCAN algorithm, USHER uses graph edit distance [58] to calculate the distance to measure the architectural similarity between two operator graphs. Basically, the edit distance algorithm finds how many addition/deletion/replacement of operators need to be performed to make the two operator graphs identical. A shorter distance means higher architectural similarity.

3.4.2 *Graph Matching in an Architectural-Similar Group*

Among the models in an architectural-similar group. USHER first randomly takes two models. Then, it generates a bipartite graph $\mathcal{B}$ containing the operators of both models. An edge e exists between two vertices from the two graphs if and only if all of the following conditions are satisfied: (i) same type (i.e., either convolutional operator or attention operator), (ii) same starting time (explained in §3.2), (iii) the weight similarity between the operators (described in §2.4) is no less than ω (e.g., 40%). It is assigned as the edge weight.

After generating $\mathcal{B}$, USHER finds the maximal weighted matching using Hungarian algorithm [59] in $\mathcal{B}$, which chooses a set of independent edges (i.e., that do not share any common vertex) such that the sum of weights is maximized. The two endpoint operators of each of the chosen edges are matched and will be merged (explained in §3.4.2). Then, USHER randomly takes another model from the remaining models and generates a new bipartite graph $\mathcal{B}'$ using $\mathcal{B}$ and the other model by repeating the same procedure. This process repeats until no more models in the group can be merged.

3.4.3 *Operator Merging Process*

As an example of operator merging, we describe the process for two *Query* operators in the attention layers of two Transformer models. It is a matrix multiplication operation: $I'_1 = W_1 I_1$, where I_1 is the input and W_1 is the Query weight matrix. Now, we explain how USHER modifies this operation for operator merging. If I_1 and I_2, as well as W_1 and W_2, do not have the same size, we apply zero padding to make them the same size.

Fig. 11 shows the overall process of merging two Query operators of two graphs. USHER creates a Super-Operator to merge operators, which consists of several individual operators, each of which performs a specific task as described below. First, it extracts out the largest common submatrix between W_1 and W_2, denoted by A_{W_1,W_2} using template matching [60]. It creates a matrix W^s, which contains A_{W_1,W_2} at the same position as W_1 (or W_2), and zeros in other entries. It also creates another matrix W_1^R, which is the same as W_1, except that the entries associated with A_{W_1,W_2} are all zero, and creates matrix W_2^R from W_2 similarly. Second, as illustrated in Fig. 12a, USHER concatenates the inputs I_1 and I_2 into a matrix as

$I_c = [I_1, I_2]$ and creates a new general matrix multiplication (GEMM) operator that performs $W^s I_c = [W^s I_1, W^s I_2]$. This way, the new GEMM operator executes the matrix operations of the original two operators corresponding to A_{W_1,W_2} at the same time, while W^s is still loaded in the GPU cache, thus maximizing its usage.

Also, as illustrated in Fig. 12b, for each of the original operators, USHER creates a Query operator to perform the remaining matrix multiplication operations that are not associated with W^s: $W_1^R I_1$ and $W_2^R I_2$. Third, I_1' can be calculated simply as $I_1' = W^s I_1 + W_1^R I_1$. However, the entries in $W^s I_2$ need to be repositioned. This is because A_{W_1,W_2} is positioned in W^s according to its position in W_1. This repositioned $W^s I_2$ would be generated if A_{W_1,W_2} were positioned in W^s according to its position in W_2. Finally, after the repositioning, I_2' is calculated as $I_2' = W^s I_2 + W_2^R I_2$.

While merging a Super-Operator with another Query operator O_q, USHER merges each Query operator inside the Super-Operator with O_q.

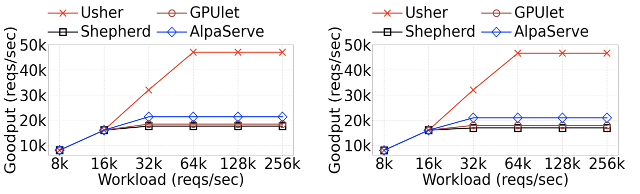
4 Implementation Details

We developed USHER using Python and the implementation is available at [61]. We used Tensorflow for the inference executions of the models, but note that our techniques are general and can be incorporated on other serving platforms. After the XLA operator graph optimization [62] is performed on the operator graph in TensorFlow, we converted it into the framework-independent ONNX format to ensure USHER works for other ML frameworks (e.g., PyTorch, MXNet) as well. We found the GPU kernels called by an ML framework during the execution of an operator by profiling the operator using Nvidia Nsight [52] with the `print-gpu-trace` option turned on. We used `achieved_occupancy` and `dram_utilization` options in Nsight to measure the Creq and Mreq of a kernel, respectively. In each GPU, we used Nvidia MPS [13] to divide the GPU computation resource among the models based on their requirements. After merging the operator graphs in ONNX format, we applied the TVM optimization [63] from Nvidia TensorRT [64] to further optimize the merged graph and executed the merged graph as a single `CUDA Context` in MPS, which was allocated the sum of `CUDA_MPS_ACTIVE_THREAD_PERCENTAGE`s assigned to the models whose operator graphs were merged.

5 Performance Evaluation

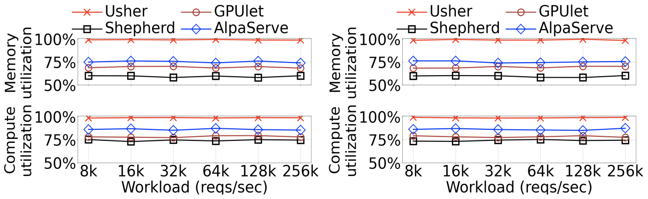
5.1 Experimental Setup

Unless otherwise specified, the experiment settings are the same as those in §2. In addition to the models described in Table 1, we also used two multi-model applications that include multiple DL models [2, 50]: video surveillance (SLO: 500ms) [2] and social media (SLO: 750ms) [65]. In addition to the Microsoft Azure Function trace 2019 (MAF1) with steady and dense request arrival rates, we also experimented with MAF trace 2021 (MAF2) with bursty arrival rates [66].



(a) MAF1 (b) MAF2

Figure 13: Goodput comparison of different methods in real testbed for a fixed cluster.



(a) MAF1 (b) MAF2

Figure 14: GPU computation and memory utilization comparison of different methods in real testbed for a fixed cluster.

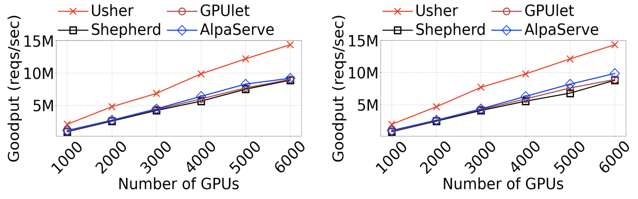
Testbed. We conducted both real testbed and simulation experiments. The real testbed is a cluster with 6 AWS EC2 p3.8xlarge servers, each of which consists of 4 V100 Nvidia GPUs and the GPUs are inter-connected via NVLinks. In the simulation, we increased the number of GPUs up to 6000 to simulate a large enterprise-grade GPU cluster [67]. As it is prohibitively expensive to actually execute the models using these many GPUs, we report the result directly from the scheduler decision, without actually running the models. In simulation, we experimented with tremendously large workloads reaching up to 15M requests/second to simulate the large workloads in enterprise-grade clusters. We tested for both fixed and non-fixed cluster setups. We compared USHER with Shepherd [3], GPUlet [14], and AlpaServe [4].

5.2 Comparison Results

Our key results include: USHER (i) achieves up to 2.6× higher goodput in a fixed cluster and (ii) requires up to 3.5× lower cost in a non-fixed cluster.

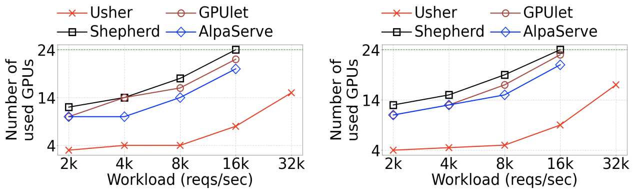
5.2.1 Fixed Cluster

Fig. 13 shows the average goodput in the real testbed with varying average workloads (averaged across the total duration of 2 weeks for a trace). Fig. 14 shows the average Cuti and Muti per GPU. USHER achieves 1×-2.6× higher goodput, 22%-24.2% higher Cuti and 38.9%-40.1% higher Muti compared to Shepherd. This is because USHER performs



(a) MAF1 (b) MAF2

Figure 15: Goodput comparison of different methods in simulation for a fixed cluster.



(a) MAF1 **(b) MAF2**

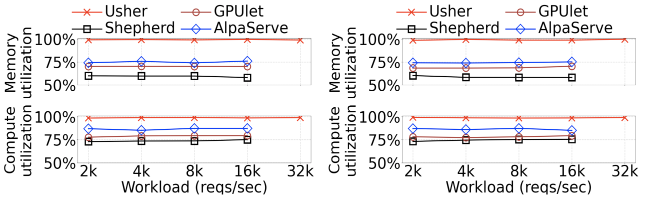
Figure 16: Number of used GPUs in real testbed for a homogeneous non-fixed cluster. The maximum number of GPUs was 24.

model multiplexing in each GPU in an interference-aware manner, whereas Shepherd allows only one model in each GPU. We observed that the models in each of the following sets were multiplexed in USHER for at least half the total duration of the experiment: {YOLO-v3, ResNeXt-101, Inception-v4, GNMT, BERT}, {ResNet-101, EfficientNet-B7, BERT, GPT-2}, {SqueezeNet, Llama-2}, and {R-CNN, ShuffleNet-v2, GNMT, GPT-2}.

USHER achieves 1×-2.2× higher goodput, 19%-23% higher Cuti and 25.1%-32.2% higher Muti compared to GPUlet and AlpaServe. GPUlet and AlpaServe only try to optimize the GPU computation use, while USHER addresses the interference between models not only in the computation space but also in the memory and cache spaces. Also, USHER has several strategies in its IR-scheduler such as multiplexing C-heavy models with M-heavy models and holistic workload division to maximize the utilizations of both computation and memory spaces. USHER performs consistently for both traces, indicating its resilience to different request arrival patterns. The minimal rescheduling overhead of USHER (i.e., 0.51s from Table 2) enables it to quickly adapt to the bursty workload of MAF2. Nonetheless, if the workload exhibits very frequent burstiness, then the benefits of USHER may be reduced. However, such extreme workloads are uncommon in real-world settings [3, 4] (e.g., the production workload illustrated in §5.4, where burstiness occurs after every 45s-300s) and thus the rescheduling overhead of USHER is reasonable enough to not have any adverse impact on its performance.

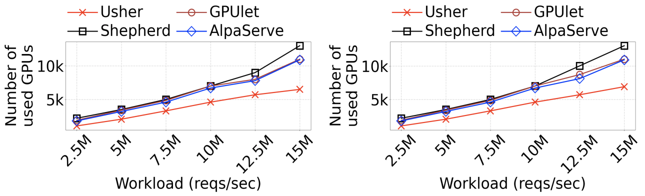
Goodput of USHER becomes stable at around 47k reqs/s, whereas Shepherd, GPUlet, AlpaServe become stable at much less goodput values. At this point, the method has used up all the GPU resources in the fixed cluster. Fig. 14 establishes that merely increasing the workload cannot saturate the GPUs. This is because it is the batch size that mainly determines the resource consumption of a model and a system cannot choose a larger batch size that leads to a latency exceeding the SLO. To cope up with the increased workload, a system scales out, i.e., increases the number of used GPUs.

Fig. 15 shows the goodput in simulation with varying number of V100 GPUs. USHER achieves 1.5×-1.9× higher goodput compared to the comparison methods due to the same reasons described above. With the increase in the number of GPUs, the goodput of USHER increases 1.6×-2.1× faster than other methods, indicating the higher scalability of USHER.



(a) MAF1 **(b) MAF2**

Figure 17: GPU computation and memory utilization of different methods in real testbed for a homogeneous non-fixed cluster.



(a) MAF1 **(b) MAF2**

Figure 18: Number of used GPUs of different methods in simulation for a homogeneous non-fixed cluster.

5.2.2 *Non-fixed Cluster*

For the non-fixed cluster, we first considered homogeneous V100 GPUs. Then, the cost is proportional to the number of used GPUs. We report the average number of GPUs required by a method at a second. Next, we considered heterogeneous GPUs: K80, V100, A100, and H100. The GPU types have varying costs following AWS on-demand pricing [68].

Homogeneous GPUs. Fig. 16 shows the number of used GPUs in a homogeneous real testbed to complete all inference requests within their SLOs. Fig. 17 shows the average Cuti and Muti per GPU. USHER requires 2.5×-3× fewer GPUs, and achieves 19.3%-24.4% and 24.9%-40% higher Cuti and Muti, respectively, compared to Shepherd, GPUlet, and AlpaServe. As the comparison methods either do not employ multiplexing or suffer from increased latency due to inter-model interference, they require more GPUs.

Fig. 18 shows the number of used GPUs in simulation. USHER uses 1.7×-2.1× fewer GPUs due to the same reasons explained above. In both real testbed and simulation, with the increase of the workloads, the increase rate in the number of GPUs of USHER is slower than other methods especially when the workload is very high. These results show the cost-effectiveness of USHER even for large workloads.

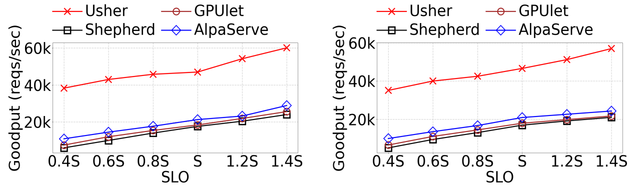
shows the average Cuti and Muti per GPU. USHER requires 2.8×-3.5× lower cost, and achieves 19%-24.1% and 25.2%-40.3% higher Cuti and Muti, respectively, due to the same reasons explained above. USHER performs slightly better for heterogeneous GPUs compared to homogeneous GPUs as USHER can choose the optimal GPUs from varying GPU types depending on their cost-performance trade-offs.



(a) MAF1 **(b) MAF2**

Figure 22: Goodput comparison with varying SLO values in real testbed for a fixed cluster. S denotes the default SLO (Table 1).

Fig. 21 shows the cost per hour in simulation. USHER incurs 1.9×-2.2× lower cost for the same reasons described above. With the increase in workload, its cost increases slower than other methods, especially when the workload is very high.

Overheads. Table 2 presents the average time overhead and average impact on accuracy of different methods. USHER's grouping of models takes only 0.1s and it needs to be updated only when there is addition or deletion of models in the system. The decision-making times of the scheduling in different methods are comparable. This is because all the methods employ time-efficient heuristics to accelerate the scheduling process in order to excel in autoscalability when workload changes (§5.4). USHER's operator graph merging takes slightly more time than its scheduling. Hence, after the scheduling, the requests are executed using individual model graphs. After the graphs are merged, the requests are then executed on the merged graph. For the models whose GPU placement has changed during scheduling, each method takes 0.69s-0.72s to load the models from host memory to GPU memory. Table 3 presents the average model loading time of USHER for each model shown in Table 1. Rescheduling does not happen so frequently [3,4], e.g., after every 45s-300s from Fig. 24. As a result, considering the scheduling time required in USHER, there is enough time left before another scheduling occurs to realize the benefits of USHER. The accuracy loss is only 0.0003% per request batch of a model due to the operator graph merging. This is because, while finding the longest common submatrix in the merging process, USHER takes two weight values as the same only when their absolute difference is very low (i.e., $\leq 10^{-7}$) (§2.4). Table 3 shows the average accuracy loss per request batch for each model in USHER.

Figure 23: Number of used GPUs with varying SLO values in real testbed for a homogeneous non-fixed cluster. The maximum number of GPUs was 24. S denotes the default SLO (Table 1).

Table 2: Overheads of the methods.

Methods	Grouping of models	Scheduling algorithm		Operator graph merging based on weight similarity	Impact on model accuracy due to operator graph merging
		Decision making	Model loading		
USHER	0.1s	0.51s	0.63s	2.3s	-0.0003%
Shepherd	0	0.5s	0.62s	0	0
GPUlet	0	0.46s	0.64s	0	0
AlpaServe	0	0.63s	0.65s	0	0

5.3 Performance on Varying SLOs

5.3.1 Fixed Cluster

Fig. 22 shows the goodput with varying SLO values in the same real testbed setup of Fig. 13 with workload=256k reqs/sec. In the figure, S denotes the default SLO of each model as defined in §2, and $m_f S$ denotes that the SLO is multiplied by $m_f \in \{0.4, 0.6, 0.8, 1, 1.2, 1.4\}$. USHER achieves 2.2×-2.7× higher goodput than the comparison methods for the same reason described in §5.2.1. As SLO decreases, goodput also decreases for each method. This is because, in the fixed GPU resources of the cluster, more requests miss their SLO deadlines as the SLO becomes stricter. The result shows that USHER retains its higher goodput compared to the existing methods even when the SLO is ultra-low.

5.3.2 Non-fixed Cluster

Fig. 23 shows the number of used GPUs with varying SLO values in the same real testbed setup of Fig. 16 to complete all inference requests within their SLOs with workload=8k reqs/sec. The result shows that USHER achieves 3.2×-4.3× fewer GPUs than the comparison methods for the same reason

Table 3: Model loading and accuracy overheads in USHER.

Model name	Model loading	Impact on model accuracy due to operator graph merging
YOLO-v3	0.44s	-0.0002%
R-CNN	0.57s	-0.0003%
MobileNetSSD-v2	0.495s	-0.0003%
ResNet-50	0.51s	-0.0002%
ResNet-101	0.586s	-0.0004%
ResNeXt-50	0.531s	-0.0004%
ResNeXt-101	0.7s	-0.0003%
SqueezeNet	0.31s	-0.0001%
ShuffleNet-v2	0.39s	-0.0002%
MobileNet-v2	0.395s	-0.0002%
DenseNet-121	0.4s	-0.0002%
DenseNet-201	0.49s	-0.0002%
Inception-ResNet-v2	0.6s	-0.0002%
Inception-v3	0.53s	-0.0003%
Inception-v4	0.58s	-0.0003%
EfficientNet-B7	0.64s	-0.0004%
GNMT	0.89s	-0.0002%
BERT	0.78s	-0.0004%
GPT-2	1.18s	-0.0004%
Llama-2	1.59s	-0.0003%

described in §5.2.2. As SLO decreases, the number of used GPUs increases for each method. This is because each method needs to create more replicas of a model to execute more requests in parallel as the SLO becomes stricter. Otherwise, the requests would have to wait longer for the required GPU resource, leading to SLO violation. The result shows that USHER retains its superior cost-efficiency compared to the existing methods even when the SLO is very strict.

5.4 Microanalysis on Autoscalability

To better evaluate the system autoscalability during rescheduling, we measured the number of used GPUs and the in-queue wait time of a request at each second during a randomly chosen window of 1000 seconds. We used the MAF2 trace in the homogeneous non-fixed cluster real testbed. Fig. 24 shows the results. Each method increases the number of GPUs when the workload surges up and decreases it when the workload surges down. USHER requires 1.6×-3.9× fewer GPUs compared to the comparison methods, due to its interference-minimizing and resource utilization-maximizing design. The in-queue wait time is almost the same for all the methods and also varies by only 0.8ms-1.4ms as the workload surges up or down. This means that all the methods excel in autoscalability, but USHER requires much fewer GPUs.

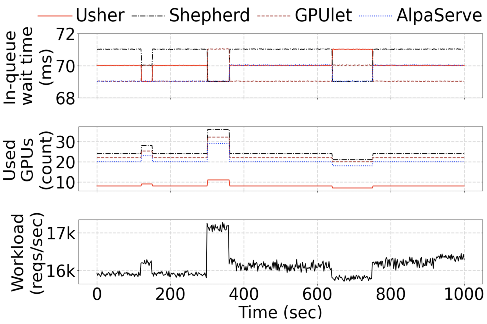

Figure 24: Microanalysis on autoscalability.

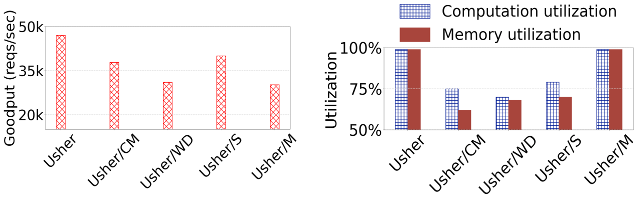
Table 4: Performance of USHER's GK-Estimator.

Methods	Accuracy of computation requirement calculation	Accuracy of memory requirement calculation	Cost	Time
USHER's GK-Estimator	99.98%	99.98%	**0**	**31.6ms**
Profiling	**100%**	**100%**	42.7$	4.8hr



(a) Goodput **(b) GPU utilization**

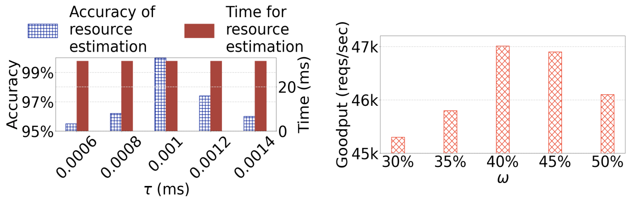
Figure 25: Performance of different variants of USHER.

5.5 Ablation Study

In this section, we evaluate the effectiveness of each proposed strategy of USHER. We first evaluated the cost- and time-efficiency of USHER's GK-Estimator compared to the existing profiling approaches in estimating the resource requirements of a new model. Table 4 shows the results averaged across the models in Table 1. The GK-Estimator takes 100% less cost and time with comparable accuracy. This is because the profiling approach needs to actually execute the model in the GPUs for different BSs and GPU types, whereas USHER's GK-Estimator only needs to analyze the kernel-level computation graph.

To measure the effectiveness of the other methods in USHER, we created several variants of USHER as follows. 1) USHER/CM skips the step to classify the models in a group to C-heavy and M-heavy. 2) USHER/WD does not conduct workload division between multiple GPUs if one GPU can support the workload to satisfy the SLO. 3) USHER/S does not sort the models based on their computation and memory requirements. 4) USHER/M does not have the OG-Merge.

Fig. 25 shows the goodput and GPU utilization performance of USHER and its different variants in the same setup as Fig. 13a with workload=256k reqs/s. The results show that USHER achieves 24.3%-51.6% higher goodput than USHER/CM, USHER/WD, and USHER/S. This is because, by skipping a method in each of these variants, the Cuti and Muti decrease by 24%-41.4% and 42%-59.6%, respectively, resulting in much lower goodput. USHER achieves 55.7% higher goodput than USHER/M because OG-Merge reduces the interference in GPU cache, resulting in lower latency.



(a) Impact of τ **(b) Impact of ω**

Figure 26: Sensitivity of USHER on its parameters.

5.6 Sensitivity on Parameters

We did the following experiments in the fixed cluster real testbed setup using MAF1 trace with 256k reqs/s workload.

Impact of τ (in §3.2). Fig. 26a shows the accuracy and time for resource estimation of a model with varying values of τ. All τ values lead to the same time for resource estimation. However, we chose $\tau = 0.001$ms as it leads to the highest accuracy of resource estimation since it can correctly capture which GPU kernels will be executed concurrently.

Impact of ω (in §3.4.2) Fig. 26b shows the goodput of USHER for different values of ω. We chose $\omega = 40\%$ as it provides the highest goodput. When $\omega > 40\%$, the number of operators that can be merged is reduced, leading to higher cache interference. When $\omega < 40\%$, more operators can be merged. However, the overhead of additional operations in Fig. 11 outweighs the benefit.

6 Limitations and Discussion

Precision Quantization. The current version of USHER implements FP16 quantization of weights. In the future, we will explore the impact of various precision quantizations (e.g., FP8, FP32) on various factors such as accuracy, interference, and resource utilization and extend USHER to adaptively select the most suitable precision quantization for each model based on the above factors.

Model Parallelism. USHER supports model parallelism out of the box for large models. We assume that model parallelism is enabled by the underlying framework (e.g., DeepSpeed decides how to do model parallelism on Llama-2 in our experiments (§2)), and USHER simply uses it. An interesting future work would be to jointly optimize the model parallelism and placement strategies of USHER to further enhance the resource utilization.

7 Related Work

Inference Serving Systems without Spatial Multiplexing. Many of the systems avoid spatial multiplexing of models within a GPU to prevent inter-model interference [3, 7, 11, 65, 69–81]. Shepherd [3] aggregates request streams into similar-sized groups for high computation utilization and schedules placement to maximize goodput within each group. Several methods [7, 65, 71–76] rely on profiling to find the optimal request batch size for each model, aiming for high GPU utilization and goodput. However, these methods suffer from low resource utilization due to lack of spatial multiplexing (§2.1). Additionally, offline profiling to calculate the resource requirements of a model is time-consuming and costly.

Inference Serving Systems with Spatial Multiplexing. A set of systems adopt spatial multiplexing to enhance GPU utilization while maximizing goodput [1, 2, 4, 12, 14, 21, 23, 50, 82–85]. GPUlet [14] proposes a heuristic for placing models in GPUs to maximize computation space utilization. AlpaServe [4] explores the best placement scheduling by leveraging model parallelism. However, due to inter-model interference in spatial multiplexing, these systems may suffer from longer inference latency (§2.1). Additionally, these systems fail to maximize both GPU computation and memory utilizations (§2.1). Orion [86] is a recent work that maximizes resource utilization by spatially multiplexing the best-effort jobs (e.g., training), while avoiding multiplexing the high-priority jobs (e.g., inference) so that they are not impacted by inter-model interference. However, in our scenario where all the jobs are high-priority inference, Orion will fail to maximize utilization due to the lack of multiplexing. A group of methods [21–23] propose merging layers and sharing parameter weights across multiple models to reduce the memory requirement. However, the merging processes cannot solve the interference in GPU cache as they do not maximize the usage of cache contents.

8 Conclusion

Spatial multiplexing has the potential to increase resource utilization of the GPUs to design a cost-efficient inference serving system. However, it requires careful system design to address the challenges of spatial multiplexing, i.e., maximizing the utilizations of both computation and memory spaces, while minimizing inter-model interference. To this end, we propose USHER. USHER has a lightweight interference-aware scheduler that schedules the models to jointly maximize GPU computation and memory utilizations. During the scheduling, USHER uses a novel lightweight GPU kernel-based estimator to compute the resource requirement of each model. Finally, USHER has a novel operator graph merging approach to minimize interference in GPU cache. Experimental results on both real testbed and large-scale simulations show that USHER achieves up to 2.6× higher goodput and 3.5× better cost-efficiency compared to existing systems.

Acknowledgments

We sincerely thank the anonymous reviewers of OSDI and our shepherd for their invaluable feedback. We are grateful to Kevin Skadron for the discussion on GPU architecture. This research was supported in part by U.S. NSF grants NSF-1827674, NSF-2206522, NSF-1822965, FHWA grant 693JJ31950016, Microsoft Research Faculty Fellowship 8300751, and Commonwealth Cyber Initiative (CCI), an investment in the advancement of cyber research, innovation, and workforce development. Abstract

High-demand LLM inference services (e.g., ChatGPT and BARD) support a wide range of requests from short chat conversations to long document reading. To ensure that all client requests are processed fairly, most major LLM inference services have request rate limits, to ensure that no client can dominate the request queue. However, this rudimentary notion of fairness also results in under-utilization of the resources and poor client experience when there is spare capacity. While there is a rich literature on fair scheduling, serving LLMs presents new challenges due to their unpredictable request lengths and their unique batching characteristics on parallel accelerators. This paper introduces the definition of LLM serving fairness based on a cost function that accounts for the number of input and output tokens processed. To achieve fairness in serving, we propose a novel scheduling algorithm, the Virtual Token Counter (VTC), a fair scheduler based on the continuous batching mechanism. We prove a 2× tight upper bound on the service difference between two backlogged clients, adhering to the requirement of work-conserving. Through extensive experiments, we demonstrate the superior performance of VTC in ensuring fairness, especially in contrast to other baseline methods, which exhibit shortcomings under various conditions. The reproducible code is available at `https://github.com/Ying1123/VTC-artifact`.

1 Introduction

In a very short time, Large Language Models (LLMs), such as ChatGPT-4 Turbo [36], have been integrated into various application domains, e.g., programming assistants, customer support, document search, and chatbots. The core functionality rendered by LLM providers to these applications is serving their requests. In addition to the response accuracy, the request response time is a key metric that determines the quality of service being provided. Furthermore, LLM providers seek to utilize their resources efficiently so they can reduce costs and increase their competitiveness in the market.

Today's LLM serving systems [20, 24] typically use First-Come-First-Serve (FCFS) to schedule incoming requests. While simple, this scheduling discipline has several drawbacks. One such drawback is the lack of *isolation*: a client sending a disproportionate number of requests can negatively impact the service of all the other clients sharing the same server (i.e., slow down their requests or even cause timeouts) even when they send very little traffic. In multi-tenant personalized serving (S-LoRA [43], Punica [8]) that uses a dedicated adapter for each user, it is important to ensure fairness among the adapters as well. One solution to address this problem is to limit the incoming load of each client. Many of the existing LLM services do this today by imposing a request-per-minute (RPM) limit [37] for each client.

Unfortunately, RPM can lead to low resource utilization. A client sending requests at a high rate will be restricted even if the system is underutilized. This leads to wasted resources, an undesirable situation given the cost and the scarcity of GPUs. Thus, we want a solution that provides not only isolation (like RPM limit) but also high resource utilization.

This is a common problem in many other domains like networking and operating systems. The solution of choice to achieve both isolation and high resource utilization in those domains has been *fair queueing* [30]. Fair queueing ensures that each client will get their "fair share". In the simplest case, if there are n clients sharing the same resource, the fair share is at least $1/n$ of the resource, which means that each client gets at least $1/n$ of the resource. Furthermore, if some clients do not use their share, other clients with more demands can use it, hence leading to higher resource utilization.

In this paper, we apply fair sharing to the domain of LLM serving at the token granularity. We do it at the token rather than request granularity to avoid unfairness due to request heterogeneity. Consider two clients, client A sends requests of 2K tokens each (both input and output), and client B sends requests of 200 tokens each. Serving an equal number of

[*] Part of the work was done when Ying was visiting UC Berkeley.

requests for each client would be unfair to client B as her requests consume much fewer resources than client A's requests. This is similar to networking where fair queuing is typically applied to the bit granularity, rather than packet granularity.

Despite these similarities, we cannot directly use the algorithms developed for networking and operating systems, as LLM serving has several unique characteristics. First, the request output lengths are unknown in advance. In contrast, in networking, the packet lengths are known before the packet is scheduled. Second, the cost of each token can vary. For instance, the cost of processing an input (prompt) token is typically lower than that of an output token, because input token processing is parallelizable. In contrast, the cost of sending a bit or the cost of a CPU time slice are the same irrespective of the workload. Third, the *effective* capacity of an LLM server (i.e., processing rate expressed in token/sec when the request queue is non-empty) can vary over time. For example, longer input sequences take more memory. This limits the number of batched parallel requests during generation, leading to GPU under-utilization and a lower processing rate. In contrast, the network or CPU capacity is assumed to be fixed.

In this paper, we discuss the factors that need to be considered when defining fairness in the context of LLM serving. We show how different definitions can be incorporated into a configurable service cost function in Section 3. While the cost function can be customized, a simple metric of counting input and output tokens at different prices is extensively used in analysis for the sake of simplicity. We then present a fair scheduling algorithm called *Virtual Token Counter (VTC)* that can be easily adapted for different service cost functions. At a high level, VTC tracks the services received for each client and will prioritize the ones with the least services received, with a counter lift each time a client is new to the queue. It updates the counters at a token-level granularity on the fly, which addresses the unknown length issue. VTC integrates seamlessly with current LLM serving batching techniques (Section 2.1), and its scheduling mechanism does not depend on the server's capacity, overcoming the problem of the dynamically fluctuating server capacity. We also provide theoretical bounds of fairness for VTC in Section 4.1. The serving architecture of VTC is illustrated in Figure 1.

In summary, this paper makes the following contributions:

- This is the first work to discuss the fair serving of Large Language Models to the best of our knowledge. We identify its unique challenges and give the definition of LLM serving fairness (Section 3).
- We propose a simple yet effective fair-serving algorithm called VTC. We provide rigorous proofs for VTC on fairness guarantee, which gives fairness bound within 2× of the optimal bound (Section 4).
- We conduct in-depth evaluations on our proposed algorithm VTC. Results confirm that our proposed algorithms are fair and work-conserving (Section 5).

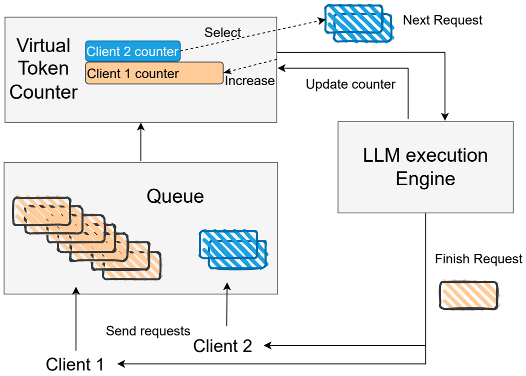

Figure 1: Serving architecture with Virtual Token Counter (VTC), illustrated with two clients. VTC maintains a queue of requests and keeps track of tokens served for each client. In each iteration of the LLM execution engine, some tokens from some clients are generated. The counters of these clients are correspondingly updated. When the condition of adding new requests is satisfied (e.g. memory is released when some other requests finish), VTC will be invoked to choose the requests to be added. VTC achieves fairness by prioritizing clients with the lowest counter and carefully handling clients' leave and rejoin (Section 4.1).

2 Background

In this section, we first introduce how an LLM serving system operates. Then we describe existing methods for ensuring fairness in LLM serving.

2.1 Large Language Models Serving

LLM serving with a single request First, a request contains information about its arrival time (a), input tokens (x), and its associated client (u). Formally, we represent a request using a three-tuple (a, x, u). The system generates output tokens based on the input tokens. For instance, the input tokens can be an incomplete sentence, and the system generates the rest of the sentence [35].

The generation procedure consists of two stages: the initial **prefilling** stage, and the **decoding** stage [39]. Mathematically, x is a sequence of tokens $(x_1, x_2, ..., x_n)$. In the prefilling stage, the LLM computes the probability of the first new tokens: $P(x_{n+1}|x_1, ..., x_n)$. In the decoding stage, the system *autoregressively* generates a new token. At time t ($t \geq 1$), the process is written as: $P(x_{n+t+1}|x_1, ..., x_{n+t})$.

The decoding stage ends when the LLM generates a special end-of-sentence (EOS) token or the number of generated tokens reaches a pre-defined maximal length.

LLM serving with multiple requests In the online serving scenarios, multiple clients submit requests to the serving system. To process these requests, the system maintains two concurrent streams: A monitoring stream adds requests to a waiting queue; an execution stream selects and executes request(s) from the waiting queue.

Naively, the execution stream can choose to execute requests one by one. However, this is highly GPU inefficient due to various natures of the LLM generation procedure. For instance, the decoding steps must be carried out sequentially where the arithmetic intensity is relatively low in a single step. Contemporary serving systems usually perform batching that executes multiple requests concurrently to maximize the system throughput. The most widely used approach in LLM serving is continuous batching [50]. Algorithm 1 shows the pseudocode for continuous batching.[2] The monitoring stream enqueues requests to a waiting queue. The execution stream performs a check on whether there are finished requests at the end of each decoding step. If there are, the system removes these requests and adds new requests from the queue.

Fairness with continuous batching We can naturally integrate fairness policies into the continuous batching algorithm, by designing a fair `select_new_requests()` function in Algorithm 1. Intuitively, the execution stream should keep track of how much service a particular client has received, and prioritize clients that haven't received much service in the next selection. We formally define fairness in the LLM serving context in Section 3 and design a method with theoretical guarantee in Section 4.

We adopt a continuous batching scheme in which a request only leaves the batch when it generates an EOS token or reaches the pre-defined maximum number of generated tokens (i.e., no preemption). This paper focuses on integrating fair scheduling with continuous batching, and we leave an investigation on preemption as an orthogonal future work (discussed in Appendix C.3).

Algorithm 1 LLM serving with Continuous batching

```
Initialize current batch $B \leftarrow \emptyset$, waiting queue $Q \leftarrow \emptyset$
▷ with monitoring stream:
while True do
    if new request $r$ arrived then
        $Q \leftarrow Q + r$
▷ with execution stream:
while True do
    if can_add_new_request() then
        $B_{new} \leftarrow$ select_new_requests(Q)
        prefill($B_{new}$)
        $B \leftarrow B + B_{new}$
    decode($B$)
    $B \leftarrow$ filter_finished_requests($B$)
```

2.2 Existing Fairness Approaches

Fairness is a key metric of interest in computer systems that provide service to multiple concurrent clients [5]. A *fair* LLM serving system should protect clients from a misbehaving client who may try to overload the serving system by submitting too many requests.

RPM Limit Per Client As a common practice of API management (e.x. [37]), specific rate limits are established for each client's API usage to prevent potential abuse or misuse of the API and ensure equitable access for all clients. This limitation is on the metric request-per-minute (RPM). Once a client reaches the RPM limit, the client is only allowed to submit more requests in the next time window. However, it's important to note that while these limits are effective in managing resource allocation during periods of high demand, they may not be *work-conserving* when the number of active clients is low. In such scenarios, the system's capacity might be underutilized, as the imposed limits prevent the full exploitation of available resources.

Fair Queueing [30] The fairness problem has been extensively studied in the past for traditional compute resources, such as CPU cycles and network bandwidth. Fair queuing and its variants (e.g., Weighted Fair Queuing (WFQ) [11], Self-clocked Fair Queueing [15], and Start-time Fair Queueing (SFQ) [17]) have been proposed to achieve the fair allocation of link bandwidth in packet-switching networks.

In the traditional packet-switching network, a *flow* f is referred to as a sequence of packets $p_f^0, p_f^1, \dots p_f^n$ transmitted by a source. Each packet p_f^j is of length l_f^j. A flow is *backlogged* during the time interval $[t_1, t_2)$ if it has one or more outstanding packets waiting in the queue at any time $t \in [t_1, t_2)$.

All fair queueing algorithms maintain a system *virtual time*, $v(t)$, which intuitively measures the service received by a continuously backlogged flow in terms of bits forwarded. Each packet, p is associated two tags: *Start* tag $S(p)$ and a *Finish* tag $F(p) = S(p) + l_p$. The Start tag (a.k.a. packet's virtual starting time) is computed based on both the system virtual time and the Finish tag (a.k.a. packet's virtual finishing time). These algorithms schedule packets in the ascending order of either the Finish or Start tags.

In networking, fairness is simply defined as follows: for any two flows, f and g, that are backlogged during time interval $[t_1, t_2)$, we have

$$\left|W_f(t_1, t_2) - W_g(t_1, t_2)\right| \leq U(f, g), \qquad (1)$$

where $W_f(t_1, t_2)$ and $W_g(t_1, t_2)$ denote the service received in bits by flow f and g, respectively, during interval $[t_1, t_2)$, and $U(f, g)$ is a function of the properties of flows f and g (e.g., maximum packet length) and the system (e.g., link capacity).

[2] For a simple presentation, we consider an implementation that only uses continuous batching for decode steps but keeps the prefill step separated. as how TGI [21] adopted the original proposed iteration-level scheduling in Orca [50]. For more discussions, see Appendix C.1.

Intuitively, for packets-switching networks, the allocation of a link bandwidth is fair if, for any time interval during which two flows are backlogged, each of these flows receives approximately the same service in terms of the number of bits being forwarded during that interval. A scheduling algorithm is said to be *work-conserving* if a link always forwards packets when the queue is not empty [23].

There exists a distinct strand of research [3, 6, 47] focusing on the fair scheduling of preemptible tasks (e.g., CPU scheduling). The Completely Fair Scheduler (CFS) [1], implemented in Linux 2.6.23 and applying fair queuing to CPU scheduling, is closely related to our algorithm. In CFS, a "vruntime" is maintained for each task, and the task with the smallest "vruntime" is scheduled next. The tasks can be presented with a small time slice, aiming to maximize overall CPU utilization while also maximizing interactive performance.

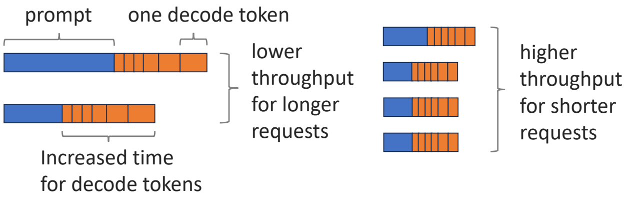
2.3 Challenges

There are several unique challenges in LLM serving that prevent a direct application of fair-queuing-like algorithms. The first challenge is that the definition of fairness in the context of LLM serving is unexplored, and likely very different than that discussed in fair-queuing literature.

Traditional fairness is defined by measuring the cost of requests, which is usually a fixed value that is easy to estimate in either network or operating systems. For example, in networking, requests correspond to packets, and the cost is usually the number of bits of a packet. However, in LLM generations, how to define the cost of a request is not obvious. The cost per token can vary. Especially, processing an input (prompt) token is typically less expensive than processing an output token, as input tokens are processed in parallel while output tokens must be generated sequentially. Batching the output tokens from different requests can parallelize the fully connected layers but is still slower than processing input tokens for the attention layers.

Additionally, in LLM serving, the server has variable token-rate capacity, although the memory allocated for a batch is constant. Firstly, even if the request queue is not empty, we are not guaranteed that each batch is full. This is because we need to preserve spaces for future generated tokens, and also because the tokens added to the batch are not at the token but the request granularity. Secondly, the number of tokens processed highly depends on the requests' arrival patterns because of the continuous batching mechanism (Section 2.1). Furthermore, the capacity depends on the mix between input and output tokens of existing requests. If all requests have long past tokens, then the capacity is likely to be low (See Figure 2). Then there is no way to define a fixed amount of equal share.

The second challenge is the characteristic of unknown output length before finishing a request. This prevents a direct adaptation of classical algorithms like SFQ and Deficit Round Robin (DRR) [45] into the LLM serving. SFQ-style algorithms can provide good bounds in fairness by setting the Start and Finish tags through virtual time, as introduced in Section 2.2. However, computing Start and Finish tags requires knowing the request length in advance. DRR performs round-robin scheduling with a "deficit counter" mechanism to achieve fair scheduling of packets of variable length. In DRR, each client is assigned a specific quantum of service. It tracks the "deficit" of service for each client to ensure fairness over time. During each round, the scheduler allows each client to dispatch as many requests as possible, provided that the total length of these requests does not exceed the sum of the client's assigned quantum for that round and any accumulated deficit from previous rounds. Without knowing the length in advance, DRR cannot determine how many jobs can be scheduled within the quantum. Compared to CPU scheduling, although exploring adequate preemption is worthwhile in LLM serving, it cannot occur frequently. We need to define service fairness in LLM serving and operate at the granularity of individual tokens when frequent preemption is not possible. Additionally, the Completely Fair Scheduler (CFS) in CPU scheduling does not account for the concurrency of each task. It seeks fairness among individual tasks rather than among streams of tasks that can be executed concurrently. [3]



prompt
one decode token
lower throughput for longer requests
Increased time for decode tokens
higher throughput for shorter requests

Figure 2: An illustration of how request length can affect the cost and server capacity in terms of throughput. The visualized length is not precise but for illustration purposes only.

We will give the definition for LLM serving fairness in Section 3 and give a scheduling algorithm to achieve the LLM serving fairness in Section 4. We will outline our algorithm in a basic format for clarity, while details on its general form and integration with existing serving frameworks can be found in Appendix C.1. Although our algorithm is closely related to CFS, we also discuss the adaptation of DRR in Appendix C.2. Further discussions on future work are included in Appendix C.3.

3 Definition of Fairness in LLM Serving

In this section, we discuss the cost of a request, and the measurement of the service a client has received (Section 3.1). After defining the measurement of service, we can define fairness among clients in Section 3.2.

[3] Our algorithm does not consider preemption. Discussion about preemption is in Appendix C.3.

Notation	Explanation
$W_f(t_1,t_2)$	service received by f during interval $[t_1,t_2)$ (write as $W(t_1,t_2)$ when f is clear in the context)
n_p	number of processed input tokens
n_q	number of processed output tokens
w_p	weight of input tokens in the cost function
w_q	weight of output tokens in the cost function
$h(n_p,n_q)$	customized cost function
c_i	virtual token counter for client i
Q	waiting queue of requests to be processed
$i \in Q$	$\exists r \in Q$, r is a request from client i
L_{input}	maximum number of input tokens in a request
L_{output}	maximum number of output tokens in a request
M	maximum number of tokens that can be fitted in a running batch
U	invariant bound: $\max(w_p \cdot L_{input}, w_q \cdot M)$

Table 1: The upper half includes notations for service measurement. The lower half includes notations for the VTC algorithm and its analysis. The terms n_p, n_q can refer to either a single request or a single client, depending on the context.

3.1 Measurement of Service

In this subsection, we discuss the measurement of the service a client has received. Specifically, we define $W_f(t_1,t_2)$ and $W_g(t_1,t_2)$ from Equation (1) in the context of LLM serving. We omit the subscript and write $W(t_1,t_2)$ when the client is clear from the context or is irrelevant. The number of processed input and output tokens are denoted as n_p, n_q. Notations that will be introduced and used multiple times in this paper are summarized in Table 1.

Number of tokens A straightforward way to measure the service provided to a client is by summing the number of input tokens that have been processed and the number of output tokens that have been generated so far, i.e., $W(t_1,t_2) = n_p(t_1,t_2) + n_q(t_1,t_2)$ during the time window $[t_1,t_2)$.

Number of FLOPs Alternatively, one can measure the total FLOPs used in each stage, i.e., $W(t_1,t_2) = FLOP_{input}(t_1,t_2) + FLOP_{output}(t_1,t_2)$. This can be more precise because it captures the difference among tokens in attention computation, where tokens with longer prefixes require more computation.

However, both of these formulations cannot accurately reflect the actual LLM serving cost: The computation of the tokens at the prefill stage can be parallelized and achieve high GPU utilization. However, at the generation stage, we can only generate tokens one by one, as each token depends on all previous tokens as described in Section 2.1.

Weighted number of tokens To better reflect the actual LLM serving cost, a more accurate measure should capture the difference in costs of the prefilling and generation phases. One simple way to implement this idea is by using a weighted combination of the prefilling (input) tokens and decoding (output) tokens, inspired by the pricing mechanism used in OpenAI's API[4]. Formally, let w_p be the weight of input tokens and w_q be the weight of output tokens. Then, we have $W(t_1,t_2) = w_p \cdot n_p(t_1,t_2) + w_q \cdot n_q(t_1,t_2)$. Due to its simplicity, we will use this measure extensively in our analysis and evaluation.

Customized, unified representation. The definition of fairness in LLM serving can also be extended to other aspects, such as the weighted number of FLOPs or a more sophisticated method introduced in [31] that uses piecewise linear functions for the number of input and output tokens. Generally, the service can be represented as a function of the number of input and output tokens (n_p, n_q, respectively). Let $h(n_p,n_q)$ be the cost function that is monotonically increasing according to n_p and n_q. Our method can easily accommodate different h (Section 4.2).

3.2 Fairness in LLM Serving

In this paper, we apply fair sharing to the domain of LLM serving to provide performance isolation across multiple clients sharing the same LLM server. In particular, we employ the classic formulation of max-min fairness [5], which computes a *fair share* for the clients sharing a given server. In a nutshell, given the metric of service fairness, if a client sends requests at no more than its fair share, all its requests are served. In contrast, if a client sends requests at more than its fair share, its excess requests will be delayed or even dropped. As a result, a misbehaving client cannot deny the service to other clients, no matter how many requests it sends. To achieve max-min fairness, an idealized serving system follows desirable properties as below:

1. **Backlogged clients** Any two clients f,g that are continuously backlogged during a given time interval $[t_1,t_2)$ should receive the same service during this interval, i.e. $W_f(t_1,t_2) = W_g(t_1,t_2)$.

2. **Non-backlogged clients** Client f that is continuously backlogged during time interval $[t_1,t_2)$ should not receive less service than another client, g, that is not continuously backlogged during the same time interval, i.e., $W_f(t_1,t_2) \geq W_g(t_1,t_2)$.

3. **Work-conservation** As long as there are requests in the queue, the server should not be idle.

The first property means that two clients sending requests at more than their fair share will get the same service, regardless of the discrepancy between their sending rates. The second property says that a client sending requests at a higher rate will not get less service than a client sending at a lower rate. Basically, the first two properties say that a misbehaving client is contained (i.e., doesn't receive more service than other backlogged clients), and not punished (i.e., doesn't receive

[4] https://openai.com/pricing

less service than other non-backlogged clients). Finally, the work conserving property aims to maximize the utilization, addressing a key weakness of the RPM-based solutions.

The three properties above assume an idealized fair serving system. A practical system will approximate these properties. In general, the best we can achieve is deriving bounds that are independent of the length of the time interval, e.g., in the first property, the difference between $W_f(t_1,t_2)$ and $W_g(t_1,t_2)$ is bounded by a value that is independent of $t_2 - t_1$. We give the formal guarantees provided by our method in Section 4.1.

4 Achieving Fairness

In this section, we present our algorithm VTC with proved fairness properties in Section 4.1, and show its generalization for customized service measurement in Section 4.2. Variants of VTC, including weighted VTC and VTC with length prediction, are introduced in Section 4.3 and Section 4.4.

4.1 Virtual Token Counter (VTC)

Based on insights from prior discussions, we've identified key challenges inherent in large language model (LLM) serving that hinder direct adaptation of existing algorithms to deliver approximately fair LLM service. We then propose the Virtual Token Counter (VTC), a mechanism for achieving fair sharing in LLM Serving (Algorithm 2). To quantify the service received by a client we use the weighted number of tokens metric, as described in Section 3.1. We discuss the generalization to other metrics in Section 4.2.

Intuitively, VTC tracks the services received for each client and will prioritize the ones with the least services received, with a counter lift each time a client is new to the queue. The *counter lift* is needed to fill the gap created by a low load period of the client, so that it will not be unfairly served more in the future. In other words, the credits for a client are utilized immediately and cannot be carried over or accumulated. The virtual counters are updated each time a new token is generated, which can reflect the services received instantly. This operates at the token-level granularity, and thus addresses the unknown length issue. VTC can be easily integrated into the continuous batching mechanism, and its scheduling mechanism does not depend on the server's capacity, overcoming the problem of variable token-rate capacity.

Algorithm 2 shows how VTC can be implemented in the continuous batching framework described in Section 2.1. A more general integration for VTC is described in Appendix C.1. It maintains a virtual counter for each client, denoted as $\{c_i\}$. The counters are initialized as 0 (line 2). The program runs with two parallel streams.

The monitoring stream listens to the incoming requests, described in lines 5-14. The new request will be added to the waiting queue Q immediately. If the new request is the only request in Q for its sender client, a counter lift (lines 8-13) will happen. Because this client could have been underloaded before, its counter could be smaller than the other active counters. However, since the credits cannot be carried over, we need to lift it to the same level as other active counters, thus maintaining fairness among this client and others. Lines 9-10 address the scenario where the entire system was in an idle state. We do not reset all the counters to avoid nullifying a previously accumulated deficit upon a system restart.

Algorithm 2 Virtual Token Counter (VTC)

```
Input: request trace, input token weight $w_p$, output token
    weight $w_q$, upper bound from Equation (2) denoted as $U$.
 1: let current batch $B \leftarrow \emptyset$
 2: let $c_i \leftarrow 0$ for all client $i$
 3: let $Q$ denote the waiting queue, which is dynamically
    changing.
 4: ▷ with monitoring stream:
 5: while True do
 6:     if new request $r$ from client $u$ arrived then
 7:         if not $\exists r' \in Q, client(r') = u$ then
 8:             if $Q = \emptyset$ then
 9:                 let $l \leftarrow$ the last client left $Q$
10:                 $c_u \leftarrow \max\{c_u, c_l\}$
11:             else
12:                 $P \leftarrow \{i \mid \exists r' \in Q, client(r') = i\}$
13:                 $c_u \leftarrow \max\{c_u, \min\{c_i \mid i \in P\}\}$
14:         $Q \leftarrow Q + r$
15: ▷ with execution stream:
16: while True do
17:     if can_add_new_request() then
18:         $B_{new} \leftarrow \emptyset$
19:         while True do
20:             let $k \leftarrow \arg\min_{i \in \{client(r) \mid r \in Q\}} c_i$
21:             let $r$ be the earliest request in $Q$ from $k$.
22:             if $r$ cannot fit in the memory then
23:                 Break
24:             $c_k \leftarrow c_k + w_p \cdot input\_length(r)$
25:             $B_{new} \leftarrow B_{new} + r$
26:             $Q \leftarrow Q - r$
27:         forward_prefill($B_{new}$)
28:         $B \leftarrow B + B_{new}$
29:     forward_decode($B$)
30:     $c_i \leftarrow c_i + w_q \cdot |\{r \mid client(r) = i, r \in B\}|$
31:     $B \leftarrow$ filter_finished_requests($B$)
```

The execution stream is the control loop of an execution engine that implements continuous batching. Line 17 controls the frequency of adding a minibatch B_{new} of new requests into the running batch B. Commonly, the server will add a new minibatch after several decoding steps. The minibatch B_{new} is constructed by iteratively selecting the request from the client with the smallest virtual counter (lines 20-26). The counters will be updated when adding new requests according to the service invoked by the input tokens (line 24). After each decoding step (line 29), $\{c_i\}$ will be updated immediately according to the service invoked by the newly generated output tokens (line 30).

The VTC algorithm is (mostly) work-conserving because it only manipulates the dispatch order and does not reject a request if it can fit in the batch.

4.1.1 Fairness for backlogged clients in VTC

In this subsection, we provide the theoretical guarantee for fairness among overloaded clients in VTC. More precisely, the overload of a client is reflected by its backlog, which can be formally defined as follows. Intuitively, a client being backlogged means its requests are queued up.

Definition 4.1 (Backlog)**.** A client f is backlogged during time interval $[t_1,t_2)$, if at any time $t \in [t_1,t_2)$, f has a request that is waiting in the queue.

We adapt the traditional definition of fairness for backlogged clients in the network to our scenario. The following definition formally defined the item 1 introduced in Section 3.2, that for any interval, and any two continuously backlogged clients during the time interval, the difference of their received service should be bounded by a value that is independent of the interval length.

Definition 4.2 (Fairness adapted from [16])**.** Let $W_f(t_1,t_2)$ be the aggregated service received by client f in the interval $[t_1,t_2)$. A schedule is fair w.r.t. δ, if for any clients f and g, for all intervals $[t_1,t_2)$ in which clients f and g are backlogged, we have $|W_f(t_1,t_2) - W_g(t_1,t_2)| \leq \delta$.

In the rest of the paper, as in Algorithm 2, we let Q denote the set of requests in the waiting queue. We abuse the notation of $i \in Q$ for a client i to indicate there exists $r \in Q$, such that r is a request from client i. Let L_{input} and L_{output} be the maximum number of input and output tokens in a request. Let M be the maximum number of tokens that can be fitted in a running batch. Lemma 4.3 reflects the core design of Algorithm 2, that the virtual counters for active clients are chasing each other to ensure their maximum difference is bounded. The missing proof for Lemma 4.3 and all following theorems are in Appendix A.

Lemma 4.3. *The following invariant holds at any time in Algorithm 2 when $Q \neq \emptyset$:*

$$\max_{i \in Q} c_i - \min_{i \in Q} c_i \leq \max(w_p \cdot L_{input}, w_q \cdot M) \tag{2}$$

We then introduce our main theorem which provides a bound for Definition 4.2.

Theorem 4.4 (Fairness for overloaded clients)**.** *For any clients f and g, for any time interval $[t_1,t_2)$ in which f and g are backlogged, Algorithm 2 guarantees* [5]

$$|W_f(t_1,t_2) - W_g(t_1,t_2)| \leq 2\max(w_p \cdot L_{input}, w_q \cdot M).$$

Proof. For any f, if f is backlogged during time t_1 to t_2, we have $W_f(t_1,t_2) = c_f^{(t_2)} - c_f^{(t_1)}$. This is because the line 7 will not be reached for client f during t_1 to t_2, and the c_f keeps increasing during t_1 to t_2 by adding w_p product the number of served input tokens and w_q product the number of served output tokens. By Lemma 4.3, from Equation (2), we have

$$\begin{aligned} |W_f(t_1,t_2) - W_g(t_1,t_2)| &\leq |c_f^{(t_1)} - c_g^{(t_1)}| + |c_f^{(t_2)} - c_g^{(t_2)}| \\ &\leq 2\max(w_p \cdot L_{input}, w_q \cdot M) \end{aligned}$$

□

Remark 4.5. An empirical illustration of this theorem can be found in Figure 3a, where the difference between services received by backlogged clients is bounded, regardless of how long they have been backlogged.

Remark 4.6. Line 13 can be modified to take any value between $\min\{c_i | \exists r' \in Q, client(r') = i\}$ and $\max\{c_i | \exists r' \in Q, client(r') = i\}$. The proof of Theorem 4.4 should still hold.

Remark 4.7. To tighten the bound in Theorem 4.4, we can restrict the memory usage for each client in the running batch. This might compromise the work-conserving property, as we will demonstrate in Theorem 4.8. Therefore, there is a *trade-off* between achieving a better fairness bound and maintaining work conservation. Heuristically, predicting the request length in advance could result in a smaller discrepancy, as detailed in Section 4.4. Additionally, preemption is another method to achieve smaller differences, discussed in Appendix C.3.

We also prove in the next theorem that the bound in Theorem 4.4 is tight within a factor of 2 for a family of work-conserving schedulers. We say a scheduler is work-conserving if it stops adding requests to a partially-filled minibatch (line 22 in Algorithm 2) only when it runs out of memory[6] but not for fairness reasons.

Theorem 4.8. *For any work-conserving schedule without preemption, there exists some query arrival sequence such that for client f,g and a time period t_1,t_2, such that*

$$|W_f(t_1,t_2) - W_g(t_1,t_2)| \geq w_q \cdot M,$$

where clients f,g are backlogged during the time $[t_1,t_2)$.

As we mentioned before, output tokens are more expensive than input tokens, so normally we have $w_q > w_p$. Therefore the right-hand side of the inequality in Theorem 4.4 is $2w_q \cdot M$, which is 2× of the lower bound in Theorem 4.8.

[5] The service of a served request incurred by pre-filling (service for input tokens) is counted at the time when the request is added to the running batch (line 24 in Algorithm 2), rather than the time when prefill is finished. This is because we want to count the input tokens immediately to avoid selecting all the same k at line 20 in Algorithm 2 for B_{new}.

[6] Different implementation may have different criteria of "not enough memory". This can only be achieved heuristically because the number of output tokens is unknown before it finishes.

4.1.2 Fairness for non-backlogged clients in VTC

In this subsection, we discuss item 2 in Section 3.2. A backlogged client will not receive less service than another client. This can be reflected in the following theorem.

Theorem 4.9. *If a client f is backlogged during time interval $[t_1,t_2)$, for any client g, there is*

$$W_f(t_1,t_2) \geq W_g(t_1,t_2) - 4U.$$

Here U is the upper bound from Equation (2).

In addition to that, clients who send requests constantly less than their share should have their requests serviced nearly instantly. This property intuitively can be implied by the first item in Section 3.2, as if a low-rate client cannot be served on time, it becomes backlogged, which requires the same level of service with backlogged clients. We formally prove this property to offer a fairness assurance for clients who are not overloaded. This intuitively acts as a safeguard against misbehaving clients [10].

We start with Definition 4.10 and Theorem 4.11 discussing the aspect of latency bounds. Intuitively, if a client is not backlogged and has no requests running, the next request from it will be processed within a latency bound that is independent of the request rate of other clients.

Definition 4.10. Assume there are n active clients during $[t_1, t_2)$, and the server capacity at time $t \in [t_1,t_2)$ is defined as $S(t)$, where

$$\int_{t_1}^{t_2} S(t)\,dt = \sum_{i=1}^{n} W_i(t_1,t_2)$$

Because the server capacity is always positive and bounded, there exists $a,b \in \mathbf{R}^+$ such that $\forall$ t, $a < S(t) \leq b$.

Theorem 4.11. *Let $A(r)$ and $D(r)$ denote the arrival time and dispatch time of a request r. Assume there are in total n clients, $\forall t_1,t_2$, if at t_1, a client f is not backlogged and has no requests in the running batch, then the next request r_f with $t_1 < A(r_f) < t_2$ will have its response time bounded:*

$$D(r_f) - A(r_f) \leq 2\cdot(n-1)\cdot\frac{\max(w_p\cdot L_{input}, w_q\cdot M)}{a} \tag{3}$$

Here a is the lower bound of the capacity in Definition 4.10.

Remark 4.12. The bound in Theorem 4.11 is irrelevant to the request rate of others, giving an upper bound for latency against ill-behavior clients.

The above is about one request not getting delayed. The following theorem shows that during time period $[t_1,t_2)$, if there are n active clients sending requests, and client f is sending requests with a rate constantly less than $1/n$ of the server's capacity (with some constant gap), client f should have all its requests been served.

Theorem 4.13. *(Fairness for non-overloaded clients) For any time interval $[t_1,t_2)$, we claim the following.*

Assume a client f is not backlogged at time t_1 and for any time interval $[t,t_2), t_1 \leq t < t_2$, f has requested services less than $\frac{T(t,t_2)}{n(t,t_2)} - 5U$, where $T(t,t_2)$ is the total services received for all clients during the interval $[t,t_2)$, $n(t,t_2)$ is the number of clients that have requested services during the interval, and U is the upper bound from Equation (2).

Then, all of the services requested from f during the interval $[t_1,t_2)$ will be dispatched.

4.2 Adapt to Different Fairness Criteria

Algorithm 2 is designed for fairness with the service function $W(t_1,t_2)$ as a linear combination of the number of processed input tokens and the number of generated tokens. For a different definition of $W(t_1,t_2)$, Algorithm 2 can be easily modified to update the counter according to the other definitions described in Section 3.1.

Assume we aim for fairness using $\sum_r h(n_p^r,n_q^r)$ as the metric of service, where h is a specific function. In this context, r indexes the served requests, and n_p^r, n_q^r represent the number of input and output tokens served for request r, respectively. Line 24 will be changed to

$$c_k \leftarrow c_k + h(n_p^r, 0).$$

Line 30 will be changed to

$$c_i \leftarrow c_i + \sum_{r|client(r)=i, r\in B} \left(h(n_p^r,n_q^r) - h(n_p^r,n_q^r-1)\right).$$

The fairness bound will also be changed according to $h(\cdot,\cdot)$. Under the assumption that output tokens are more expensive than input tokens, the bound will become the maximum value of aggregated $h(\cdot,\cdot)$ for a set of requests that can be fitted in one running batch. Algorithm 4 in Appendix C.1 is the pseudocode of a general VTC framework.

4.3 Weighted VTC

VTC can be applied when clients have tiers. Similar to weighted fair queuing, clients can have different weights to represent their priority in service. If a client f has a weight w_1, that is twice the weight w_2 of client g, client f is expected to receive twice the service than client g. When they are continuously backlogged during the interval $[t_1,t_2)$, we want $\left|\frac{W_f(t_1,t_2)}{w_1} - \frac{W_g(t_1,t_2)}{w_2}\right|$ to be bounded instead of $\left|W_f(t_1,t_2) - W_g(t_1,t_2)\right|$.

Weighted VTC can be easily implemented by modifying the lines that update the virtual tokens. For example, the line 22 in Algorithm 4 will be changed to

$$c_i \leftarrow c_i + \frac{\sum_{r|client(r)=i}\left(h(n_p^r,n_q^r) - h(n_p^{r(old)},n_q^{r(old)})\right)}{w_i}.$$

Here c_i is the virtual counter of client i, and w_i is its corresponding weight.

4.4 VTC with Length Prediction

As mentioned in Remark 4.7, using VTC with length prediction can heuristically reduce the service discrepancy. In standard VTC, the counters only reflect served tokens. Tokens generated in the future can only be passively added to the counter. This results in a large service discrepancy because requests are overly added due to underestimation of their costs at the time of prompting, leading to the forced serving of over-compensated output tokens. Incorporating a prediction mechanism can help reduce this variance.

The theoretical worst-case scenario won't change, according to the lower bound proved in Theorem 4.8. But practically, the average-case service discrepancy could be smaller.

The modified pseudocode of VTC with length prediction is described in Algorithm 3 in Appendix B.3. Intuitively, when a request r is selected, the cost associated with the predicted number of output tokens is immediately added to the virtual counter of the client sending the request. During the actual decoding process, adjustments are made to the virtual counter based on the actual number of output tokens produced. If the actual number of tokens exceeds the prediction, the virtual counter is increased accordingly. Conversely, if fewer tokens are generated than predicted when finished, the virtual counter is reduced. The effectiveness of the length predictor is contingent upon both the workload and the accuracy of predictions, as demonstrated in our evaluations.

5 Evaluations

In this section, we evaluate VTC against other alternatives under different workloads. The results confirm the fairness properties introduced in Section 3 of VTC, and show that all other alternatives will fail in at least one workload.

5.1 Setup

Implementation We implement our VTC and other baseline schedulers in S-LoRA [43], a system that serves a large amount of LoRA adapters concurrently. Its backbone is a general serving system adapted from LightLLM [29]. It includes the implementation of continuous batching [50] and PagedAttention [24][7]. Our VTC scheduler is built on top of those two techniques. Our implementation is elegant and can be implemented as a thin layer on top of the existing scheduler, it contains only about 100 lines of code on top of S-LoRA. The simplicity demonstrates its wide applicability. Fairness can be considered among general clients, and our experiments are done in this way. But we would like to note that fairness also could be taken into consideration among adapters, especially under the scenario of personalization that uses one adapter per customer, which originally motivated this paper.

Baselines In this section, we benchmark VTC and the baselines as below:

- First Come First Serve (FCFS): In the First-Come-First-Serve method, requests are handled strictly in the order they are received, irrespective of the requesting client. This is the default scheduling strategy in many prevalent LLM serving systems, including vLLM [24] and Huggingface TGI [20].
- Request per minute (RPM): This method limits the maximum number of requests that a client can make to the server within a one-minute timeframe. The definition of service corresponds to Section 3. When a client exceeds this limit, subsequent requests are blocked until the limit resets at the start of the next minute.
- Least Counter First (LCF): This is a variant of VTC without the counter lift component. Each client will maintain a counter for the service it received so far. The request from the client with the smallest counter will be scheduled each time.

We also benchmark the VTC with length predictions as described below:

- VTC (predict): This variant of VTC, detailed in Algorithm 3, utilizes the average output length of the last five requests from each client to predict the output length.
- VTC (oracle): This variant employs a hypothetical output length predictor that achieves 100% accuracy.

Synthetic Workload We run Llama-2-7b on A10G (24GB), using the memory pool for the KV cache with size 10000[8]. We use various workloads to demonstrate different aspects of fairness, and compare VTC with other baselines. The detailed results are in Section 5.2. We start with synthetic workloads to give a clear message for fairness properties.

Real Workload To validate the effectiveness of VTC in more complex real-world scenarios, we also experiment with VTC and other baselines under workloads constructed from the trace log of LMSYS Chatbot Arena [52, 53], which is an LLM serving platform for real-world clients.

Ablation Study In the ablation study, to evaluate the impact of different memory pool sizes and request lengths on the scheduling fairness, we run Llama-2-13b on A100 (80GB) with a memory pool of size 35000 and 65000 respectively. For each memory pool size, we evaluate the absolute difference in the accumulated service of two clients.

[7] with block size equals 1.

[8] There are in total 10000 tokens for KV cache that can be stored on GPU.

Metrics We apply the weighted number of tokens described in Section 3.1 as the measurement of services in our evaluation. Following OpenAI pricing, we set $w_p = 1$ and $w_q = 2$.

- The service received by client i at time t is measured as $W_i(t-T, t+T)$ for a certain T.
- The absolute difference in service between clients is quantified based on accumulated services, represented as $\max_{i,j} |W_i(0,t) - W_j(0,t)|$.
- The response time of client i at time t is measured as the average first token latency of the requests sent by client i during the time window $[t-T, t+T]$.

In all settings, we set $T = 30$ seconds.

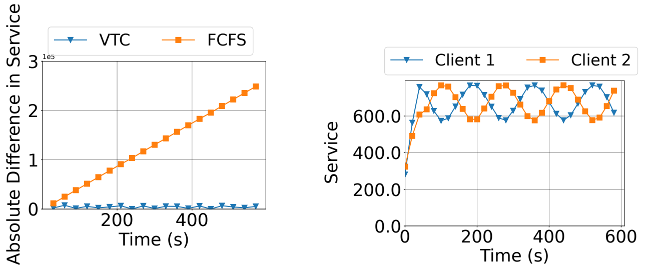
We employ *service difference* as a quantitative metric to assess the deviation from ideal fairness. A smaller difference in service indicates more equitable scheduling. Formally, the service difference between two clients is defined as the minimum of two values: the difference between their received services, and the difference between the lower service and its corresponding request rate. For example, consider two clients that received services s_1 and s_2, such that $s_1 \leq s_2$, and let r_1 denote the request rate sent from the first client. Then the service difference is defined as $\min(s_2 - s_1, |r_1 - s_1|)$.

VTC Variants The experiments for weighted VTC are presented in Appendix B.1, demonstrating its capability to serve clients with varying priorities. To illustrate the versatility of the service function beyond the linear model used in our primary analysis, we evaluate a profiled service cost function in Appendix B.2, which is a quadratic function. Additional experiments on VTC with length prediction are detailed in Appendix B.3.

5.2 Results on Synthetic Workloads

We design a set of experiments to visualize the fairness properties of VTC. We start with synthetic traces to show plots reflecting the ideal case's fairness. We experiment from the simplest setting, where clients send requests following a uniform distribution with the same input and output length, to complex settings, where requests arrive stochastically, with various input and output lengths.

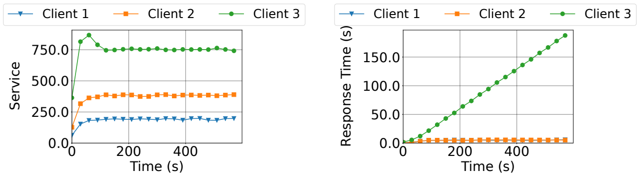
Constant request rates We start with scenarios where requests arrive deterministically with the same input and output length. In Figure 3, two clients send requests at different rates, but are both constantly overloaded. In this case, Figure 3a shows VTC can keep the difference between services received by both clients to be small. FCFS cannot maintain fairness, which always serves more for the client who is sending requests at a higher rate. Figure 3b shows the real-time received service rate for two clients in VTC, which confirms that the two received the same level of services at any time interval. This experiment empirically validates Theorem 4.4.



(a) Absolute difference for accumulated service

(b) Received service rate, calculated as an average of 60s time windows. (VTC)

Figure 3: Two clients with different request rates and both overloaded. Client 1 sends 90 requests per minute. Client 2 sends 180 requests per minute, both evenly spaced out so that each request is sent at a consistent time interval throughout the minute. Every request has input lengths of 256 and output lengths of 256. Both clients are backlogged because they exceed the server capacity.



(a) Received service rate (VTC).

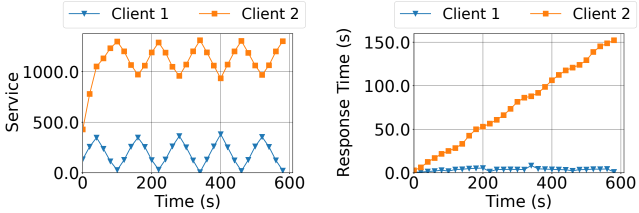
(b) Response time (VTC).

Figure 4: Client 3 who is overloaded can consume more than its share as Clients 1 and 2 are sending requests lower than their share. Clients 1, 2, and 3 send 15, 30, and 90 requests per minute, respectively, under uniform distribution. Requests have input lengths of 256 and output lengths of 256. Client 3 is backlogged, while Clients 1 and 2 are not.

In Figure 4, three clients send requests at around $2/13$, $4/13$, and $> 7/13$ of the server's capacity, respectively. In this case, Clients 1 and 2 can be served immediately when their requests arrive (Figure 4b), and Client 3 will consume the remaining capacity (more than 1/3), which is an empirical illustration of the work-conserving property of VTC. The service received for Client 1 and Client 2 have a ratio $1:2$, which is consistent with their request rates (15 versus 30).

ON/OFF request pattern In real-world applications, clients usually do not always send requests to the server. They may occasionally be idle ("OFF" phase). We call this the "ON/OFF" pattern. In Figure 5, Client 2 is always in the "ON" phase, sending requests at a rate of 120 per minute. Client 1 sends 30 requests per minute (less than half of the capacity) during the ON phase and switches to OFF phase periodically. Since Client 1 uses less than half the system capacity when it is in the ON phase, its requests are mostly processed before it switches to the OFF phase (Figure 5b). When it is in the OFF phase, Client 1 thus takes all the system capacity. The total service rate remains the same, which confirms VTC's flexibility in achieving work-conserving.

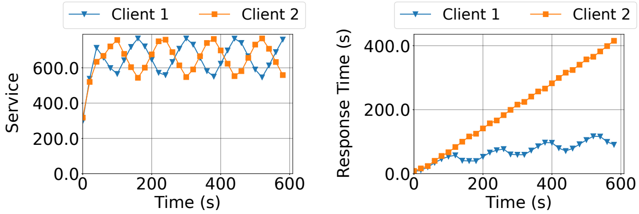
On the contrary, in Figure 6, client 1 sends much more than half the capacity during the ON phase, and makes itself always backlogged. Thus, even when it is in the OFF phase, it is still in the backlog status. In this case, Client 1 and Client 2 should still receive the same level of service rate.



(a) Received service rate (VTC).

(b) Response time (VTC).

Figure 5: ON/OFF request pattern. Client 1 sends 30 requests per minute (less than half of the capacity) during the ON phase and switches to OFF phase periodically. Client 2 is always in the ON phase, sending requests at a rate of 120 requests per minute (larger than half of the capacity). Requests have input lengths of 256 and output lengths of 256.

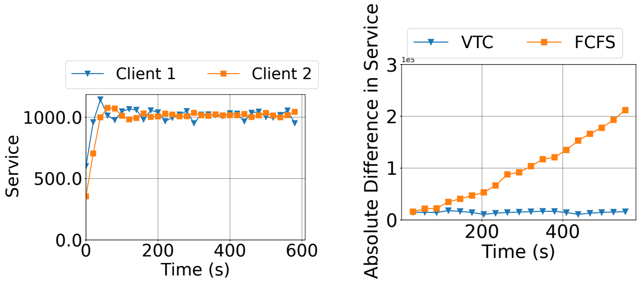


(a) Received service rate (VTC).

(b) Response time.

Figure 6: ON/OFF request pattern. Client 1 sends 120 requests per minute constantly during the ON phase (over its share), and stops sending during the OFF phase. Client 2 sends 180 requests per minute all the time (over its share). Requests have input lengths of 256 and output lengths of 256.

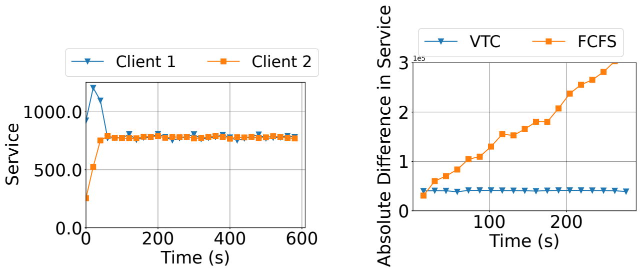
Variable input/output length and poisson process In this experiment, we simulate scenarios where requests arrive stochastically. Furthermore, they send requests with different input and output lengths. In both Figure 7 and Figure 8, Client 1 sends requests with a high rate and Client 2 sends requests with a rate lower but still over its share. Requests arrive according to a Poisson process with the coefficient of variance 1. In Figure 7, client 1 sends short requests, and client 2 sends long requests. In Figure 8, Client 1 sends requests with short input and long output, while Client 2 sends requests with long input and short output. Similarly, with the observation before, VTC maintains a bounded difference between the services received by two clients. FCFS cannot preserve fairness according to Figure 7b and Figure 8b. This confirms that VTC can work under stochastic workloads with variable lengths.



(a) Received service rate (VTC).

(b) Absolute difference for accumulated service.

Figure 7: Client 1 sends 480 requests per minute. Client 2 sends 90 requests per minute. Requests arrive according to a Poisson process with the coefficient of variance 1. Requests sent from Client 1 have input lengths of 64 and output lengths of 64. Requests sent from Client 2 have input lengths of 256 and output lengths of 256.



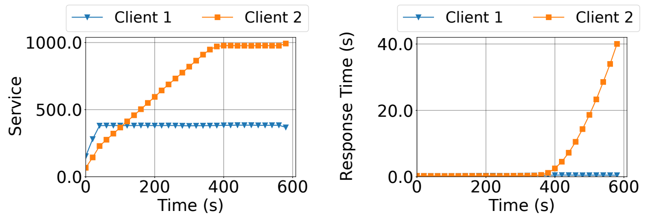
(a) Received service rate (VTC).

(b) Absolute difference for accumulated service.

Figure 8: Client 1 sends 480 requests per minute. Client 2 sends 90 requests per minute. Requests arrive according to a Poisson process with the coefficient of variance 1. Requests sent from Client 1 have input lengths of 64 and output lengths of 512. Requests sent from Client 2 have input lengths of 512 and output lengths of 64.

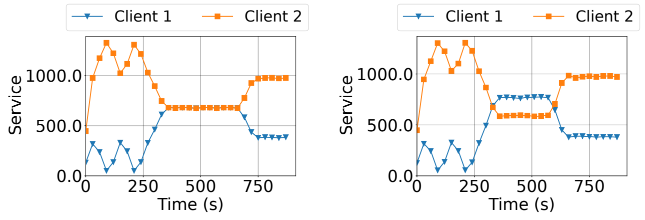
Isolation To illustrate the isolation property, we use the setup with a deterministic arrival pattern and the same input length and output length of 256. In Figure 9, Client 1 sends 30 requests per minute, which is under half of the server's capacity. Client 2 acts as an "ill-behaved" client. It sends requests at a linearly increasing rate, and gradually over half of the system capacity. We observe that the response time of requests from client 1 is roughly unchanged, empirically validating the property stated in Theorem 4.13.

Distribution shift In reality, clients' behavior may change over time. To this end, we evaluate the robustness of VTC



(a) Received service rate (VTC). (b) Response time (VTC).

Figure 9: Client 1 sends 30 requests per minute, Client 2 sends 120 requests per minute, in a uniform arrival pattern. Requests have input lengths of 256 and output lengths of 256. Client 1 sends 30 requests per minute, which is under half of the server's capacity. Client 2 sends requests at a linearly increasing rate, and gradually over half of the system capacity.



(a) Received service rate (VTC). (b) Received service rate (LCF).

Figure 10: Clients send requests in three phases, all with uniform arrival patterns. The first 5 minutes is ON/OFF phase. Client 1 sends 30 requests per minute during the ON phase (less than its share) and stops sending during the OFF phase. Each ON or OFF phase has 60 seconds. The second 5 minutes is the overload phase. Both Client 1 and Client 2 send 60 requests per minute, which causes the server to be overloaded. In the last 5 minutes, Client 1 sends 30 requests per minute (less than its share), and Client 2 sends 90 requests per minute, which causes the server to be still overloaded. Requests all have input lengths of 256 and output lengths of 256.

when the distribution of client requests shifts. In Figure 10, we construct a 15-minute workload comprising three phases. The first phase is an ON/OFF phase, in which Client 1 sends requests less than its share only during the ON phase and stops during the OFF phase. Client 2 sends requests at a constant rate, which makes the server overloaded. We can observe the pattern for the first phase to be similar to Figure 5a, which maintains a constant total service. During the second phase, because the two clients both send requests over their share, a fair server should let them receive the same level of service. Figure 10a demonstrates that VTC yields a desired pattern, similar to that shown in Figure 3b. Figure 10b reveals that LCF disproportionately serves Client 1, as it inherits Client 1's deficit from the first phase. In the last phase, the serving pattern for VTC and LCF are similar, because they simply serve all requests from Client 1 immediately as Client 1 sends requests under its share.

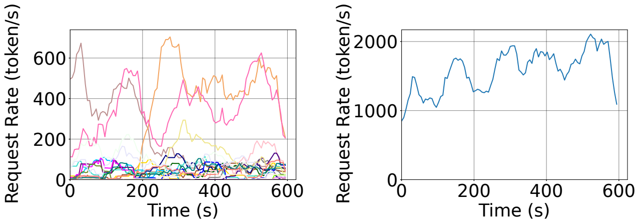


Figure 11: Request rate distribution during the sampled 10 minutes duration with re-scale. The figure on the left denotes the real-time request rate for the 27 clients. A few clients have sent many more requests than others, reflecting the original trace of a few most popular models. The figure on the right depicts the total request rate from all 27 clients.

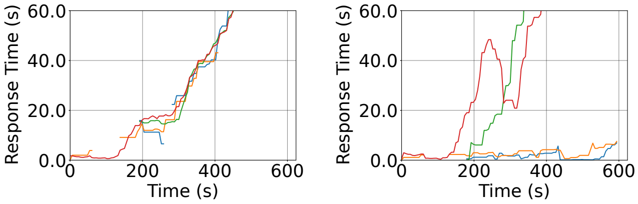

Figure 12: Response time of 4 selected clients when using FCFS (Left) and VTC (Right) in real traces. Each curve corresponds to one client. There are some curves that show disconnected because, during some periods, a client may have no requests served. Requests distribution see Figure 11.

5.3 Results on Real Workloads

We construct real workload traces from the traces of LMSYS Chatbot Arena [52, 53], following a similar process in [43]. The trace is from a server that serves multiple LLMs. To adapt it to our setting, we treat each LLM as a client. In total, there are 27 clients. To sample from this log, we define D, the duration, and R, the request rate. We then sample $R*D$ requests from the trace, and re-scale the real-time stamps to $[0,D]$. We use a duration of 10 minutes to be consistent with previous experiments, and a request rate of 210 requests per minute for the whole system. With the adapted workload, we run Llama-2-7b on A10G (24GB). In summary, the prompts from the 27 clients are collected from the real world interactions, which will be sent to the server for inference on Llama-2-7b. The timestamps are re-scaled from the real-world trace.

For better visualization of the evaluation results, we select two clients that send the most requests and two clients that send a medium number of requests. We sort 27 clients according to the number of requests they send, and depict the statistics of the $13^{th}, 14^{th}$ and $26^{th}, 27^{th}$ clients. We do not choose clients that send the least requests because they typically only send requests in a small interval.

Request distribution The request rate distribution is visualized in Figure 11. The request rate of individual clients

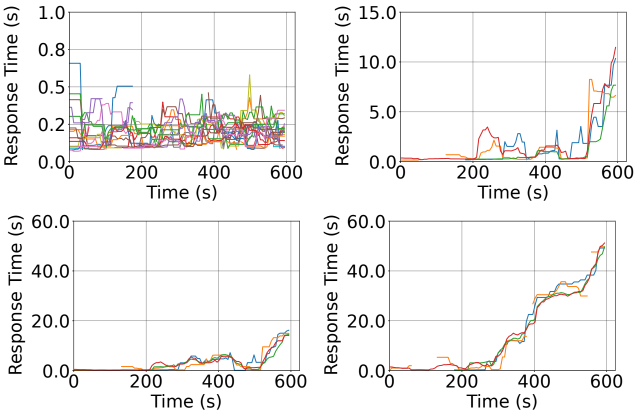

Figure 13: Response time of 4 selected clients (all 27 clients when rpm=5) when using RPM in real traces. Left-upper to right-bottom corresponds to a different rate limit (5, 15, 20, 30 requests per minutes, respectively). There are some curves that show disconnected because, during some periods, a client may have no requests served.

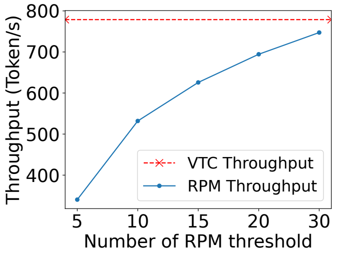

Figure 14: Throughput of RPM versus different number of requests per minute threshold. Compared with VTC, RPM consistently exhibits a lower throughput.

and the total request rate are all highly dynamic. The input and output length distribution is depicted in Figure 20 in the Appendix. The average input length is 136, and the average output length is 256. The input and output lengths have the range of $[2,1021]$ and $[2,977]$, respectively.

Effect on response time Figure 12 shows the response time of 4 selected clients on the real trace. With FCFS scheduling, the response time of all clients increases drastically because some clients send over their share, monopolizing the service and impacting other clients. With VTC, only clients that send requests over its share will have a drastic increase in the response time.

Analysis of request rate per limit approach In Figure 13, we show the response of RPM approach with different rate limits. In Figure 14, we show the corresponding throughput comparison with VTC. These plots reveal a core dilemma of the RPM approach - the system has to choose between fairness or throughput, but not both. If the rate limit is low, then the system rejects many requests from clients that send over their share. This opens the capacity for clients with fewer requests. As demonstrated in the uppermost plot in Figure 13, all requests have a similar response time. However, this low rate limit rejects more requests than needed, causing a lower throughput (cluster-wise throughput is ≈ 340 output tokens per second when RPM=5, as opposed to ≈ 779 tokens per second in VTC or FCFS). When the rate limit is set higher, the system throughput is gradually increasing, i.e., increasing from 340 tokens to 747 tokens per second. However, the response time for all requests grows up. When the request rate is set higher and higher, the response time curve converges to the one in FCFS, and there is no fairness guarantee anymore. In other words, the RPM approach can be summarized as follows: it functions as an FCFS (First-Come, First-Served) approach with admission control (rate limiting), rather than as a truly fair scheduler. Its fairness is achieved by rejecting numerous requests from other clients, which compromises the overall system throughput.

Quantitative Measurement We measured the maximum and average service difference described in Section 5.1 during the time window (10 minutes) in which we ran the experiments. Table 2 is a summary for all baselines using this quantitative measurement for real workload trace.

Scheduler	Max Diff	Avg Diff	Diff Var	Throu	Isolation
FCFS	759.97	433.53	32112.00	777	No
LCF	750.49	323.82	29088.90	778	Some[9]

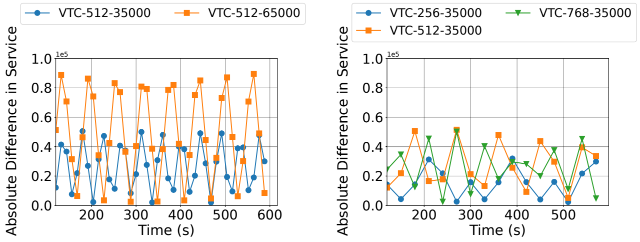
Table 2: The service difference is counted by summing the service difference between each client and the client who received the maximum services. Throughput is the total number of tokens (including input and output tokens) processed divided by the total execution time.

5.4 Ablation Study

In Figure 15, we evaluate how different memory pool sizes and request lengths will affect scheduling fairness. As shown in Figure 15a, with a larger memory pool size, the attainable batch size becomes larger. Therefore, there is greater variation in the absolute difference of accumulated services received by the clients when the memory pool is 65000 than that is 35000, which empirically validates Theorem 4.4. Figure 15b demonstrates that larger request lengths will also lead to greater variations in the service difference. This is

[9] LCF achieves isolation if the workload does not change. However, the isolation can be broken by newly joined clients whose virtual counter is lagging behind.



(a) Different memory pool size. (b) Different request length.

Figure 15: In all settings, both clients are sending requests of the same lengths with uniform arrival patterns. They send requests with different request rates but are both backlogged. Three different request lengths (256*2, 512*2 and 768*2) are evaluated for the 35000 KV cache setting.

caused by the unknown output length of request generation. At line 24 in Algorithm 2, the most conservative way of only counting the input tokens leads to over-compensation for the smallest counter, as all the potential output tokens are not counted. A shorter request length has a milder effect of over-compensation. The curves of $(512*2)$ and $(768*2)$ show the same variance. This is because at length $(512*2)$, the upper bound given by VTC has been reached.

6 Related Works

Fairness in scheduling Achieving fairness in scheduling resources in a multi-client environment has been a long-standing topic in computer science [14, 41, 42, 51]. Among these, Fair Queuing [30] has been adapted into many variants for different contexts such as CPU scheduling [3], link bandwidth allocation [11, 15, 17, 23, 38], and memory allocation [33]. Deficit round robin [45] and stochastic fair queuing [27] are non-real-time fair queuing algorithms for variable-size packets, providing guarantees for long-term fairness. There are also real-time fair queuing algorithms (e.g., WFQ [11] and SFQ [17]) that can make more strict short-term delay guarantees [12]. Our scheduling algorithm is different from these algorithms because we need to consider the batching effects across multiple clients' requests and deal with unknown request length. Further, we need to accommodate a flexible notion of fairness on both performance and GPU resource consumption.

Fairness in ML training Within the realm of deep learning, research has delved into scheduling jobs in shared clusters [7, 26, 32, 40], with a primary focus on long-duration training jobs. Machine Learning training jobs have unique characteristics and traditional fair schedulers [18, 22] designed for big-data workflow usually fail [26]. In particular, Themsis [26] points out that ML jobs are device placement sensitive, where jobs will be envious of other's placement even if they are assigned the same number of resources. It then defines a finish-time fairness metric to measure fairness in ML training scenarios. Pollux [40] further points out that ML jobs should jointly consider the throughput and the statistical efficiency, and develop a goodput-based scheduler that further improves the finish-time fairness of ML jobs. In this paper, we consider fairness in LLM serving. The fairness problem in LLM serving is quite different from the fairness problem in model training. In model training, different clients' GPUs are isolated and the problem is which GPUs are assigned to each client. Achieving fairness in LLM serving requires design for a different set of issues, including how to batch requests from multiple clients to achieve high GPU utilization.

LLM Serving Systems How to improve the performance of LLM serving systems has recently gained significant attention. Notable techniques cover advanced batching mechanisms [13, 50], memory optimizations [24, 44], GPU kernel optimizations [2, 9, 34, 48], model parallelism [2, 25, 39], parameter sharing [55], and speculative execution [28, 46] were proposed. FastServe [49] explored preemptive scheduling to minimize job completion time (JCT). However, none of these works consider fairness among clients. Our work bridges this gap, and our proposed scheduling methods can be easily integrated with many of these techniques. Our implementation used for this paper is built atop continuous batching (iteration-level scheduling) [50][10] and PagedAttention [24].

7 Conclusion

We studied the problem of fair serving in Large Language Models (LLMs) with regard to the service received by each client. We identified unique characteristics and challenges associated with fairness in LLM serving, as compared to traditional fairness problems in networking and operating systems. We then defined what constitutes fairness and proposed a fair scheduler, applying the concept of fair sharing to the domain of LLM serving at the token granularity.

Acknowledgment

We thank Aurick Qiao, Shu Liu, Stephanie Wang, Hao Zhang for helpful discussions and feedback. This research was supported by gifts from Anyscale, Astronomer, Google, IBM, Intel, Lacework, Microsoft, Mohamed Bin Zayed University of Artificial Intelligence, Samsung SDS, Uber, and VMware. Ying is partly supported by the Stanford Center for Automated Reasoning. We thank Clark Barrett for academic advising and funding support.

[10] We presented VTC on continuous batching with separated prefill and decode steps in the main context. A general integration is discussed in Appendix C.1.

A Missing Proofs in Proving Fairness of VTC

Lemma A.1. *In Algorithm 2,* $\min_{i\in Q}(c_i)$ *is non-decreasing during the time when* $Q \neq \emptyset$.

Proof. We prove the lemma by case study on each line of changing the c_i's.

- In the initialization, all $c_i = 0$, lemma holds.
- If the condition of line 7 is satisfied, at lines 8-14, a new client will be added to Q. If lines 9-10 are reached, the $\min_{i\in Q}(c_i)$ is equals to its value at the last time when $Q \neq \emptyset$. If lines 12-13 are reached, since $c_u = \max\{c_u, \min_{i\in Q} c_i\}$, the $\min_{i\in Q}(c_i)$ will not change.
- At line 24 and line 30, the c_i's can only increase, so that $\min_{i\in Q}(c_i)$ is non-decreasing.
- At line 26, if a client has cleared all its requests from Q, that the client is removed from Q, $\min_{i\in Q}(c_i)$ cannot decrease.

□

Lemma A.2. *The following invariant holds at any time in Algorithm 2 when* $Q \neq \emptyset$*:*

$$\max_{i\in Q} c_i - \min_{i\in Q} c_i \leq \max(w_p \cdot L_{input}, w_q \cdot M) \tag{2}$$

Proof. We prove the lemma by induction. During the induction, for each line of change of c_i in Algorithm 2, we use c_i' to denote the new value and c_i to denote the original value. Similarly, we use Q' to donate the new value and Q to denote the original value. We also use $c_i^{(t)}$ to denote the value of c_i at time t, and $Q^{(t)}$ to denote the value of Q at time t.

1. In the initialization, all $c_i = 0$, Equation (2) holds.

2. If a client $u \notin Q$ receive a new request and thus $Q' = Q \cup \{u\}$, line 12-13 will be reached, and thus $c_u' = \max\{c_u, \min_{i\in Q} c_i\} \geq \min_{i\in Q} c_i$. Then we have,

$$\min_{i\in Q'} c_i' = \min\{c_u', \min_{i\in Q} c_i\} = \min_{i\in Q} c_i. \tag{4}$$

Let t be the last time that u was in Q before the change, and thus $c_u^{(t)} = c_u$. From Equation (2), there is

$$\max_{i\in Q^{(t)}} c_i^{(t)} - \min_{i\in Q^{(t)}} c_i^{(t)} \leq \max(w_p \cdot L_{input}, w_q \cdot M).$$

Then we have

$$c_u^{(t)} \leq \max_{i\in Q^{(t)}} c_i^{(t)} \leq \min_{i\in Q^{(t)}} c_i^{(t)} + \max(w_p \cdot L_{input}, w_q \cdot M).$$

From Theorem A.1, there is $\min_{i\in Q^{(t)}} c_i^{(t)} \leq \min_{i\in Q} c_i$, so we have

$$c_u = c_u^{(t)} \leq \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M),$$

which can derive

$$c_u' = \max\{c_u, \min_{i\in Q} c_i\} \leq \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M).$$

Combine with Equation (2) and Equation (4), there is

$$\begin{aligned}\max_{i\in Q'} c_i' &= \max\{c_u', \max_{i\in Q} c_i\} \\ &\leq \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M) \\ &\leq \min_{i\in Q'} c_i' + \max(w_p \cdot L_{input}, w_q \cdot M)\end{aligned}$$

Therefore, Equation (2) holds after the change.

3. If a client u is left from Q at line 26, the difference $\max_{i\in Q} c_i - \min_{i\in Q} c_i$ will not increase. Because $\max(C') - \min(C') \leq \max(C) - \min(C), \forall C \supseteq C', C' \neq \emptyset$. Therefore, Equation (2) still holds.

4. At line 24, since $c_k = \min_{i\in Q} c_i$, there is

$$\min_{i\in Q} c_i \leq \min_{i\in Q} c_i' \leq c_k' \leq \min_{i\in Q} c_i + w_p \cdot L_{input}. \tag{5}$$

From Equation (2), we have

$$\max_{i\in Q} c_i \leq \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M).$$

Because:

$$\max_{i\in Q} c_i' = \max(\max_{i\in Q} c_i, c_k')$$

We have:

$$\max_{i\in Q} c_i' \leq \max(\min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M), c_k') \tag{6}$$

In Equation (5) we have derived that:

$$c_k' \leq \min_{i\in Q} c_i + w_p \cdot L_{input}$$

Thus:

$$\begin{aligned}c_k' &\leq \min_{i\in Q} c_i + w_p \cdot L_{input} \\ &\leq \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M)\end{aligned}$$

Thus:

$$\max(\min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M), c_k') = \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M).$$

Thus Equation (6) gives:

$$\max_{i\in Q} c_i' \leq \min_{i\in Q} c_i + \max(w_p \cdot L_{input}, w_q \cdot M) \tag{7}$$

Finally, combining the inequality from Equation (5) that

$$\min_{i\in Q} c_i \leq \min_{i\in Q} c_i',$$

we arrive at:

$$\max_{i\in Q} c_i' \leq \min_{i\in Q} c_i' + \max(w_p \cdot L_{input}, w_q \cdot M).$$

Therefore, Equation (2) holds.

5. At line 30, let $k = \arg\max_{i \in Q} c'_i$, so that $c'_k = \max_{i \in Q} c'_i$. Let r be the last one among requests from k that have been scheduled. Let t be the time when r was selected at line 21. Since r is the last one been scheduled from k, there is
$$\max_{i \in Q} c'_i = c'_k \leq c_k^{(t)} + w_q \cdot M \tag{8}$$
Because request r from client k has been scheduled at time t, from line 20, there is $c_k^{(t)} = \min_{i \in Q^{(t)}} c_i^{(t)}$. From Lemma A.1, we have $\min_{i \in Q^{(t)}} c_i^{(t)} \leq \min_{i \in Q} c'_i$. Combine with Equation (8), we have
$$\max_{i \in Q} c'_i - \min_{i \in Q} c'_i \leq w_q \cdot M.$$
Therefore, Equation (2) holds.

□

Theorem 4.8. *For any work-conserving schedule without preemption, there exists some query arrival sequence such that for client f, g and a time period t_1, t_2, such that*
$$|W_f(t_1, t_2) - W_g(t_1, t_2)| \geq w_q \cdot M,$$
where clients f, g are backlogged during the time $[t_1, t_2)$.

Proof. Consider at time 0 the client f sends a list of requests which cannot fit in the memory at once. Because of work-conserving, client f will fill the whole running batch. In this case, client f is backlogged, and any new query is not processed until the existing queries finish processing. Assume that all existing queries finish at time T, and that at time ε with ε close to 0, a second client g sends another batch of requests. Now during the time interval $[\varepsilon, T]$, both clients f, g are backlogged since there exist queries from both clients in the queue. At time T, client f received service from the first batch of processing, which can be up to $w_q \cdot M$ if the memory is luckily fully utilized. Thus we have
$$W_f(\varepsilon, T) = w_q \cdot M.$$
On the other hand, client g did not receive any service during the time period $[\varepsilon, T]$. Thus $W_g(\varepsilon, T) = 0$. In this case, we have constructed an instance with
$$|W_f(t_1, t_2) - W_g(t_1, t_2)| \geq w_q \cdot M.$$

□

Theorem 4.11. *Let $A(r)$ and $D(r)$ denote the arrival time and dispatch time of a request r. Assume there are in total n clients, $\forall t_1, t_2$, if at t_1, a client f is not backlogged and has no requests in the running batch, then the next request r_f with $t_1 < A(r_f) < t_2$ will have its response time bounded:*
$$D(r_f) - A(r_f) \leq 2 \cdot (n-1) \cdot \frac{\max(w_p \cdot L_{input}, w_q \cdot M)}{a} \tag{3}$$
Here a is the lower bound of the capacity in Definition 4.10.

Proof. Let the counter for f be c_f after line 13 for r_f. Before D_{r_f}, since r_f is always in the queue, the counter for f will not be lifted. Since there is no running batch of f in the server, line 21 will select r_f to be the next one for f. Lemma 4.3 shows that for any other client g,
$$c_g - c_f < \max(w_p \cdot L_{input}, w_q \cdot M).$$
In the worst case where these counters are incremented sequentially, it will take at most $2 * (n-1) * \frac{\max(w_p \cdot L_{input}, w_q \cdot M)}{a}$. Thus, giving a bound for the dispatch time of r_f. □

Theorem 4.9. *If a client f is backlogged during time interval $[t_1, t_2)$, for any client g, there is*
$$W_f(t_1, t_2) \geq W_g(t_1, t_2) - 4U.$$
Here U is the upper bound from Equation (2).

Proof. If g is not backlogged during the entire $[t_1, t_2)$, then $W_g(t_1, t_2) \leq U$, the theorem trivially holds. Next, assume g is backlogged at some point during $[t_1, t_2)$. Let t'_1, t'_2 be the first time and the last time g is backlogged between $[t_1, t_2)$. Since there is no request submitted in $[t_1, t'_1)$ and $[t'_2, t_2)$, we have
$$W_g(t_1, t'_1) \leq U, \quad W_g(t'_2, t_2) \leq U. \tag{9}$$
Since c_i's in Algorithm 2 are non-decreasing,
$$c_f^{(t_1)} \leq c_f^{(t'_1)} \leq c_f^{(t'_2)} \leq c_f^{(t_2)}, \tag{10}$$
$$c_g^{(t_1)} \leq c_g^{(t'_1)} \leq c_g^{(t'_2)} \leq c_g^{(t_2)}. \tag{11}$$
According to Lemma 4.3 there is,
$$c_g^{(t'_2)} \leq c_f^{(t'_2)} + U, \quad c_g^{(t'_1)} \geq c_f^{(t'_1)} - U.$$
By Equation (10) and Equation (11):
$$c_g^{(t'_2)} \leq c_f^{(t_2)} + U, \quad c_g^{(t'_1)} \geq c_f^{(t_1)} - U.$$
Since $W_g(t'_1, t'_2) \leq c_g^{(t'_2)} - c_g^{(t'_1)}$, there is
$$W_g(t'_1, t'_2) \leq c_f^{(t_2)} - c_f^{(t_1)} + 2U.$$
Combine with Equation (9), there is:
$$\begin{aligned} W_g(t_1, t_2) &= W_g(t_1, t'_1) + W_g(t'_1, t'_2) + W_g(t'_2, t_2) \\ &\leq c_f^{(t_2)} - c_f^{(t_1)} + 4U. \end{aligned}$$
Since f is backlogged during (t_1, t_2),
$$W_f(t_1, t_2) = c_f^{(t_2)} - c_f^{(t_1)}$$
Thus:
$$W_f(t_1, t_2) \geq W_g(t_1, t_2) - 4U$$

□

Theorem 4.13. *(Fairness for non-overloaded clients) For any time interval $[t_1,t_2)$, we claim the following.*

Assume a client f is not backlogged at time t_1 and for any time interval $[t,t_2), t_1 \le t < t_2$, f has requested services less than $\frac{T(t,t_2)}{n(t,t_2)} - 5U$, where $T(t,t_2)$ is the total services received for all clients during the interval $[t,t_2)$, $n(t,t_2)$ is the number of clients that have requested services during the interval, and U is the upper bound from Equation (2).

Then, all of the services requested from f during the interval $[t_1,t_2)$ will be dispatched.

Proof. We prove by contradiction. Assume there is a request from f that has not been dispatched in t_2, i.e., f is backlogged at t_2. Since f is not backlogged at t_1, there exists a (non-empty) set of time steps such that f becomes backlogged. We let t be the largest element in the set, i.e. f is backlogged at any time in $[t,t_2)$. We claim that $W_f(t,t_2) \ge \frac{T(t,t_2)}{n(t,t_2)} - 4U$.

From the pigeonhole principle, there is at least one client g who has received services $W_g(t,t_2) \ge \frac{T(t,t_2)}{n(t,t_2)}$. If $f = g$, the claim holds. If not, from Theorem 4.9, we have

$$W_f(t,t_2) \ge W_g(t,t_2) - 4U \ge \frac{T(t,t_2)}{n(t,t_2)} - 4U.$$

Since f swicthes from non-backlogged to backlogged at t, requests sent before t at most contributes a U increase in $W_f(t,t_2)$. Thus, requests sent in (t,t_2) at least contribute to $\frac{T(t,t_2)}{n} - 5U$, which contradicts to the assumption in the theorem. □

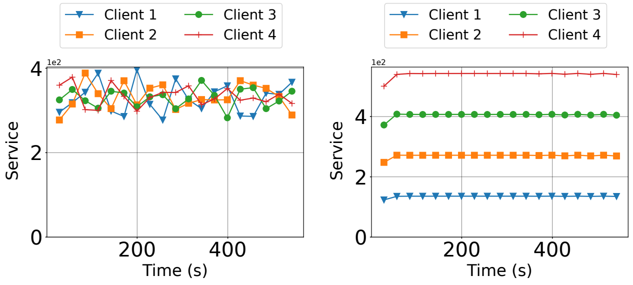
B Advanced VTC Variants

This section presents additional experiments on various variants of VTC. Appendix B.1 evaluate weighted VTC, which is introduced in Section 4.3. In Appendix B.2, we show concretely how VTC can be tailored to specific cost functions, using a profiled service cost function as an example. In Appendix B.3, we include more analysis of VTC with length prediction, which is introduced in Section 4.4. We empirically show its effectiveness in obtaining a better service discrepancy.

For all experiments shown in this section, we run Llama-2-7b on A10G (24GB), using the memory pool of 10000 tokens for KV cache.

B.1 VTC for Weighted Fairness

Figure 16 demonstrates the effectiveness of the weighted VTC in managing clients with varied priority levels. We conducted a test using a synthetic workload involving four overloaded clients. The results depicted in Figure 16a were achieved using standard VTC, which illustrates the comparable levels of service received by all four clients. In contrast, Figure 16b, which was obtained through the application of weighted VTC, shows differentiated service levels. The clients were assigned weights of 1, 2, 3, and 4, respectively, and the resulting service distribution closely adhered to these ratios.



(a) VTC

(b) Weighted VTC

Figure 16: Received service during the 10 minutes of the synthetic overloaded workload with input and output length both at 256. The figure on the left is obtained through standard VTC. The figure on the right is obtained through weighted VTC with weights 1:2:3:4 for the 4 clients.

B.2 VTC with Profiled Cost Function

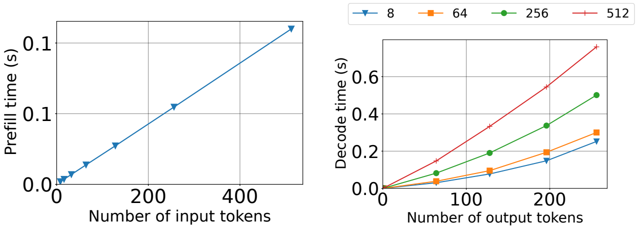
In this section, we demonstrate the generalizability of the token cost function used in VTC (see Section 4.2) by using a profiled service cost function.

To match our experimental setup, we profiled the inference time for Llama-2-7b on an A10G (24GB) across various conditions, as shown in Figure 17. We employed a batch size that utilizes the entire memory pool for each data point corresponding to specific input and output lengths. Consequently, shorter lengths allow for larger batch sizes, while longer lengths necessitate smaller ones. The prefill time is determined by dividing the total prefill time of the batch by the batch size. Similarly, the decode time is calculated by dividing the time taken to decode all tokens in the batch by the batch size. The function $h(n_p,n_q)$ is defined as the sum of prefill and decode times for the data point with input length n_p and output length n_q.

When considering the same total number of input and output tokens, the decode time for scenarios involving all output tokens is about 2 to 5 times the prefill time for scenarios involving all input tokens. The profiled cost function does not follow a linear model. We proceeded to fit the profiled data points and adjusted the coefficients to derive the following cost function:

$$h(n_p,n_q) = 2.1 \cdot n_p + n_q + 0.04 \cdot n_p n_q + 0.032 \cdot n_q^2 + 11.46$$

We conducted real trace experiments using this profiled cost function as the metric, the results of which are presented in Table 3. The disparity between VTC and other baseline methods is insignificant because clients with low request rates,



(a) Prefill Time

(b) Decode Time

Figure 17: Profiled prefill and decode time in different settings. For each data point, the batch size is set to the maximum to fulfill the memory pool (full utilization). The prefill time and decode time are all divided by the batch size. For the figure on the right, the legend for each curve denotes its number of input tokens.

when starved, do not substantially impact the overall service difference. However, as observed in Figure 18, VTC successfully maintains low response times for clients with low request rates, a feat not matched by other baselines except for LCF. In the case of LCF, clients with consistently high request rates face undue penalties, resulting in excessively high response times. We reinforce our findings by assessing the profiled cost function on a synthetically overloaded workload to highlight the differences between VTC and FCFS, as shown in Table 4.

The results empirically show that VTC can achieve fairness using a customized cost function. However, our goal is not to determine the optimal cost function or pricing model, as these can vary based on numerous factors in a production environment and may change over time. The investigation into the cost function and pricing model is designated for future research.

Scheduler	Max Diff	Avg Diff	Diff Var	Throu	Isolation
FCFS	743.23	457.29	26645.42	777	No
LCF	709.35	384.78	23299.20	778	Some
VTC	707.35	368.74	21918.67	780	Yes
VTC(predict)	617.22	337.05	11803.41	778	Yes
VTC(oracle)	**387.43**	**277.18**	**4541.57**	**783**	**Yes**
RPM(5)	230.78	151.00	823.15	340	Some
RPM(20)	445.34	270.51	5938.52	694	Some
RPM(30)	801.16	377.22	25980.39	747	Some

Table 3: Results run on real workload under the profiled cost function introduced in Appendix B.2. The service difference is counted by summing the service difference between each client and the client who received the maximum services. Throughput is the total number of tokens (including input and output tokens) processed divided by the total execution time.

Scheduler	Max Diff	Avg Diff	Diff Var	Throughput
FCFS	323.18	317.13	15.98	876
VTC	137.27	74.87	2819.40	900
VTC(oracle)	4.28	0.34	0.91	893

Table 4: Results run on the synthetic overloaded workload with 2 clients under the profiled cost function introduced in Appendix B.2. The work difference is counted by summing the work difference between each client and the client who received the maximum services.

B.3 VTC with Length Prediction

The adapted pseudocode for VTC with length prediction is detailed in Algorithm 3. In line 25, the cost associated with the predicted number of output tokens is preemptively calculated. Lines 32-37 describe the adjustments made to the cost to correspond with the actual number of output tokens produced.

Figure 19 demonstrates how length prediction reduces service discrepancies among clients in a synthetic workload scenario where all clients are overloaded. "VTC (oracle)" refers to a simulation using a predictor with 100% accuracy. "VTC (±50%)" simulates a predictor that randomly selects a value within 50% of the actual output length, either above or below. While standard VTC ensures that the absolute differences in services received by clients remain bounded and do not grow over time, VTC with length prediction significantly lowers these differences throughout the test period, even with a prediction error margin of 50%. Table 5 and Table 6 provide quantitative assessments of the service discrepancies among overloaded clients under the same conditions.

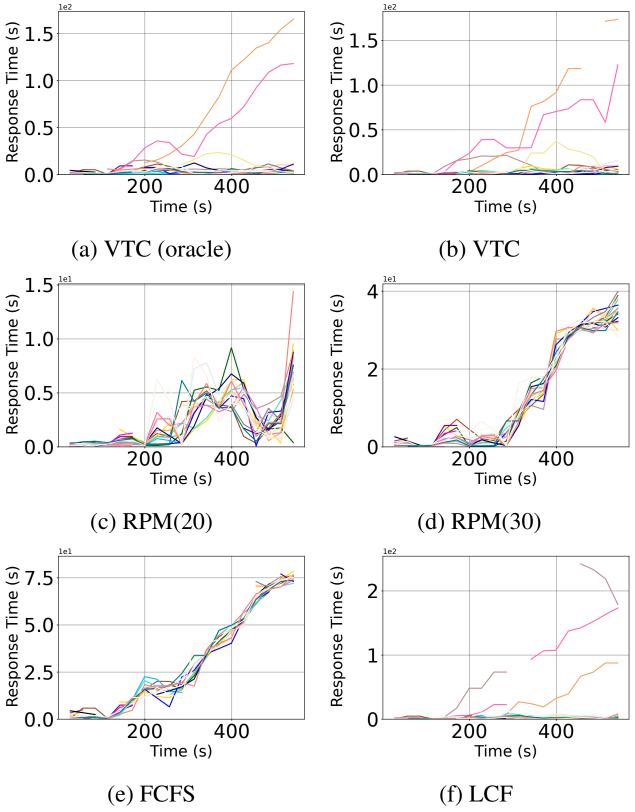
Scheduler	Max Diff	Avg Diff	Diff Var	Throughput
VTC	192.88	103.77	6981.24	893
VTC (±50%)	33.98	12.54	111.94	904
VTC (oracle)	5.87	0.51	1.71	895

Table 5: Results run on 10-minute synthetic workload same with Figure 19 for 2 clients. The service difference is counted by summing the work difference between each client and the client who received the maximum services. Throughput is the total number of tokens (including input and output tokens) processed divided by the total execution time.

C Discussions

C.1 VTC Integration in Real Systems

In Algorithm 2, we have shown an example of VTC integration with continuous batching. In implementation, VTC integration should be a simple change in the request scheduler. Generally, for an existing serving system, there are three mod-



(a) VTC (oracle)

(b) VTC

(d) RPM(30)

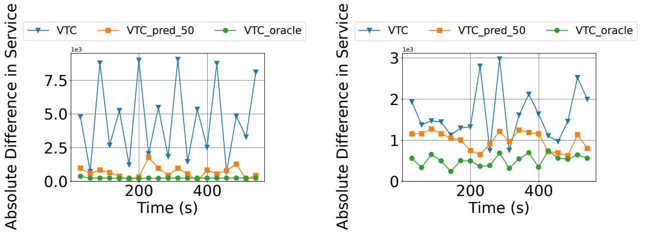
(e) FCFS

(f) LCF

Figure 18: Response time of the 27 clients during the 10 minutes of real trace simulation using different schedulers. The VTC style schedulers are using the profiled cost function introduced in Appendix B.2. There are some curves that show disconnected because, during some periods, a client may have no requests served. Requests distribution see Figure 11.

ules that need to be modified. First, the monitoring stream handles counter-lifting when a new request comes, as shown in Algorithm 4, which is the same as in Algorithm 2. Second, when new tokens have been processed, the counters should be updated according to a pre-defined cost function as discussed in Section 4.2. Third, when new requests need to be selected for processing, we schedule the request from a user with the lowest counter first. The added modules are demonstrated in Algorithm 4. We are assuming a customized cost function $h(n_p, n_q)$ as introduced in Section 3.1. At line 22, n_p^r, n_q^r denote the number of processed input and output tokens, and $n_p^{r(old)}, n_q^{r(old)}$ denote the number of processed input and output tokens before processing the new tokens.

Those modules for maintaining the virtual token counters and selecting requests according to the counters could be additive features of an existing serving system. However, in some cases, VTC is possibly in conflict with a scheduling algorithm that optimizes performance while being against fairness. Cache-aware scheduling introduced in [54] is an example in which requests with shared prefixes will always be prioritized. A natural solution to combine the two is adding a policy of switching between the two schedulers by setting tolerable fairness bounds. We leave such exploration as future research.



(a) 2 Clients

(b) 8 Clients

Figure 19: The figures illustrate the maximum difference in accumulated service received by clients during a 10-minute period of synthetic workload, where both the input and output lengths are set at 256. The left figure is derived from a simulation involving two clients, while the right figure comes from a simulation involving eight clients. In both scenarios, the request rate for each client surpasses the available capacity, resulting in continuous backlogging of each client.

Scheduler	Max Diff	Avg Diff	Diff Var	Throughput
VTC	322.16	162.20	5151.49	875
VTC (± 50%)	99.43	66.32	487.10	875
VTC (oracle)	43.23	36.34	56.52	875

Table 6: Results run on 10-minute synthetic workload same with Figure 19 for 8 clients. The service difference is counted by summing the work difference between each client and the client who received the maximum services. Throughput is the total number of tokens (including input and output tokens) processed divided by the total execution time.

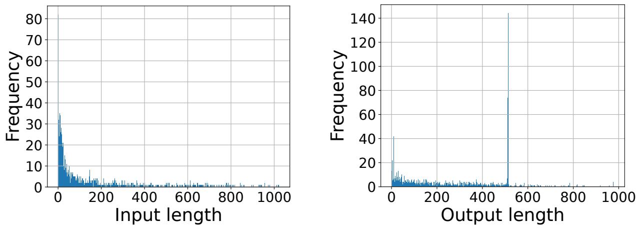


Figure 20: Request input and output length distribution in the real workload trace during the sampled 10 minutes duration with re-scale. The average input length is 136, and the average output length is 256. The input and output lengths have the range of $[2, 1021]$ and $[2, 977]$, respectively.

C.2 Adapted Deficit Round Robin

We have briefly discussed in Section 2.3 why Deficit Round Robin (DRR) cannot be directly applied. In this section, we

Algorithm 3 VTC with Length Prediction

            let $k \leftarrow \arg\min_{i \in \{client(r) | r \in Q\}} c_i$
            let $r$ be the earliest request in $Q$ from $k$.
            if $r$ cannot fit in the memory then
                Break
            $c_k \leftarrow c_k + w_p \cdot input\_length(r)$
            $c_k \leftarrow c_k + w_q \cdot predicted\_output\_length(r)$
            $B_{new} \leftarrow B_{new} + r$
            $Q \leftarrow Q - r$
        forward_prefill($B_{new}$)
        $B \leftarrow B + B_{new}$
    forward_decode($B$)
    ▷ Adjust the cost of output tokens
    for each $r \in B$ do
        $\delta \leftarrow output\_len(r) - predicted\_output\_len(r)$
        if $\delta > 0$ then
            $c_{client(r)} \leftarrow c_{client(r)} + w_q$
        if $r$ is finished and $\delta < 0$ then
            $c_{client(r)} \leftarrow c_{client(r)} + w_q \cdot \delta$
    $B \leftarrow$ filter_finished_requests($B$)
```

Algorithm 4 General VTC

```
Input: request trace, input token weight $w_p$, output token
    weight $w_q$, upper bound from Equation (2) denoted as $U$.
let current batch $B \leftarrow \emptyset$
let $c_i \leftarrow 0$ for all client $i$
let $Q$ denote the waiting queue, which is dynamically
changing.
▷ with monitoring stream:
while True do
    if new request $r$ from client $u$ arrived then
        if not $\exists r' \in Q, client(r') = u$ then
            if $Q = \emptyset$ then
                let $l \leftarrow$ the last client left $Q$
                $c_u \leftarrow \max\{c_u, c_l\}$
            else
                $P \leftarrow \{i \mid \exists r' \in Q, client(r') = i\}$
                $c_u \leftarrow \max\{c_u, \min\{c_i \mid i \in P\}\}$
        $Q \leftarrow Q + r$
▷ when process new request:
if add_new_request() then
    let $k \leftarrow \arg\min_{i \in \{client(r) | r \in Q\}} c_i$
    let $r$ be the earliest request in $Q$ from $k$.
    $Q \leftarrow Q - r$
    original process when selecting $r$.
▷ when new tokens been processed:
$c_i \leftarrow c_i + \sum_{r|client(r)=i} \left( h(n_p^r, n_q^r) - h(n_p^{r(old)}, n_q^{r(old)}) \right)$
```

discuss an adaptation of Deficit Round Robin [45] and show it is equivalent to our proposed VTC scheduler.

The original DRR can be described as follows:

1. The algorithm maintains a constant Q, which is the quantum that each client has.
2. Every client maintains a variable C_i that represents its deficit, which is initialized as 0.
3. On each round, the algorithm visits each client with a non-empty queue and schedules its requests as many as possible if the incurred cost P is less than or equal to $Q + C_i$. The C_i is then updated to $Q + C_i - P$ if $P > C_i$ or $C_i - P$ if else.

The obstacle to applying DRR in LLM serving is that we do not know how many requests we should schedule to meet the requirement of $P \leq Q + C_i$ since the number of output tokens is unknown in advance.

We then give an adapted version for LLM serving:

1. The algorithm maintains a constant Q, which is still the quantum that each client has.
2. Every client maintains a variable C_i that represents its debt, which is initialized as 0.
3. In each round, the algorithm processes each client. If $C_i \leq 0$, it refills C_i by adding Q to it. Should the updated C_i become positive, the algorithm schedules as many requests as possible, such that the cost associated with the prompt tokens P slightly exceeds C_i with the addition of the last scheduled request. After scheduling, P is subtracted from C_i.
4. Each time a new token is decoded, the associated cost is deducted from the respective C_i. Consequently, C_i may become negative, exceeding the value of Q multiple times, and it might require waiting through several

rounds before it can be scheduled again.

Fairness is no longer strictly bounded by Q, yet a smaller Q promotes a tighter constraint. When $Q = \varepsilon$ is extremely small, smaller than the cost of a single prompt token, the algorithms revert to functioning like the VTC algorithm. This is because each round results in one of two outcomes: either all C_i values remain non-positive, prompting another round, or the highest C_i turns positive and the corresponding client is scheduled. The client with the highest C_i is the one who has received the least service, which corresponds to having the smallest virtual counter in VTC.

If a client has no requests in the queue at a given time, it will cease to be refilled once $C_i \geq 0$. When a new request arrives, its C_i will be within $(0, \varepsilon]$, approximating $\max_i C_i$. The $\max_i C_i$ remains within the range of $(0, \varepsilon]$ because the algorithm persistently adds ε to C_i to maintain it positive, but then rapidly pulls it back into the negative by scheduling new requests. This process mirrors the counter lift mechanism in VTC.

In addition to its similarity to VTC, practically, simulating repeated round-robin with a small quantum Q is inefficient. Therefore, we focus solely on analyzing VTC in this paper, leaving the discussion of the round-robin simulation here for reference.

C.3 Future Work

Preemption As we mentioned in Section 2.1, this paper focuses on how to integrate fair scheduling with continuous batching, and leaving an investigation on preemption as an orthogonal future work. But we still would like to discuss how preemption will affect the VTC algorithm, and point out a possible future research on it.

The nature of unpredictable length in a no-preemption framework directly affects the fairness bound in the main theorem Theorem 4.4, which is $U = 2\max(w_p \cdot L_{input}, w_q \cdot M)$. Intuitively, the worst case occurs when many requests from one client are added, generating a large number of tokens that cannot be preempted. During the process, other clients cannot catch up arbitrarily because the memory is occupied. Essentially, this is caused by an underestimation of a future number of tokens, similarly explained in the ablation study (Section 5.4) and VTC with length prediction (Section 4.4).

In Theorem 4.7, we mentioned that we could restrict the memory usage for each client in the running batch to obtain a better bound. However, this can potentially lower the overall throughput because the memory may not always be fully utilized. Having a preemption mechanism could be a good solution to address the problem of underestimating and tightening the bound. Basically, if the difference in service is larger than a threshold, we can preempt the requests in processing and swap in requests from clients with lower counters.

VTC for distributed systems Integrating VTC in a distributed LLM serving system is an interesting direction for future work. For a distributed setup where there are many replicas of serving engines, we will have a central request dispatcher where we can keep the token counter and enforce the algorithm (this is similar to hierarchical fair sharing [4] in the network domain, and multi-queue fair queuing [19]). The bound now is dependent on the total memory capacity of all the serving engines. However, in the distributed setting, the counter will be updated by different serving engines concurrently, raising the problem of counter synchronization, which will be interesting to explore as a future work.

VTC and Auto-scaling The VTC algorithm does not rely on a constant capacity. Adding and removing GPUs will not affect the algorithm but may need a hierarchical virtual counter as discussed in the paragraph about distributed systems. However, auto-scaling is a possible approach to mitigate the issue of throughput degradation in RPM. The resources can be auto-scaled to fit the fluctuating traffic, but this requires flexible and responsive resource management. Auto-scaling has its own challenges, including operational cost overhead, inaccurate workload prediction, and delays. A combination of VTC and auto-scaling is a future direction worth exploring.

MonoNN: Enabling a New Monolithic Optimization Space for Neural Network Inference Tasks on Modern GPU-Centric Architectures

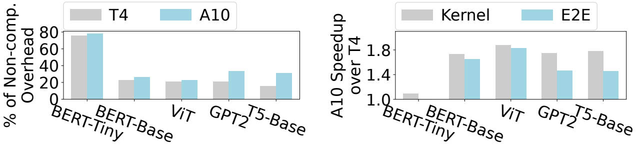
Shuaiwen Leon Song [†]
[†]*The University of Sydney* [‡]*Alibaba Group*

Abstract

In this work, we reveal that the kernel-by-kernel execution scheme in the existing machine learning optimizing compilers is no longer effective in fully utilizing hardware resources provided by the advances of modern GPU architectures. Specifically, such scheme suffers from severe non-computation overhead and off-chip memory traffic, making the optimization efforts from the state-of-the-art compiler techniques greatly attenuated on the newer generations of GPUs. To address this emerging challenge, we propose *MonoNN*, the first machine learning optimizing compiler that enables a new monolithic design and optimization space for common static neural network (NN) inference tasks on a single GPU. MonoNN can accommodate an entire neural network into a single GPU kernel, drastically reducing non-computation overhead and providing further fine-grained optimization opportunities from the newly formed monolithic optimization space. Most importantly, MonoNN identifies the resource incompatibility issue between various NN operators as the key design bottleneck for creating such a monolithic optimization space. Then MonoNN effectively tackles it by systematically exploring and exploiting the parallelism compensation strategy and resource trade-offs across different types of NN computations, and by proposing a novel schedule-independent group tuning technique to significantly shrink the extremely large tuning space. Finally, MonoNN provides a compiler implementation that incorporates our proposed optimizations and automatically generates highly efficient kernel code. Extensive evaluation on a set of popular production inference tasks demonstrates that MonoNN achieves an average speedup of 2.01× over the state-of-the-art frameworks and compilers. Specifically, MonoNN outperforms TVM, TensorRT, XLA, and AStitch by up to 7.3×, 5.9×, 1.7× *and* 2.9× in terms of end-to-end inference performance, respectively. MonoNN source code is publicly available at `https://github.com/AlibabaResearch/mononn`.



(a) Percentage of non-computation overhead on two generations of inference GPUs.

(b) GPU kernels-only speedup vs end-to-end (E2E) speedup by shifting hardware from T4 to A10.

Figure 1: Low hardware utilization for inference caused by growing non-computation overhead.

1 Introduction

In recent years, machine learning (ML) inference tasks have become one of real-world systems' most fundamental computation types. Existing optimization approaches [2, 7, 18, 24, 39, 41, 42] transform an ML computational graph into hundreds or thousands of computation kernels, and offload them onto high-performance AI accelerators, e.g., GPUs, for drastic latency reduction. However, with the increasing hardware advances of these complex GPUs on computation capability, the traditional kernel-by-kernel execution scheme is no longer effective in fully utilizing hardware resources.

Take XLA [2] as an example, which is one of the most popular and effective optimizers for ML workloads, Fig.1a shows the non-computation overheads (i.e., the end-to-end inference latency minus the pure kernel execution time on GPU) of five popular models on two generations of NVIDIA GPUs. Typically, the non-computation overhead mainly originates from frequent context switches between the host and GPU, e.g., framework scheduling and kernel launching. With the significant increase in computing power from T4 to A10, although the NN operators are executed faster, the non-computation

[◇] Work was done when interned at Alibaba.

[*] Equal contribution.

overheads tend to dominate the end-to-end performance, As illustrated in Fig.1b, the achieved end-to-end performance speedup can be far less than the kernel execution speedup when shifting across generations of hardware.

Moreover, the recent increase in computing power remains faster than that of memory bandwidth in recent generations of GPUs [42], making off-chip memory traffic among different GPU kernels within a model a significant performance bottleneck. Furthermore, there is a common scenario that often occurs in real-world systems and exacerbates the situation: CPUs are usually busy with data pre-/post-processing for real-time ML tasks, causing further delays in scheduling and launching their GPU kernels and subsequently increasing the non-computation overhead. To the best of our knowledge, although the kernel fusion scope and the corresponding techniques might be different, all the existing ML compilers [7, 18, 24, 39, 41, 42] suffer from performance issues discussed above due to the fundamental kernel-by-kernel execution scheme. Therefore, there is an urgent demand for a general solution with minimal non-computation overhead that can be widely applied to common ML inference tasks.

In this paper, we make a key observation that there exists *a monolithic design and optimization space* accommodating a wide spectrum of prevalent static DNN models in single GPU inference (Sec.3). MonoNN keeps the computation flow of the entire neural network on the GPU side without going back to the host to seek scheduling control. Such a scheme effectively avoids the non-computation overhead caused by the CPU-GPU context switch. With the structure of modern static DNNs consisting of repetitive layers, it would be more justified to aggressively enlarge the fusion scope, even result in a single kernel[1].

However, it is non-trivial to provide a general optimization scheme to consolidate all types of computations of an entire neural network into a *monolithic kernel*, while guaranteeing high performance and providing further fine-grained optimization opportunities from the newly formed monolithic optimization space. We observe that the main difficulty in forming such an optimization space is resource incompatibility between different types of neural network computations. On the one hand, a resource configuration that favors some operators can lead to a dramatic drop in performance on some other operators (e.g., low thread-level parallelism for GEMM computation is inefficient for element-wise operators). On the other hand, the resource configuration (e.g., parallelism configuration, register, and shared memory allocation) is fixed during the lifetime of a GPU kernel. Failure in reconciling such resource incompatibility in a monolithic kernel will result in poor performance. Furthermore, accommodating all operators of a complete NN into one GPU kernel results in an extremely large optimization space, making it very difficult for performance tuning on the whole computation graph.

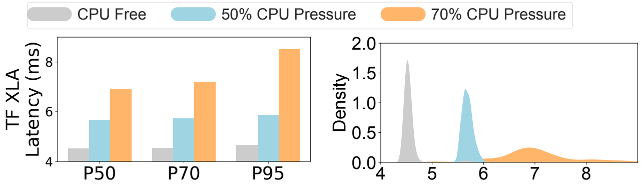
To address these emerging problems, we propose MonoNN, an ML optimizing compiler that enables a new monolithic optimization space for common NN inference tasks on modern GPU-centric architectures. Specifically, to address the significant resource incompatibility issue and accommodate the different resource requirements from various operators, we propose a *context-aware instruction rescheduling* technique (Sec.4.2.2). The key insight is to exploit the hidden instruction-level parallelism (ILP) for memory-intensive computations (e.g., element-wise, reduction) to compensate for the loss of the thread-level parallelism (TLP) under the monolithic kernel context. To further accelerate memory access, MonoNN classifies the memory access patterns into *streaming* and *temporal*, and comprehensively exploits all types of on-chip memory resources for the access patterns accordingly (Sec.4.3). It further exploits whole-graph level transformation inside the kernel to rearrange independent subgraphs together to reduce global thread barrier overhead (Sec.4.4). Finally, we systematically abstract the optimization space of the monolithic kernel and propose a *schedule-independent group tuning* approach to drastically compress the tuning space (Sec.5). Extensive evaluation on a set of neural network inference tasks demonstrates that MonoNN outperforms the state-of-the-art optimizers with an average of 2.01× speedup. Specifically, MonoNN outperforms TVM, TensorRT, XLA, and AStitch by up to 7.3×*,* 5.9×*,* 1.7× *and* 2.9× in end-to-end inference performance. To summarize, this work makes the following contributions:

- To the best of our knowledge, MonoNN is the first ML optimizing compiler that discovers a new monolithic optimization space for common static DNNs' inference scenarios that are served on a single GPU, and provides automatic high-performance kernel generation. This is also the first study that explores and evaluates this monolithic optimization design space and its limitations so that the community has a better understanding of the tradeoffs;
- It is the first optimizing compiler that explicitly exploits instruction-level parallelism optimization for memory-intensive operators to compensate for thread-level parallelism loss, enabling a new optimization dimension for neural network inference optimization;
- MonoNN enables a sophisticated compression mechanism to significantly shrink the tuning space for our proposed monolithic NN kernel;
- Extensive evaluation results have demonstrated the effectiveness of MonoNN on both single inference tasks as well as multi-inference processing scenarios.

2 Background and Motivation

Emerging Challenges in Optimizing NN Inference. From an optimization perspective, operators in neural network (NN) models can be classified into two categories, compute-intensive operators and memory-intensive opera-

[1] We also present a study on the fusion granularity under the monolithic optimization space in Sec.7.3



(a) Tail latency. (b) Latency distribution (ms).

Figure 2: T5 model latency statistics under each CPU pressure. The input sequence length is 128. (a): P50/P70/P90 tail latency. (b): latency distribution.

tors. Compute-intensive operators are typically composed of heavy arithmetic computations (e.g., GEMM and Conv), while memory-intensive operators are typically bounded by memory bandwidth (e.g., element-wise and reduction operations). Note that previous studies [18, 41, 43] have concluded both types of operators can dominate the execution time.

With the rapid growth of computing power for recent GPU generations[2], the execution time of compute-intensive operators decreases drastically. For example, Tensor Core brings an order of magnitude improvement in arithmetic unit throughput for compute-intensive operators since NVIDIA Volta architecture [3] (similarly, Matrix Core was also introduced in AMD GPUs since CDNA architecture [8]). However, there exists a disproportionate performance gain between hardware throughput improvement and end-to-end inference speedup. For instance, for the two common inference GPUs, NVIDIA A10 GPU has 1.9× more half-precision floating point throughput than its predecessor NVIDIA T4, while we only observe a 1.6× end-to-end inference speedup for the BERT model[3] [19] with XLA compiler optimization enabled [2]. Furthermore, we identified two emerging fundamental difficulties in optimizing inference scenarios on increasingly advanced modern GPUs:

(i) Continuous advances in computation throughput leads to an increasing portion of non-computation overhead.

Faster GPUs can offer shorter per-kernel execution in NN inference. However, the major portion of performance gains from hardware speed improvements for regular-size models begins to diminish as non-computation overhead becomes a notable portion of end-to-end latency. This new bottleneck mainly originates from frequent non-computation overhead which includes (1) context switch between host and GPU accelerator due to framework scheduling and kernel launch, and (2) off-chip memory traffic between operators.

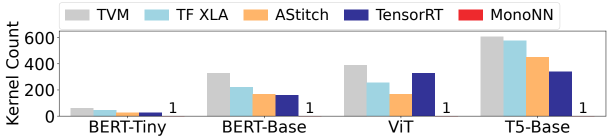


Figure 3: Number of inference GPU kernels for existing frameworks and MonoNN (1).

As the breakdown of the overall context switch overhead in Fig.1a, our measurements indicate that the framework scheduling accounts for 38.3% while the kernel launching overhead accounts for around 61.7% (see Sec.7.2.5 for more details). As for off-chip memory traffic, the memory bandwidth growth across hardware generations is generally slower than that for arithmetic throughput. Fig.1a demonstrates the non-computation inference overhead via XLA optimizations for five common models. It is worth noting that A10 suffers from more severe non-computation inference overhead than its predecessor T4 as newer generations of GPUs have much shorter per-kernel duration. Fig.1b illustrates that there is an average of 1.64× kernel execution speedup benefiting from shifting the underlying accelerator from T4 to A10. Unfortunately, such speedup decreases to 1.48× for the end-to-end latency as the non-computation overhead is not the highest optimization priority for the existing inference engines. Thus, the non-computation inference overhead for neural network models is becoming increasingly essential for the next generations of faster GPU hardware [6].

(ii) Ever-present, non-negligible CPU workloads exacerbate non-computation overhead.

Moreover, a commonly neglected factor is that CPU is usually busy with pre- and post-processing of input and output for NN tasks in real-world execution. Thus, CPU contention often further delays the scheduling and kernel launching of a large number of GPU kernels within a model execution. This further exacerbates the CPU-GPU context switch overhead and makes it a much more severe problem, causing an additional slowdown of model inference tail latency. In Fig.2a, when measuring the tail latency under XLA optimizations on a server with a 64-core CPU (128 threads) and an NVIDIA A10 GPU under 50% (70%) CPU utilization, the tail latency increases by 25% (52%), 26% (58%), and 26% (82%) at P50, P70, and P95, respectively, over the latency of an idle CPU. Fig.2b shows a detailed inference latency distribution of 1000 times of inference when CPU is under various utilization. With the increasing CPU contention, the end-to-end inference latency belongs to a wider range of much slower outliers. Note that it is impractical to designate a specific CPU core exclusively just for kernel launching in the datacenter because the CPUs are typically very busy performing pre-/post-processing. Besides, designating such a core requires a hardcoded list of CPU cores to be isolated from the default CPU scheduler in the system boot phase, resulting in rebooting for every new

[2] In this work, we focus our discussion on the most widely-adopted general-purpose AI accelerators: GPUs. Although the technical terminologies used in this paper are adopted from NVIDIA GPUs [4, 5], our proposed techniques aim to serve as general principles that are valuable for modern general-purpose machine learning system designs, and are applicable to other SIMT accelerators [8].

[3] Data is collected under TensorFlow XLA v2.7 with Tensor Core enabled, using 1 as the batch size and 128 as the sequence length.

inference service deployment.

Challenges in the State-of-The-Art Designs. TVM [18] applies a basic fusion strategy but still unnecessarily launches a large number of kernels. Some recent works propose more advanced fusion techniques to alleviate the problems above. AStitch [41, 42] leverages hierarchical GPU memory to fuse multiple memory-intensive operators with complex data dependencies into a single GPU kernel, named stitch optimization. TensorRT [11] also exploits a similar strategy since v8.

Although it helps reduce the kernel number to some extent, it still results in a large number of kernels since it is not capable to fuse globally along with all the compute-intensive operators, for which the bottlenecks that we discussed above still exist. As illustrated in Fig.3, TVM, XLA, TensorRT, and AStitch are all launching a large number of kernels during model inference. Furthermore, Rammer [24] partially addresses this problem with a persistent-thread technique [14, 17] to generate the schedule of multiple operators within one kernel. However, Rammer is incapable of handling the resource incompatibility between different operators in an entire neural network (see Sec.3.1). As a result, Rammer has to partition the neural network into separate GPU kernels for NN inference. For example, Rammer still launches 734 kernels on GPU for BERT-Large [19] model inference.

3 Monolithic Optimization Space

To address the emerging challenges discussed in Sec.2, we explore the *monolithic optimization space* where the entire neural network can be compiled into a single GPU kernel. This approach is appealing because it only incurs minimal non-computation overhead and enables the opportunities for whole graph optimization within the same kernel space. However, a general approach enabling this optimization space is non-trivial, especially when handling various NN models with very different execution patterns. Here we summarize two major challenges to auto-generate a highly-efficient GPU kernel containing all the operators of a given neural network.

On-chip Resource Limit

Figure 5: Optimization space comparison.

3.1 Main Challenges of Enabling A Monolithic Kernel Optimization Space

Challenge 1: Resource incompatibility between compute-intensive and memory-intensive operators. The resource incompatibility between compute-intensive and memory-intensive operators hinders the state-of-the-art techniques to consolidate all operators into a monolithic kernel. Compute-intensive operators usually require a large amount of on-chip resources (e.g., registers and shared memory) whereas memory-intensive ops rely on massive concurrent threads to hide off-chip memory access. Thus, *it is extremely difficult to accommodate all types of operators by creating a GPU kernel with both high on-chip usage and massive concurrent threads due to the resource constraints on modern GPUs*. For example, the active TLP on an SM core will inevitably drop when a kernel uses a large number of registers and shared memory due to the limited on-chip resources. We illustrate this phenomenon quantitatively using GPU kernels from a TensorRT optimized BERT [19] and the Pareto-optimal on-chip resource allocation curve on an NVIDIA A10 GPU in Fig.4. Compute-intensive kernels in NN models tend to be closer to the upper-left corner, representing high on-chip resource allocation and relatively low achieved concurrently active threads. In contrast, memory-intensive kernels tend to be closer to the bottom-right corner, representing low on-chip resource allocation and massive concurrently active threads (or high TLP). All data points in Fig.4 are subject to resource constraints and thus will not be above the Pareto-optimal curve.

Challenge 2: Extremely high implementation cost and huge tuning space. Modern ML models usually consist of thousands of operators with diverse computation patterns, resulting in intricate data dependencies. Manual implementation and optimization are no longer viable for developing a monolithic kernel. In terms of compiler optimization, the monolithic kernel approach significantly expands the optimization search space as all the operators coexist within the same kernel. Consequently, it becomes exceedingly challenging to identify suitable configurations and implementations for each operator to achieve optimal end-to-end inference efficiency within a monolithic kernel collectively.

3.2 A High-level Glance of MonoNN

The ultimate objective of MonoNN is to create an efficient joint optimization space for both compute-intensive operators (*CI Ops*) and memory-intensive operators (*MI Ops*). However, as elaborated in Fig.4 and Sec.3.1, these two types of operators naturally reside in disjoint optimization space in conventional solutions due to resource incompatibility. We conceptually illustrate this observation in Fig.5(a).

MonoNN enables a new monolithic optimization space that can effectively accommodate both *CI Ops* and *MI Ops*. The key idea is to align the optimization space of *MI Ops* as closely as possible with that of *CI Ops* (Fig.5(b)). Specifically, MonoNN leverages the hidden instruction-level parallelism (ILP) to offset the reduction in TLP for memory-intensive subgraphs, thereby achieving a similar resource allocation to *CI Ops* (Sec.4.2.2). Furthermore, MonoNN strategically utilizes abundant on-chip resources, including registers, shared memory, and cache, to buffer and prefetch off-chip data based on an analysis of memory access patterns (Sec.4.3). This approach enables both *CI Ops* and *MI Ops* to coexist within the same monolithic kernel efficiently. Additionally, MonoNN explores global optimization opportunities to minimize global synchronizations between computations, further enhancing the efficiency of neural network models (Sec.4.4).

4 System Design

4.1 Overview of MonoNN

Fig.6 illustrates the overview of MonoNN. MonoNN first formulates the input neural network into different subgraphs for subsequent optimizations (Fig.6(1), Sec.4.2.1). Then, MonoNN enables the hidden parallelism of memory-intensive subgraphs through context-aware instruction rescheduling (Fig.6(2), Sec.4.2.2), and comprehensively optimizes the usage of various on-chip resources according to memory access patterns (Fig.6(3), Sec.4.3). Next, it reorders and clusters subgraphs to reduce the required Global Thread Barriers (*GTBs*) to minimize the synchronization overhead (Fig.6(4), Sec.4.4). Finally, MonoNN abstracts, compresses, and tunes for the large monolithic optimization space with *schedule-independent group tuning*, and compiles the monolithic kernel into an executable binary (Fig.6(5)-(6), Sec.5).

4.2 Exploiting Hidden Parallelism for Memory-intensive Subgraphs

We address the resource incompatibility issue discussed in Sec.3 for memory-intensive computations with *context-aware instruction rescheduling* (the compute-intensive computations will be discussed in Sec.4.5.) MonoNN performs instruction rescheduling under the context of *monolithic optimization space* to recover potential TLP loss for memory-intensive computations with high-level instruction-level parallelism (ILP) enhancement. Thereby, MonoNN fully leverages the abundant registers under the new monolithic optimization space to unleash the hidden potential of reaching high performance.

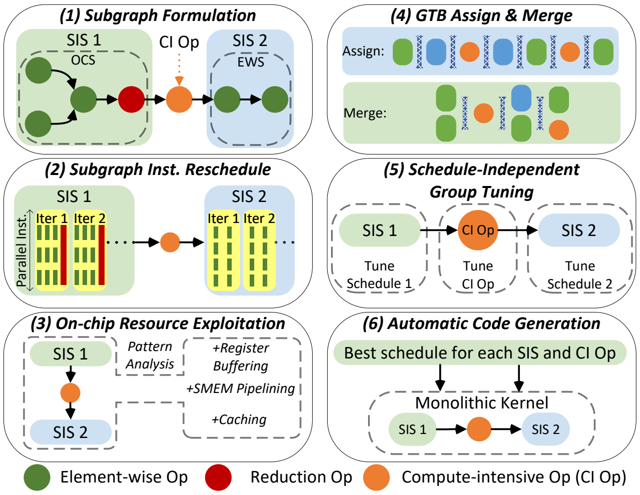

Figure 6: MonoNN overview. *SIS*: Schedule-independent subgraph. *EWS*: Element-wise subgraph. *OCS*: Output-only contracted subgraph.

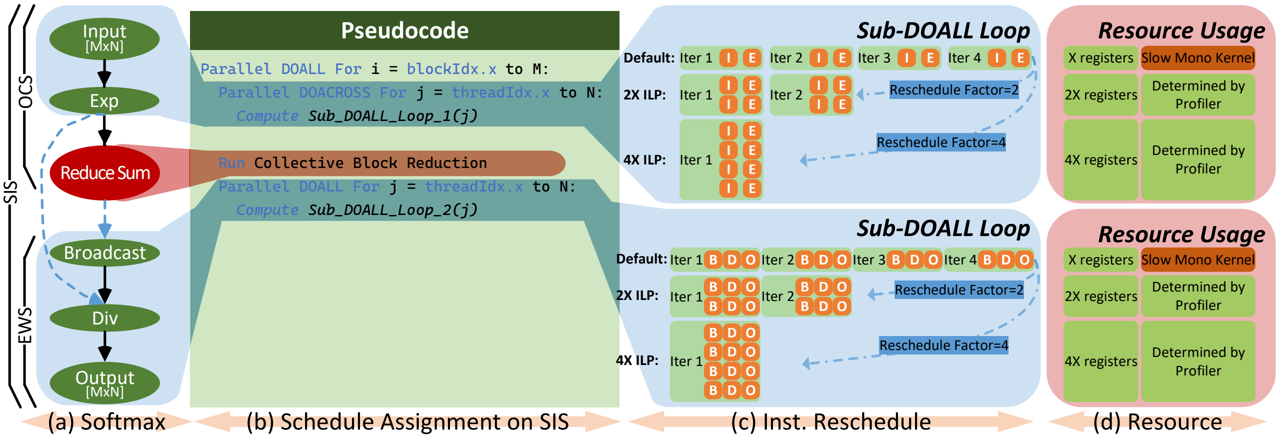
4.2.1 Memory-intensive Subgraph Formulation

Before unveiling the details of *context-aware instruction rescheduling*, we first present how subgraphs are formulated as the basic units of optimization exploration. MonoNN converts the whole graph of a model into one kernel. Instead of optimizing and generating the code of the whole graph all in one shot, MonoNN generates the schedules[4] of different partitions (i.e., subgraphs) of the graph separately under the same monolithic context, and then stitches them together with shared memory or global memory data buffering.

Subgraph Formulation. The compute-intensive operators divide the whole computation graph into a set of memory-intensive subgraphs. We use the following criterion to further categorize memory-intensive subgraphs based on data dependencies between data elements in input and output tensors.

Formally, for a subgraph with m input tensors $[\mathcal{X}_0, \mathcal{X}_1, \cdots \mathcal{X}_{m-1}]$ and n output tensors $[\mathcal{Y}_0, \mathcal{Y}_1, \cdots \mathcal{Y}_{n-1}]$, the computation of the subgraph is: $[\mathcal{Y}_0, \mathcal{Y}_1, \cdots \mathcal{Y}_{n-1}] = f([\mathcal{X}_0, \mathcal{X}_1, \cdots \mathcal{X}_{m-1}])$. If each pair of $\mathcal{X}_i \in [\mathcal{X}_0, \mathcal{X}_1, \cdots \mathcal{X}_{m-1}]$ and $\mathcal{Y}_i \in [\mathcal{Y}_0, \mathcal{Y}_1, \cdots \mathcal{Y}_{n-1}]$ that $\frac{\partial \mathcal{Y}_i}{\partial \mathcal{X}_i} \neq 0$ satisfies $\forall ey \in \mathcal{Y}_i, \left|\{ex | \frac{\partial ey}{\partial ex} \neq 0, ex \in \mathcal{X}_i\}\right| \leq 1$, in which ex represents a scalar data element in tensor $\mathcal{X}_i$ and ey represents a scalar data element in tensor $\mathcal{Y}_i$. It indicates that all data elements in any of the output tensors rely on at most one data element in one input tensor. We call a subgraph with such property as an *element-wise subgraph* (**or EWS**).

[4] In code generation, *schedule* means how the threads are mapped to hardware to process the data (e.g., tiling size, on-chip resource configuration, parallelism configuration for GEMM code generation).



```
Parallel DOALL For i = blockIdx.x to M:
  Parallel DOACROSS For j = threadIdx.x to N:
    Compute Sub_DOALL_Loop_1(j)
  Run Collective Block Reduction
  Parallel DOALL For j = threadIdx.x to N:
    Compute Sub_DOALL_Loop_2(j)
```

Figure 7: Context-aware instruction rescheduling for `softmax` computation.

Otherwise, if there exists an output tensor element that relies on multiple input tensor elements, the subgraph contains contraction operations that combine several data elements into one (one-on-many element-level data dependency). We refer to such a subgraph as a *contracted subgraph* (**CS**). In machine learning graphs, contractions are often represented by `reduce` operations (e.g., reduce-sum) in the intermediate representation (IR). If all the `reduce` ops of a subgraph are the output operations, we call the subgraph an *output-only contracted subgraph* (**OCS**). Note that a *CS* is either an *OCS* or could be decomposed into *OCS* and *EWS*.

Basic Codegen Scheme. MonoNN will first identify all the largest *OCS* through reverse traversal on the memory-intensive subgraphs. The remaining subgraphs are then *EWS*, which can be converted into DOALL loop [13] (i.e., loop with no inter-iteration dependency) for full parallelization.

An *OCS* contains the contraction computation in `reduce` op. The `reduce` ops in typical inference graphs are doing contraction over elements residing in a continuous address in memory (e.g., $Reduce([x,y]) => [x,1]$). For `reduce` ops on GPU, the non-contracted dimension (e.g., x in the above example) forms a DOALL loop *without* inter-iteration dependency. Whereas the inner contracted dimension (e.g., y in the above example) forms a DOACROSS loop [13] *with* inter-iteration dependency due to contraction computation. Note that in some cases, it might be beneficial to use a uniform schedule for adjacent subgraphs with loop fusion if certain locality constraints are met. For example, in Fig.7(a), an *OCS* followed by an *EWS* can use a uniformed schedule by fusing the outer loop, as the output of *OCS* can buffer on on-chip cache for subsequent read from *EWS*. This technique, also known as stitch fusion [42], is shown as dotted lines in Fig.7(a). We call subgraphs that have independent schedule *schedule-independent subgraphs*, *SIS* in short. Several subgraphs that use a uniform schedule after loop fusion are regarded as one *SIS* (e.g., Fig.7(b) shows an *SIS* after fusing an *OCS* and an *EWS*). The schedule within an *SIS* is constrained by loop structure and block locality, while the schedules among different *SIS* are independent. Different *SIS* with its own schedule is finally stitched together under MonoNN with global memory buffering for intermediate transferring.

4.2.2 Context-Aware Instruction Rescheduling

We illustrate how to enable the hidden parallelism given an *SIS* subgraph with the example in Fig.7(a). Note that the contracted dimension of the `reduce` op is *N*, which maps to the inner loop (i.e., parallel threads within a thread block), The non-contracted dimension is *M*, which maps to the outer loop (i.e., different thread blocks).

According to the property of *OCS*, it can be divided into a sub-*EWS* followed by a `reduce` op. Thus, the inner loop of *OCS*, which is a DOACROSS loop, can be converted to a sub-DOALL loop (Fig.7(c)) followed by the corresponding reduction. With the conversion above, the inner-loop of the *SIS* is converted to the computation sequence of "*sub-DOALL loop* ⇒ *reduction* ⇒ *sub-DOALL loop*" (Fig.7(b)-(c)).

The key insight of context-aware instruction rescheduling is to rearrange the instructions according to the property of the DOALL loop.

In Fig.7(c), the DOALL loop has no inter-iteration dependencies, allowing MonoNN to explore the default schedule as well as the ILP enhanced schedules (e.g., 2*X* ILP) by merging instructions from different iterations into parallel instructions within the same iteration to ensure stall-free instruction issue. Theoretically, all schedules shown in Fig.7(c) achieve near-maximum overall parallelization ($TLP \times ILP$), with the default schedule yielding varied TLP for different operators, thus necessitating numerous GPU kernels. In contrast, MonoNN can identify a schedule that maximizes overall parallelization and optimally fits TLP into a single monolithic kernel. The optimization space for utilization abundant registers (Fig.7(d)) and corresponding performance in the monolithic kernel will be explored, as determining the best scheduling factor involves balancing ILP and resource usage. We will discuss

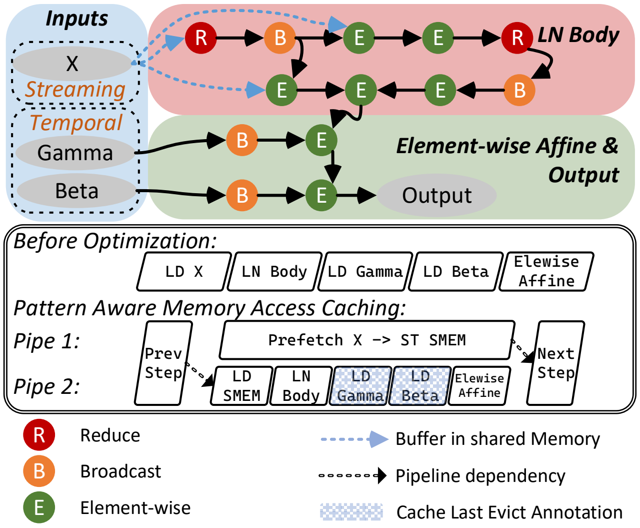


Figure 8: On-chip resource exploitation for layer norm.

how to find the optimal rescheduling factor for each *SIS* in Sec.5

4.3 On-Chip Resource Exploitation

For an SIS memory-intensive subgraph, global memory access often takes up a significant amount of execution time, particularly when thread-level parallelism (TLP) is limited in a monolithic context. Along with boosting parallelism through instruction rescheduling as discussed in Sec.4.2.2, MonoNN performs a comprehensive on-chip memory resource exploitation to maximize the use of memory resources based on access patterns.

We observe that there are two major memory access patterns for an *SIS* subgraph: (1) *Streaming*: Each element of the input tensor is accessed once in the computation graph. (2) *Temporal*, Each data item in the input tensor is read multiple times by its consumers, commonly due to `broadcast` operators in modern ML models. MonoNN implements a series of memory access optimizations based on these patterns.

(I) Streaming Access Optimization. MonoNN leverages the abundant shared memory resource allocated by the compute-intensive computations in the monolithic kernel to pipeline the streaming global memory access with other computations. As mentioned, the outer loop of an *SIS* subgraph is a DOALL loop, where different iterations are independent. MonoNN organizes the computations between different iterations of the outer loops to form a computation pipeline and a memory copy pipeline. Particularly, during the computation of each outer loop iteration, it will prefetch the streaming accessed input data for the next iteration into the shared memory buffer. Fig.8 presents the input data access pipelining for layer norm [15]. *LN Body* represents the main layer norm computation and *Element-wise affine* represents the following element-wise affine transformation parameterized by *Gamma* and *Beta*. The memory access to input *X* is prefetched onto shared memory in the computation pipeline, fully overlapping the data fetching and computation. Note that the input *X* in Fig.8 is consumed by multiple operators. If the shared memory is not enough for the data buffering, MonoNN will not make a pipelined buffer *X*. Instead, MonoNN will buffer *X* on the register file (or local memory if facing register spills), for which the multiple consumers will reuse the data through the faster register file rather than the global memory.

(II) Temporal Access Optimization. If the input data access is temporal rather than streaming, MonoNN will annotate cache hints to these memory operations to guide the cache behavior to preserve the data on the cache as long as possible (e.g., *evict_last* in NVIDIA GPU semantics). MonoNN will annotate memory read as temporal access from the node with a smaller tensor shape until an empirical value is reached to accommodate as many tensors as possible and prevent cache thrashing. As shown in Fig.8, *Gamma* and *Beta* have temporal locality because they are connected to the subsequent `broadcast` op. A load of *Gamma* and *Beta* will be annotated with *evict_last* for longer cache occupation, improving the temporal locality in *SIS*.

4.4 Global Thread Barrier Merging

As mentioned in Sec.4.2, there are cross thread block data dependencies between different *SIS* subgraphs. MonoNN inserts global thread barrier (**GTB**) between *SIS* subgraphs to ensure correctness. Note that *GTBs* are also required between compute-intensive operators and *SIS* subgraphs. Similar with [42], *GTB* in MonoNN is implemented in two stages: one-block-wait-all and one-block-notify-all. Each block has a flag in global memory (typically cached in GPU L2) to represent whether the corresponding thread block has arrived. The first thread block waits for all the remaining blocks to report waiting, and then notifies them to proceed. Furthermore, the inner-kernel *GTB* is much shorter than the non-computation overhead as the latter is composed of both kernel launching and framework scheduling overheads. The overhead measurement results of inner-kernel *GTB* [42] and kernel launching [37] from the previous studies are aligned with our observation that a typical kernel launching overhead is often multiples of a *GTB* length, e.g., a single kernel launching with framework scheduling is around $8 \sim 10$ microseconds which is $4 \sim 5\times$ of a *GTB* length.

Longest-path based GTB merging. One *GTB* introduces minimal synchronization overhead, but this can accumulate when the number of *GTBs* is large. We have observed that some *SIS* subgraphs do not exhibit producer-consumer or topology dependencies. By clustering these independent *SIS* subgraphs in topological order, MonoNN can eliminate the need for *GTBs* between them. To address graph complexity, we propose the *longest-path based GTB merging* approach to find the optimal *SIS* clustering strategy. For example, in Fig.9, the nodes (A-E) represent the *SIS* subgraphs, with *GTBs*

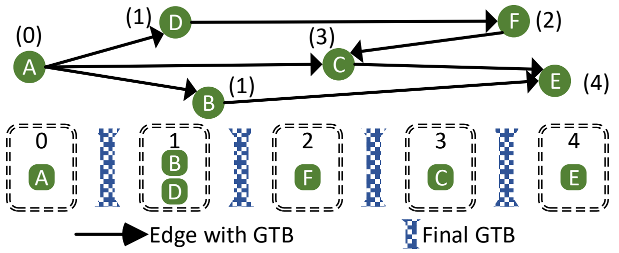

Figure 9: Global thread barrier merging. The numbers above nodes represent the longest distance from the source node to the current node.

required between them (indicated by edges). MonoNN calculates the longest path to each node from the first node. Nodes with the same longest path length (e.g., B and D in Fig.9) can be clustered together for *GTB* merging. Traditional topology ordering methods only order nodes and do not cluster them, making them inadequate for guiding *GTB* merging.

4.5 Optimizing Compute-Intensive Operators

While the memory-intensive subgraphs are effectively optimized to maximally leverage on-chip resources, the compute-intensive operators in MonoNN directly adopt the existing implementations from CUTLASS [1] as tunable basic building blocks: the tuning space of CUTLASS is included in the tuning space for the monolithic kernel.

5 The MonoNN Compiler

This section details the design and implementation of an optimizing compiler that automatically generates efficient monolithic kernels using the techniques outlined in Sec.4. Unlike previous works that focus on tuning single operators or subgraphs [18,42], MonoNN optimizes the entire graph, resulting in a vast optimization space. This complexity makes finding the optimal global configuration challenging. We explain how we systematically abstract this extensive optimization space in Sec.5.1 and how we reduce it to efficiently identify a suitable global configuration in Sec.5.2.

5.1 Optimization Space Abstraction

First, we categorize the proposed optimizations into two types: (1) Deterministic optimizations are always beneficial. Including *comprehensive on-chip resource exploitation* (Sec.4.3) and *global thread barrier merging* (Sec.4.4). (2) Tunable optimizations: All other optimizations not included in the deterministic category are considered tunable. We classify the tunable factors of the monolithic kernel into three main classes:

(I) Code generation schedule of each operator in a neural network. In the code generation process, element-wise operators follow the code generation schedule of `reduce` operators through input-inline. Thus, we only need to tune the schedule of `reduce` operators and compute-intensive operators (*CI Ops*). Note that a grid-stride loop will be used to iterate over its input elements if an element-wise operator cannot find a `reduce` or *CI Ops* that it associates with. There are two common schedules for row-major `reduce` operators. One is to reduce a row of elements with all threads in a thread block. The other one is to reduce a row with one warp. For *CI Ops*, MonoNN will jointly consider all the tunable factors, including tiling size, on-chip resource configuration, parallelism configuration, hardware intrinsic (e.g., Tensor Core instruction and CUDA async-copy), input prefetching, etc.

(II) Context-aware instruction rescheduling factor. ILP is important for the *SIS* subgraphs to compensate for parallelism loss under the constraint TLP in a monolithic kernel. A too-small rescheduling factor may be insufficient to improve the overall parallelism. A rescheduling factor that is too large will use massive registers and may cause register spilling. MonoNN explores a spectrum of the rescheduling factors for each memory-intensive operator (*MI Op*). Specifically, for each *MI Op*, MonoNN explores up to 32*X* rescheduling factors [5] via *context-aware instruction rescheduling*. In Sec.7.2.1, we quantitatively evaluate how different ILP rescheduling factors impact *MI Ops* on performance.

(III) TLP and on-chip resource of the overall monolithic kernel. TLP on GPUs is defined as the thread block size and number of blocks for a GPU kernel, and on-chip resource constraints are critical performance factors for efficient program execution. For the monolithic kernel, these factors not only affect the optimal execution configuration (e.g., tiling size) for *CI ops*, but also impact the optimal rescheduling for *context-aware instruction rescheduling* and optimal code generation schedule for memory-intensive subgraphs (e.g., warp reduction vs block reduction). The candidate block sizes for tuning are 128 and 256 for MonoNN, which are the main block sizes used in the existing machine learning compilers [2, 7] and CUTLASS for achieving good performance for both *CI Ops* and *MI Ops*. Other block sizes may also be trivially included to the optimization space. Our monolithic kernel requires that all thread blocks be able to be scheduled onto GPU concurrently in one wave to avoid deadlock in synchronization. Thus, the total thread block number should be no more than the max number of thread blocks that GPU can tolerate. Specifically, the number of candidate TLP choices is $N_{TLP} = \left|\{128, 256\}\right| \times N_{blocks-per-sm} = 2 \times N_{blocks-per-sm}$, where $N_{blocks-per-sm} = \left|\{1, 2, ..., N_{max-blocks-per-sm}\}\right|$ We empirically choose $N_{max-blocks-per-sm}$ as 5 because too many co-existing thread blocks will result in insufficient available on-chip cache per block and further slow down *CI Ops*.

[5] The range of ILP is constrained by on-chip resources and thus is up to 32 for hardware we evaluated.

5.2 Schedule-Independent Group Tuning

5.2.1 Extremely Large Tuning Space

The tuning complexity on the optimization space is up to: $O_{naive} = (S_C)^{N_C} \times (S_M \times N_{ILP})^{N_M} \times N_{TLP}$.[6] Indicates the code generation schedules for *CI ops* ($(S_C)^{N_C}$), schedules and ILP sizes for *SIS* ($(S_M \times N_{ILP})^{N_M}$), and candidate TLP sizes for the monolithic kernel (N_{TLP}). All operators in an *SIS* share the uniform schedule. If there exists a `reduce` operator in the *SIS*, we only need to enumerate the schedule of one reduce operator; otherwise, it will adopt a grid-stride loop as the schedule. A uniformed ILP will apply to all operators in the same *SIS* since all operators in the same *SIS* share similar resource and parallelism requirements. Unfortunately, this is an excessive tuning space and will have a size of approximately 10^{500} for a BERT-base model.

5.2.2 Tuning Space Compression

We make two important observations for the monolithic kernel. (1) A monolithic kernel is separated into a set of *SISs* and *CI Ops* by *GTBs*. The code generation schedules for different subgraphs are not interleaved. We call an *SIS* or a *CI Op* as a *schedule-independent group* (SIG). (2) The connection between two *schedule-independent groups* is the TLP and on-chip resource allocation. Meanwhile, the overall kernel's TLP and on-chip resource allocation are fixed throughout the monolithic kernel. According to the observations above, the code generation schedule of different *SIGs* can be safely tuned individually without missing the optimal solution.

Based on the above observations, we propose *schedule-independent group tuning* to compress the tuning space significantly. Different *SIGs* are tuned independently for each candidate TLP setting. Particularly, MonoNN concatenate the best-tuned configurations of all the *SIGs* to get the overall best configuration. Finally, we chose the TLP setting that performs the best and all its associated configurations.

For a *schedule-independent group* that is a *CI Op*, we enumerate S_C code generation schedules. There are N_C such groups, and the overall complexity is $N_C \times S_C$ under each overall TLP configuration. For a *schedule-independent group* that is an *SIS* subgraph, we enumerate the possible code generation schedules and overall ILP sizes. There are N_M such groups, and the overall complexity is $N_M \times S_M \times N_{ILP}$ under each overall TLP configuration. As a result, the shrunken tuning complexity of our monolithic kernel is up to:

$$O_{opt} = (N_C \times S_C + N_M \times S_M \times N_{ILP}) \times N_{TLP}.$$

It is worth noting that MonoNN will check the *SIG* hash and reuse the tuning result if an identical *SIG* has been tuned previously. This will prevent duplicated tuning effort under repetitive neural network layers.

29:     return $BestSolution, BestTime$
```

Algo.1 details the tuning procedure in MonoNN begins with sampling *MonoNNTune* in line 25. MonoNN takes Cartesian product between candidate block size $C_{block-size}$ and co-existing blocks per SM $C_{blocks-per-sm}$ (line 4). The optimal solution under each TLP will be tuned independently (line 26). MonoNN will optimize every *SIG* in the neural network (line 15). For memory-intensive subgraphs, the best solution across all rescheduling factors will be selected as the final solution of the current subgraph (line 10-12). MonoNN iterates over the solution under each distinct TLP and chooses the one with the shortest duration as the final solution (line 26-29).

5.3 Implementation

We implement MonoNN with 64k lines of C++ code on top of XLA compiler [2] and integrate it into TensorFlow [12] framework as a drop-in replacement to the backend execution engine. This allows MonoNN to accelerate existing TensorFlow models without requiring any code changes. Additionally, MonoNN can compile a neural network into a standalone assembly file that can be directly executed, potentially offering better performance by eliminating the runtime overhead from the deep learning framework. In Sec.7, we only report the performance number from the first mode for a fair comparison across frameworks. Unlike AStitch [42], MonoNN does not support cross-block reduction. We are not aware of any performance degradation on evaluated models as the

[6] N_C (or N_M): number of *CI ops* (or *SIS*). S_C (or S_M): possible schedules of *CI ops* (or SIS). N_{ILP} (or N_{TLP}): possible ILP (or TLP) sizes.

reduction dimension for these popular models are all small.

6 Scope, Impact, and Limitations

The current optimization scope of MonoNN mainly focuses on general static DNNs where different layers have similar computational sizes. For example, MonoNN effectively supports various popular Transformer models without dynamic control flows, including Transformer encoder models such as BERT, encoder-decoder models such as T5, and every step of the decoder models such as GPT-like models. We compare the performance of different fusion granularity in Sec.7.3, ranging from basic element-wise fusion, stitch fusion, layer-wise monolithic kernel (i.e., one monolithic kernel per layer) to a single monolithic kernel of the entire model.

MonoNN established a new monolithic optimization space for common static DNN inference scenarios by resolving the long-existing global optimization challenge within a single kernel, addressing the resource incompatibility problem of various operators. MonoNN introduce key contributions such as *Context-Aware Instruction Rescheduling* (Sec.4.2.2), *On-Chip Resource Exploitation* (Sec.4.3), and *Global Thread Barrier Merging* (Sec.4.4). Moreover, MonoNN is designed to be forward-looking, performing even more effectively for the upcoming GPU architectures. The increased computing power of future GPUs will likely exacerbate issues related to off-chip memory access and CPU-GPU context switch overhead. Moreover, as supported by [6], distributed shared memory access can enable more flexible and efficient intermediate data buffering for large-scale operator fusion.

Despite the contribution of MonoNN, several potential limitations should be noted. (1) MonoNN mainly addresses common static DNN inference scenarios rather than the models with dynamic control flows [22, 36]. However, users can still optimize the subgraphs separated by control flow operators using MonoNN techniques. (2) MonoNN focuses on DNN inference scenarios that fit within a single GPU, covering a wide range of real-world inference service cases. Extending MonoNN to incorporate collective communication primitives is beyond the scope of this work, but users can still optimize the subgraphs separated by the communication operators using MonoNN. (3) MonoNN may be less effective for DNNs with varied tensor sizes in different layers due to the imbalanced workloads in the single monolithic kernel. While our experiments did not show significant performance regression, this potential limitation in the monolithic kernel should be highlighted.

7 Evaluation

Model specifications: We use a set of representative machine learning applications as our evaluation workloads, including BERT-Base, BERT-Large [19], Transformer T5-Small, T5-Base [30] for natural language processing, ViT [20] for image recognition (with both Convolution and Transformer components), CLIP [29] for computer vision and text, OPT [38] for text generation (OPT-125M version). All the models are publicly available from Huggingface [34]. For all BERT-like and Transformer-like models, we used sequence length equal to 128 unless specified elsewhere.

Software specifications: We compare MonoNN against TensorFlow [12] (v2.7), XLA [2] (v2.7), TensorRT v8.2[7] (via TF-TRT integration [7]), TVM (commit f6f9056) [18], AStitch [42], Rammer [24], PyTorch [28] (v1.12.1), and CUDAGraph [9] (via PyTorch integration). We use CUDA v11.6 and cuDNN 8 for all the experiments[8]. We enable Tensor Cores for all the frameworks we evaluated except in Sec.7.5 cause Rammer [24] only supports SIMT cores.

Hardware Platforms: *A10 server*: NVIDIA A10 GPU (Ampere), and two Intel(R) Xeon(R) Platinum 8369B CPUs. *T4 server*: NVIDIA T4 GPU (Turing), and two Intel(R) Xeon(R) Platinum 8163 CPUs. *A100 server*: NVIDIA A100 80GB SXM (Ampere), and two Intel(R) Xeon(R) Platinum 8369B CPUs.

7.1 End-to-End Performance Comparison

7.1.1 Overall Results

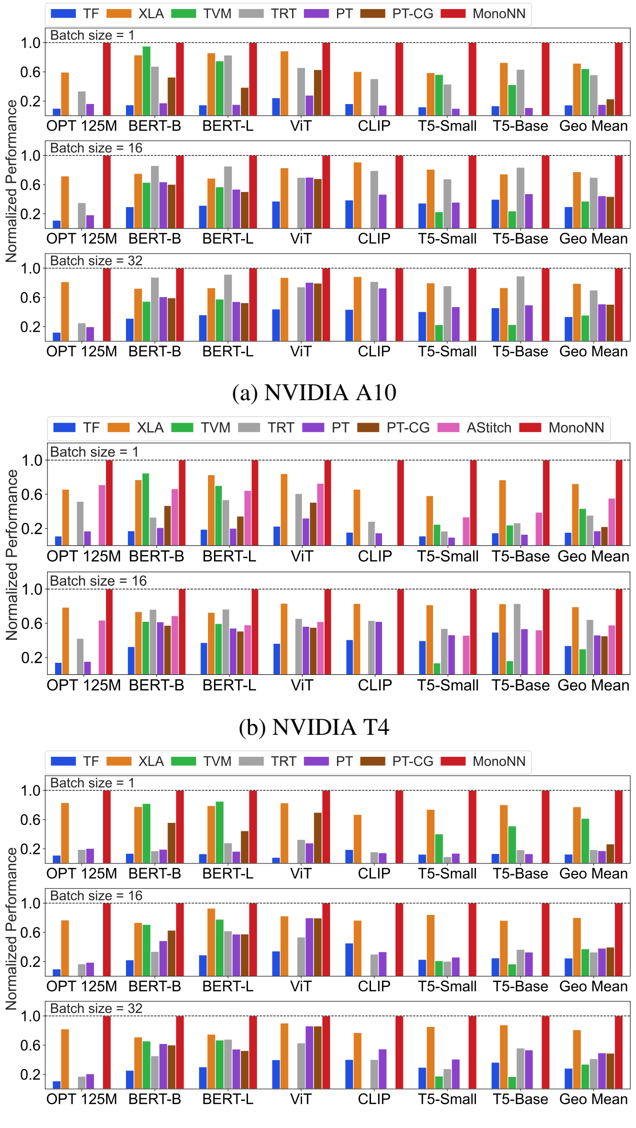
Fig.10 shows the end-to-end performance speedup on NVIDIA A10, T4, and A100 GPU for all experiments with three batch size variations. *Geo Mean* refers to the geometric mean across all models. All the execution time is normalized against the best optimizer in the group. TVM failed to optimize OPT, ViT, and CLIP due to incomplete operator support. PyTorch-CUDAGraph failed to optimize OPT, CLIP, and T5 for unsupported operations in the graph-capturing phase.

As demonstrated in Fig.10, on A10 GPU, MonoNN achieve 6.9×, 1.4×, 1.6×, 1.8×, 6.6×, and 2× average speedup over Tensorflow, XLA, TVM, TensorRT, PyTorch, and PyTorch-CUDA Graph on batch size 1, respectively. In addition, for batch size 16, and 32, MonoNN achieve on average 1.88×, and 1.80× speedup over baselines. On NVIDIA T4, MonoNN achieve 6.5×, 1.4×, 2.3×, 2.8×, 5.8×, 2.3×, and 1.8× average speedup over Tensorflow, XLA, TVM, TensorRT, PyTorch, PyTorch-CUDA Graph, and AStitch on batch size 1, respectively. In addition, for batch size is 16, MonoNN achieves on average 1.91× speedup over all baselines. We also have comprehensively tested MonoNN on A100 as detailed in Fig.10c.

Given the diverse set of baselines we compare against, the extent of performance improvements can vary. MonoNN consistently achieves the best performance across all baselines, with significant improvements observed for all testing batch sizes. It is important to note that reduced performance gains with larger batch sizes are anticipated, as

[7] TensorRT 8 is the latest version at the time of submitting the paper (Dec. 2022), with much performance improvement compared to TensorRT 7.

[8] AStitch is using its released artifact (CUDA 10.2 and cuDNN 7).



(a) NVIDIA A10

(b) NVIDIA T4

(c) NVIDIA A100

Figure 10: MonoNN End-to-End speedup (higher is better).

larger batches generally lead to better device utilization, leaving less room for performance enhancements. For example, XLA/TensorRT/MonoNN show on average 4.9×->2.6×->2.3× / 3.8×->2.3×->2.0× / 6.9×->3.4×->3.0× performance gain over the TF baseline when expanding the batch size from 1 -> 16 -> 32 on A10 respectively.

We test CUDA Graph via Pytorch integration. Despite the failure in some of the models in our benchmark, CUDA Graph achieves on average 2.6×, 0.95×, 0.98× speed up over PyTorch when batch size is $1, 16, 32$ on A10. Obviously, the performance gain of the CUDA Graph diminishes drastically (even with no performance gain) when the batch size is larger than one. The average speedup is far less than the achieved performance speedup of MonoNN. Specifically, MonoNN outperforms PyTorch-CUDA Graph by an average of 2× (batchsize=1) and continues to outperform it when batchsize is larger than 1. We attribute the reason as follows. On the one hand, MonoNN can perform various optimizations in the monolithic optimization space that CUDA Graph cannot, e.g., whole graph-level optimizations, instruction rescheduling, on-chip resource exploitation, and *GTB* merging. On the other hand, as pointed out by previous literature [37], a new GPU kernel has several types of overhead (e.g., kernel launching, kernel initialization) but CUDA Graph can only optimize kernel launching.

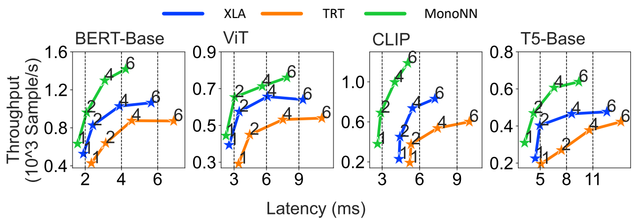


Figure 11: MPS Performance.

XLA achieves the best average speedup among our baselines. But XLA can only explore register-level data buffering rather than multi-dimensional optimization techniques in MonoNN. We only run AStitch [42] experiment on T4 GPU (with CUDA 10.2) because the artifact released does not support newer NVIDIA A10 architecture.

In addition, we evaluate MonoNN and the baselines on A10 using longer input for the BERT model. We use an input sequence length equal to 512, which is the maximum sequence length supported by the model's pre-trained positional embedding. As illustrated in Tab.1, MonoNN achieves on average 1.94×, 1.52×, and, 1.48× speedup over baselines when batch size is 1/16/32 respectively.

	TF	XLA	TRT	PT	PT-CG	MonoNN
BS=1	0.27	0.90	0.44	0.39	0.57	1
BS=16	0.40	0.87	0.75	0.63	0.62	1
BS=32	0.42	0.90	0.79	0.63	0.63	1

Table 1: Normalized performance.

Among the evaluated models, the OPT-125M model has the smallest computation shape; only a single output token is generated at each step. This results in severe non-computation overhead, making MonoNN especially advantageous.

7.1.2 Impact on Throughput with MPS

This section is to demonstrate that MonoNN's optimizations can perform well for GPU-shared scenarios for higher throughput. In the real-world inference scenario, a common approach is to share a single GPU with multiple inference tasks to improve inference throughput and hardware utilization. NVIDIA Multi-Process Service (MPS) [10] is one of the most widely adopted solutions for GPU sharing. We test our solution with *MPS* for BERT-Base, ViT, CLIP, and T5-Base on A10 and plot the latency-throughput curve in Fig.11. The

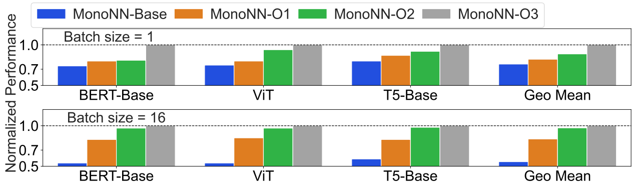

Figure 12: Ablation study on NVIDIA A10.

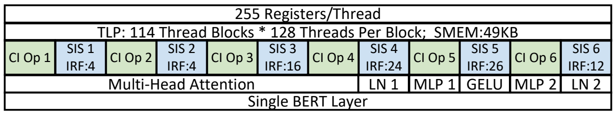
numbers on the line indicate how many instances are used in *MPS*. The batch size is one in this experiment. MonoNN consistently outperforms baselines, achieving 1.5 × −2× QPS throughput under the same latency constraint. It demonstrates that a monolithic kernel is capable of delivering meaningful speedup in GPU-shared inference. In practice, we divide TLP for each instance by the number of instances co-existing in *MPS* to ensure all instances can run concurrently on a single GPU.

7.1.3 Ablation Study

Fig.12 dissects the main optimizations in MonoNN. We build *MonoNN-Base*, a lightweight monolithic kernel generator that has all the optimization techniques of MonoNN except for the three: *context-aware instruction rescheduling*, *comprehensive on-chip resource exploitation* and *global barrier merging*. Note that *MonoNN-Base* is different from the baselines in Fig.10. *MonoNN-Base* is already a strong baseline that has many basic optimization techniques. It is a single monolithic kernel with minimal non-computation overhead, achieving better performance than TensorFlow and on par with XLA. We then build *MonoNN-O1-O3* by gradually applying the above optimizations one by one in order. *MonoNN-O3* is the full MonoNN. We observe 5%, 6%, and 12% speedup for *O1*, *O2*, and *O3* optimization on batch size 1, and 35%, 15%, and 3% speedup on batch size 16. *Context-aware instruction rescheduling* shows much more performance gain for batch size 16 because larger tensor shapes need higher parallelism, thus requiring ILP compensation more. In addition, we observe instruction rescheduling does not improve performance on *OPT-125M* model as the text generation model only produces a single token in each inference and a small tensor shape does not need a larger rescheduling factor. *Comprehensive on-chip resource exploitation* also shows higher performance gain on batch size 16 as larger tensors need more comprehensive solutions to accelerate off-chip memory access. *GTB Merging* shows larger performance gain when batch size is one because synchronization overhead is invariant to batch size and thus will take a larger portion when kernel duration is short.

7.2 MonoNN Optimization Breakdown

In this section, we dissect our optimization techniques proposed in Sec.4 and present a deep-dive into the solution generated by MonoNN with both conceptual and quantitative analysis to help understand optimizations in monolithic kernel better. Fig.13 shows the identified *CI Ops* and *SIS* in a BERT-Base model. We present a detailed analysis when the inference batch size is 16 on NVIDIA A10.



255 Registers/Thread

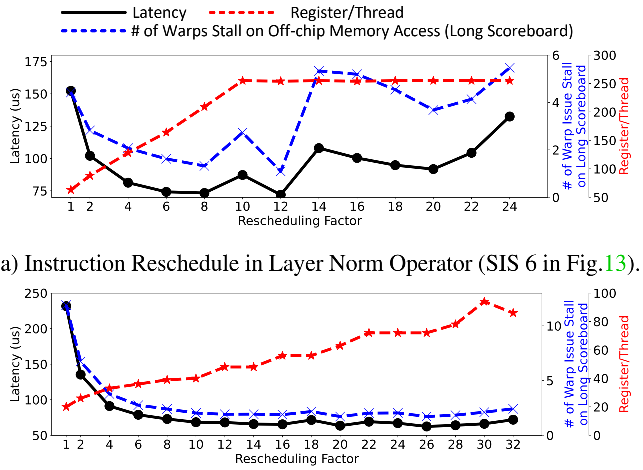
TLP: 114 Thread Blocks * 128 Threads Per Block; SMEM:49KB

CI Op 1 | SIS 1 IRF:4 | CI Op 2 | SIS 2 IRF:4 | CI Op 3 | SIS 3 IRF:16 | CI Op 4 | SIS 4 IRF:24 | CI Op 5 | SIS 5 IRF:26 | CI Op 6 | SIS 6 IRF:12

Multi-Head Attention | LN 1 | MLP 1 | GELU | MLP 2 | LN 2

Single BERT Layer

Figure 13: Identified *SIS* and *OCS* on a BERT layer, including TLP and on-chip resource usage of the monolithic kernel and instruction rescheduling factor (IRF) for each *SIS*.



(a) Instruction Reschedule in Layer Norm Operator (SIS 6 in Fig.13).

(b) Instruction Reschedule in GELU Operator (SIS 5 in Fig.13).

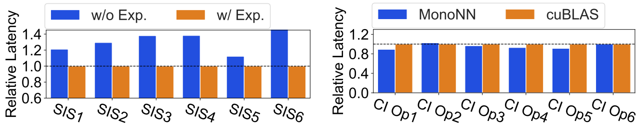
Figure 14: Context-aware instruction rescheduling analysis.

7.2.1 Context-Aware Instruction Rescheduling Analysis

Context-Aware Instruction Rescheduling (Sec.4.2.2) can increase ILP with more register usage. We show the rescheduling analysis of two subgraphs in Fig.14. As demonstrated in Fig.14a, when the rescheduling factor is too low, the average number of warps per SM per cycle that stall on off-chip memory access is high due to the low parallelism (both TLP and ILP), resulting in high inference latency. On the other hand, a too-high factor will cause register pressure and even register spilling. Slight register pressure often does not indicate degradation in performance, but register spilling often results in drastic performance degradation. We observe register pressure when the rescheduling factor is 10 and register spilling when the rescheduling factor is larger than 22. The best factor for *SIS6* is 12. *SIS5* in Fig.14b has less register usage compared to *SIS6*, for which the best rescheduling factor is 26.

7.2.2 On-chip Resource Exploitation Analysis

Comprehensive On-chip Resource Exploitation (Sec.4.3) can further exploit the on-chip cache and shared memory based on the data access pattern of the subgraph. Fig.15a shows performance improvement after applying this optimization



(a) *SIS* latency after Exploitation. (b) *CI Ops* latency.

Figure 15: Operator latency breakdown.

for subgraphs corresponds to Fig.13, achieving 1.3× speedup on average. Note that this is additional performance gain over *Context-Aware Instruction Rescheduling*.

7.2.3 Performance of Compute Intensive Operators

We also detailed the performance of *CI Ops* in the monolithic kernel. All *CI Ops* need to follow the same TLP setting but the tensor shape for each *CI Op* could be different. Thus, handling different tensor shapes with a unified TLP setting is critical. MonoNN achieves this by leveraging intra-thread block tuning choices from CUTLASS. Through extensive evaluation, we found that intra-block tuning can generate satisfactory solutions for *CI Ops*. We illustrate the performance of *CI Ops* in monolithic kernel in Fig.15b. With the highly-tuned open-source vendor code (i.e., CUTLASS), all operators achieve on-par performance with the cuBLAS. Surprisingly, in some cases, the *CI Op* found by MonoNN is slightly better than cuBLAS. The reason we judiciously suspect is MonoNN performs an exhaustive search over all possible solutions whereas cuBLAS uses heuristics.

7.2.4 Global Thread Barrier Merging Analysis

GTB is necessary for a monolithic kernel to ensure correctness. But each *GTB* involves a small overhead, approximately 2*us* based on our evaluation. Thus we need to minimize such overhead with *longest-path based GTB merging* (Sec.4.4). We compare *GTB* number before and after merging optimization. We observe 516, 658, 319, 710, and 366 *GTBs* in BERT-Base, CLIP, OPT-125M, T5-Base, and ViT model respectively. The *GTB* number reduced to 146, 185, 185, 315, and 184 respectively after *GTB* merging.

7.2.5 Dissecting Non-computation Overhead

	Bert-Base	ViT	T5-Base	OPT-2
Framework	0.41	0.57	0.44	0.61
Kernel Launch	0.71	0.51	0.72	1.74

Table 2: Context switch overhead breakdown (in ms).

Framework scheduling overhead and kernel launching overhead are two major sources of non-computation overhead. Tab.2 shows the separated framework scheduling and kernel launching overhead after optimization with XLA. It shows that the kernel launch overhead accounts for 61.7% of the overhead on average, larger than that of framework overhead. To measure the two kinds of overhead, we build two XLA variants. The first variant *XLA-framework* executes all framework scheduling logic as XLA, except it does not launch GPU kernel but returns immediately for each operator. Therefore, the inference latency of *XLA-framework* is pure framework overhead. The second variant *XLA-framework-and-kernel* has the same functionality as XLA, except that it launches empty GPU kernels (GPU kernels that do nothing) rather than the original kernels. The inference latency of *XLA-framework-and-kernel* is the summation of framework overhead and kernel launch overhead.

7.3 Fusion Granularity Analysis

	EleWise	Stitch	Layer	Layer+CUDAGraph	Monolithic
OPT	0.68	0.73	0.93	0.93	**1**
MultiModal	0.49	0.61	**1.10**	**1.10**	1

Table 3: Relative performance at each fusion granularity

We further analyze how kernel fusion granularity impacts inference performance on the models we evaluated to have a better understanding of the optimization space we proposed. Specifically, we control the fusion scope of MonoNN to generate code at different fusion granularity. From small to large, 1) **EleWise**: Element-wise fusion [2, 18]. 2) **Exhaustive memory-intensive fusion (Stitch)**: perform exhaustive fusion optimization on memory-intensive subgraphs using shared memory and global memory. This scope is similar to TensorRT [11] and AStitch [42]. 3) **Layer**: each layer of the neural network will be generated into a kernel with monolithic optimization. Note that from this scope, efficient code generation is unrealistic without the techniques proposed in this work. 4) *Layer+CUDAGraph* additionally apply CUDA Graph to the generated kernels. 5) *Monolithic*: the entire neural network is fused into a single kernel.

We choose OPT-125M and a customized multimodal model and benchmark them on A10 with a batch size equal to one. The multimodal model contains a transformer-based text encoder and a CNN+transformer-based image encoder. The setting with the best performance is highlighted in bold. We observe for a regular model like OPT with repetitive layers, monolithic kernel trend to achieve the best performance because all the optimization choices are essentially the same across layers. But for the multimodal model with complex structure, we observe the text encoder and image encoder trend to explore different optimization spaces due to divergence in computation tensor shape.

7.4 MonoNN Tuning Speed

MonoNN uses a grid search tuner with caching to tune the entire network. The modern neural network usually has many

	Bert-Base	Bert-Large	T5-Small	T5-Base
MonoNN	22	70	17	68
TVM	172	220	51	116

Table 4: MonoNN end-to-end compilation time in minutes.

repetitious layers so that MonoNN avoids tuning them redundantly by caching the result from previous layers. We further apply many engineering-level optimizations to speed up tuning, which will not be highlighted in this paper. To this end, we found that MonoNN tuner can provide satisfactory tuning speed. We detailed quantitative numbers in Tab.4 collected from A10 GPU.

7.5 Comparison with Rammer

We compare MonoNN with Rammer [24] on BERT-Large inference. Rammer failed in optimizing all Huggingface public models in Fig.10 due to unsupported operators (e.g., Einsum, BroadcastTo). The only common inference model that we can find is the BERT-Large model from Rammer's official repository using fixed batch size 1. Thus, we cannot test other batch sizes on Rammer. In addition, Rammer does not support Tensor Cores. We thus compare with Rammer on NVIDIA T4 GPU after disabling Tensor Core usage for MonoNN. MonoNN shows 1.28× speedup over Rammer on BERT-Large model when using batch size equal to one and sequence length equal to 512.

8 Related Work

Most of the popular ML compilers focus on either single-operator or subgraph-level kernel generation. [16, 18, 26, 31, 32, 39, 41, 43] focus on compute-intensive operators optimization, with basic fusion support for memory-intensive ops, whereas [27, 41, 42] explore the stitch optimization of memory-intensive subgraphs. From graph level, [23, 33] explore graph transformation optimizations to accelerate neural network execution, which is orthogonal to our work.

Notably, holistic optimizations for machine learning workloads have received increased attention in recent years. VersaPipe [40] utilizes persistent-thread technique [14, 17] to execute a computation graph in a pipelined manner, in which the large kernel is spitted into several small kernels to avoid resource incompatibility problem. This approach is not sufficient to support computation graphs with massive operators, like machine learning graphs. Rammer [24] utilizes the persistent-thread technique to support large scope fusion, in which the task re-slicing and scheduling help to fill up execution units. Rammer does not touch the incompatibility problem and cannot support the monolithic optimization of an entire neural network efficiently. For example, the demoed BERT model of Rammer consists of 734 kernels on GPU. The persistent thread scheduling of VersaPipe and Rammer also introduces extra scheduling overhead, while MonoNN applies effective static scheduling to avoid such overhead. Moreover, neither VersaPipe nor Rammer explores the optimizations of on-chip resource exploitation and GTB merging like in MonoNN. BOLT [35] can fuse GEMM and its following operations into single kernels under restricted locality constrain. It cannot generate the monolithic kernel due to the incompatibility problem. Müller et al. [25] manually fuse all operators of a tiny MLP, small enough to fit on-chip, into a single GPU kernel for accelerated execution. In contrast, MonoNN explores a general approach for automatically high-performance code generation for common-sized models. There are ad hoc solutions to speed up single operator (e.g., LayerNorm) with instruction level parallelism on GPU [21]. None of the above work tackles the challenge of monolithic kernel generation.

9 Conclusion

We reveal that the kernel-by-kernel execution scheme is no longer effective in fully utilizing modern GPUs for various machine learning workloads, causing notable non-computation overhead and off-chip memory traffic. We propose the *monolithic kernel* execution scheme to tackle these problems, providing a vast new optimization space. We propose *context-aware instruction rescheduling* and *comprehensive on-chip resource exploitation* techniques to cope with the incompatibility problem between compute-intensive and memory-intensive operators. We systematically abstract the monolithic optimization space and propose *schedule-independent group tuning* approach to compress the extremely large tuning space. We develop a compiler integrating the optimizations automatically. Extensive evaluation on a set of inference tasks demonstrates that MonoNN outperforms state-of-the-art optimizers with on average 2.01× speedup.

ACKNOWLEDGMENT

We appreciate the guidance from the OSDI reviewers and our shepherd during the review and revision process. We also extend our gratitude to Minmin Sun, Feiwen Zhu, Kai Zhu, Zaifeng Pan, Bohua Chen, and Wenyi Zhao at Alibaba Group for their valuable suggestions. This research is funded by Alibaba Group through the Alibaba Innovative Research Program. Donglin Zhuang and Haojun Xia are affiliated with the School of Computer Science at the University of Sydney, Australia, and conducted this work during their internship at Alibaba. Shuaiwen Leon Song is the corresponding author of this paper.
